All samples are uniquely identified, labeled, and documented in the field at the time of collection. Samples collected in the field are transported to the laboratory via overnight shipping. Samples are packed in ice to keep them cool during collection and transportation.

2.2.1 Permit Requirements

Analytical methods are either specified or recommended for the constituents included in the NPDES Permit monitoring requirements. The Permit provisions related to the analytical portion of this monitoring effort are summarized below:

- Special Condition S2.A(7)(15): For PCBs use U.S. Environmental Protection Agency (EPA) Method 1668. Reporting limits are described in the QAPP.
- Special Condition S2.A(7)(17): For PBDEs use draft EPA Method 1614. Reporting limits are described in the QAPP.
- Special Condition S2 does not specify an analytical method for Dioxin. Appendix A of the Permit recommends EPA Method 1613 for analysis of Dioxin (Chemical Abstracts Service [CAS] No. 176-40-16).

Table 2-2 lists the methods used to analyze samples collected from the Facility influent and effluent, as per the approved QAPP.

Table 2-2. Analytical Methods

Constituent	Analytical protocol
PCB congeners	EPA 1668A
PBDEs	EPA 1614
Dioxin	EPA 1613B

2.2.2 Quality Objectives and Control

Quality objectives are established for this project to control the degree of total error in data results. These objectives are established to achieve an acceptable level of confidence in decisions made from the collected data. The established objectives include the following:

- implement procedures for field sampling, sample custody, equipment operation and calibration, laboratory sample analysis, data reduction, and data reporting that will provide for the consistency and thoroughness of data generation
- assess the quality of data generated to ensure that collected data are scientifically valid, of known and documented quality, and legally defensible, where appropriate
- ensure that the QAPP and associated project plans are properly implemented

- document field conditions, sampling, and other activities using appropriate field reports to sufficiently re-create each sampling, analytical, testing, and monitoring event

Data quality control is determined by the analysis of sample blanks and duplicates.

Three types of blanks are used in this study:

- Rinsate blanks, also called "equipment blanks," are collected by running a sample of ultrapure water prepared by AXYS through the sampling equipment after it has been cleaned but before it is used for sampling. The rinsate blank indicates the extent to which contaminants are introduced through the sampling procedure, equipment, or exposure to ambient air during the sample collection. Rinsate blanks were collected at the NVIPS, SVIPS, and effluent sampling locations during the October 2012 event, and at one sampling location for all subsequent events. An additional rinsate blank was collected at the DMI MH1 track-down sampling location for the June 2013 sampling event. Rinsate blanks were tested for the toxic pollutants subject to testing at a given site during a given event. Rigorous decontamination procedures were followed to minimize equipment contamination (e.g., sampler tubing was shipped to AXYS for cleaning prior to each sampling round).
- Travel blanks are bottles of ultrapure water, prepared by AXYS, that accompany the samples en route from the sampling locations to the laboratory. The travel blank remains unopened until analyzed and helps to distinguish between potential bias introduced by contamination of sample water during transfer, shipping, and handling as opposed to contamination from sampling equipment. Travel blank(s) are prepared and provided by AXYS for each sample event. Travel blanks were tested for all pollutants subject to testing at a given site during a given event.
- Laboratory blanks are samples of ultrapure water prepared by AXYS that never leave the laboratory. They are tested alongside the samples and are used to determine potential sources of contamination or bias in the laboratory itself.
- Field duplicates are used to assess repeatability of sampling and analysis, and to evaluate analytical precision. One field duplicate was collected during each sampling event, and analyzed by the laboratory as a blind, meaning that the lab was not informed where the sample was collected. Field duplicates were tested for a single pollutant (PCBs, Dioxin, or PBDE) during each event.

In addition to rinsate, travel, and laboratory blanks, matrix spikes are used to assess analytical interferences related to the sample matrix. The laboratory tests known quantities of specific analytes in samples of ultrapure water and in field samples, and determines the percent recovery of the analyte in the field sample. Matrix spikes were performed on every sample.

The Quality Control Comment/Action Records for each test event are included in Appendix A.

2.3 Sampling Results

This section summarizes the analytical results from the toxics sampling conducted from October 2012 through December 2014. NVIPS and SVIPS were sampled bimonthly and the effluent was sampled quarterly in compliance with the NPDES Permit requirements. Track-down samples from the collection system were taken from June 2013 through December 2014. Appendix B contains the complete laboratory results for the samples collected in 2014. In the County's previous Annual Reports, PCB totals were reported without adjusting for blank contamination. However, the City of Spokane, the largest wastewater discharger to the Spokane River, has been calculating total PCBs using a 10x all-blanks censoring approach. Ecology used a similar blank censoring method for its recent study of PCBs in the Palouse River watershed (Lubliner, 2009). To facilitate comparison with the City data, this Annual Report shows all total PCB data (influent, effluent, and trackdown samples) calculated using a 10x all-blanks censoring approach.

2.3.1 Influent/Effluent

Table 2-3 lists the total daily flows at the NVIPS and SVIPS on the sampling dates. On several dates the total amount pumped to the Facility was slightly less than the total flow in the interceptors because some flow was conveyed to the City of Spokane Riverside Park Water Reclamation Facility. On average, the NVIPS and SVIPS accounted for roughly 28 percent and 72 percent, respectively, of the total flow entering the Facility on the sampling dates.

Table 2-3. NVIPS and SVIPS Daily Flows

Year	Sampling dates	Flow pumped to Facility (mgd) [a]		
		NVIPS	SVIPS	Total
2012	October 10–11	1.82	4.87	6.69
	December 18–19	1.83	4.42	6.25
2013	February 6–7	1.84	5.06	6.90
	April 16–17	1.83	4.90	6.73
	June 25–26	1.99	4.48	6.47
	August 20–21	2.03	5.11	7.14
	October 22–23	1.73	4.98	6.71
	December 17–18	1.95	5.13	7.08
2014	February 10–11	1.94	5.21	7.15
	April 21–22	1.97	4.40	6.37
	June 23–24	2.03	4.43	6.45
	August 12–13	2.10	5.16	7.26
	October 20-21	2.00	5.21	7.20
	December 8–9	2.06	5.31	7.37

a. The interceptors can send flow to the Facility or to the City of Spokane Riverside Park Water Reclamation Facility. Listed flows do not include flows in the interceptor that were pumped to the City of Spokane Riverside Park Water Reclamation Facility.

PCBs have been sampled from the influent pump stations during 14 sampling events from October 2012–December 2014. The effluent was sampled during nine different events. The total PCB concentrations measured at influent trunk line and effluent sampling locations throughout the entire sampling period are plotted in Figure 2-2.

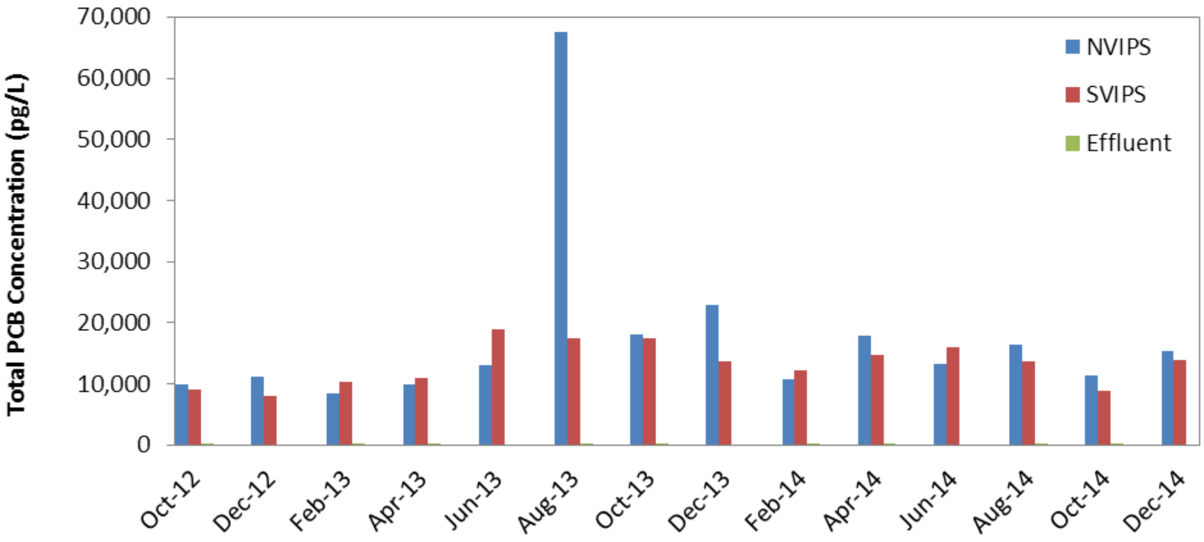

Figure 2-2. Total PCB concentrations in influent trunk line and effluent samples, Oct. 2012–Dec. 2014

Figure 2-3 presents the same effluent sampling data shown in Figure 2-2, zoomed in 100x on the y-axis to show the very low levels of PCBs in the effluent samples as compared to the influent samples.

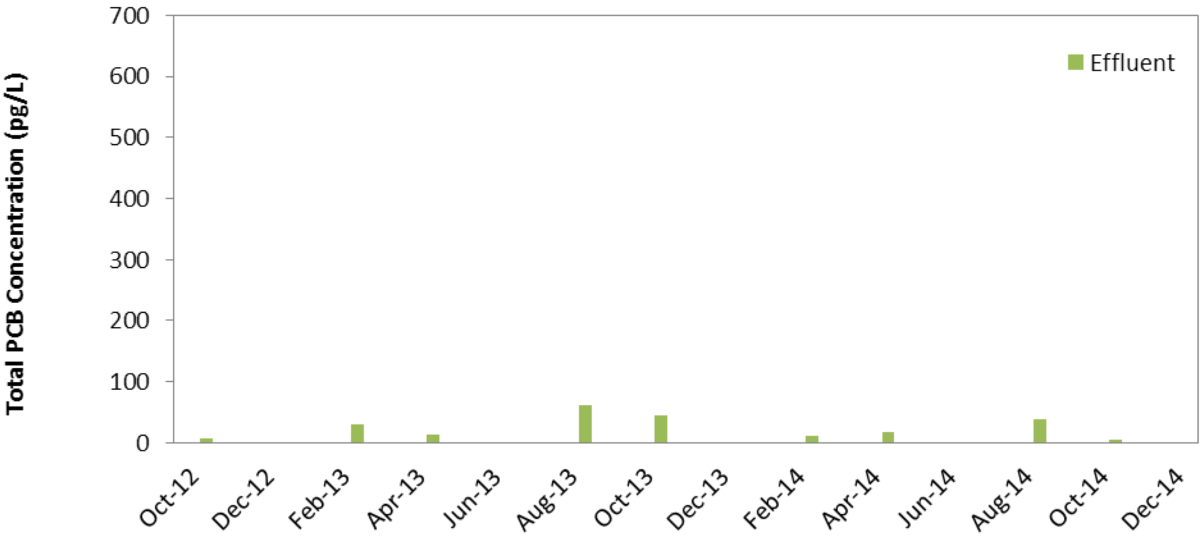

Figure 2-3. Total PCB concentrations in effluent samples, Oct. 2012–Dec. 2014

Table 2-4 summarizes the total PCB concentrations in influent trunk line and effluent samples measured during 2012-2014. Figure 2-3 shows the statistical variation in the data for each sample for the entire sampling period. PCB concentrations in the NVIPS and SVIPS samples ranged from 8,060 to 67,630 picograms per liter (pg/L). Effluent PCB concentrations ranged from 6 to 62 pg/L.

Table 2-4. Total PCB Concentrations (pg/L) and Statistics for 2012--2014 for Influent Trunk Line and Effluent Samples

Statistics	NVIPS	SVIPS	Effluent
Number of Samples	14	14	9
Mean	17,580	13,240	30
Standard Deviation	14,960	3,480	20
Minimum	8,370	8,060	6
Maximum	67,630	18,920	62

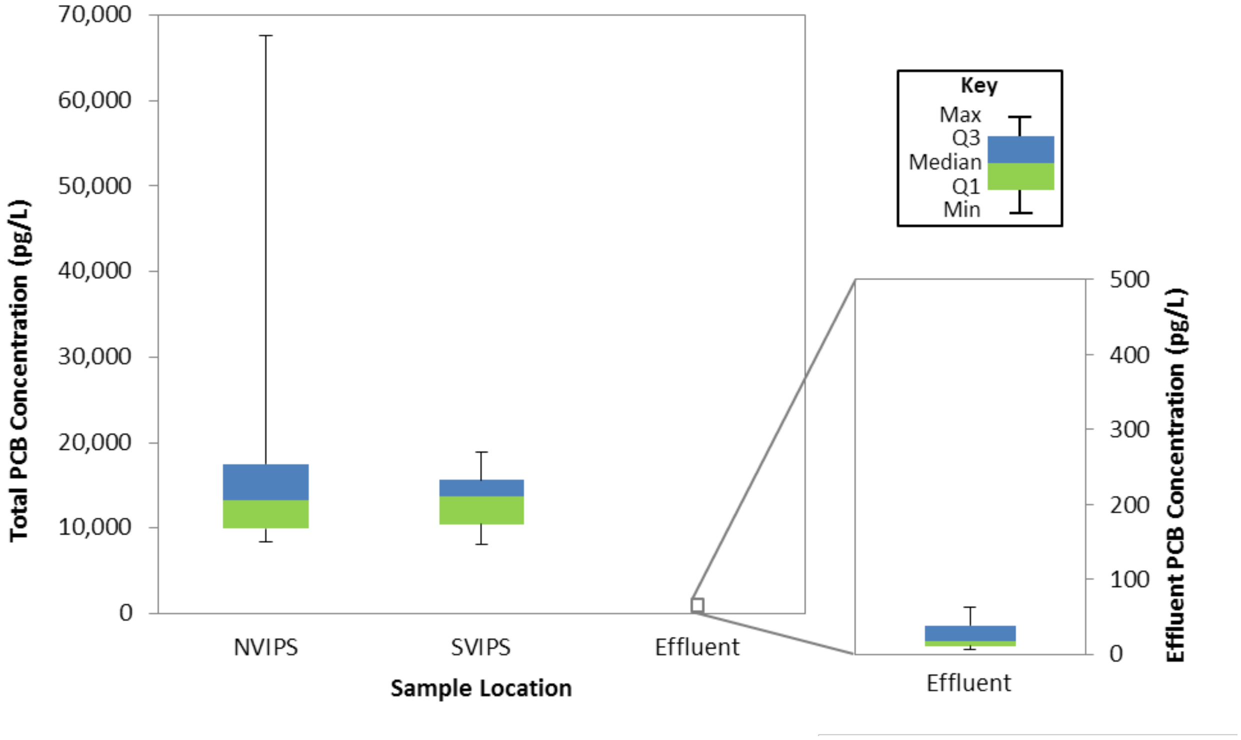

Figure 2-4. Box-whisker plot of total PCB concentrations in influent trunk line and effluent samples

For the majority of the sampling events, the total PCB concentration in the NVIPS and SVIPS samples were similar. If the August 2013 total PCB concentration at the NVIPS is excluded, the total PCB concentrations averaged 13,730 and 13,240 pg/L for the NVIPS and SVIPS, respectively. The August 2013 event is discussed in detail in the 2014 Annual Report.

PCB concentrations in effluent samples were much lower than the influent (NVIPS and SVIPS) samples. In Figure 2-4, the box-whisker plot shows the median, first and third quartile, and minimum and maximum values for the influent and effluent samples. The first quartile (Q1) represents the value where 25 percent of the data is less than this value. The third quartile value (Q3) represents the value where 75 percent of the data is less than this value. Based on the average concentrations of PCBs and flows measured at the NVIPS, SVIPS, and effluent locations, the Facility is removing greater than 99 percent of the total mass of PCBs entering the Facility.

Table 2-5 presents Dioxin results for 2012-2014. Only 1 of the 37 influent and effluent samples contained Dioxin at levels above the laboratory quantitation criteria. This sample (NVIPS, June 2013) had a reported concentration of 1.03 pg/L. Based on these results, continued Dioxin analysis is unlikely to improve the County's toxics management program.

Table 2-5. Summary of Dioxin Data (pg/L)

Statistics	NVIPS	SVIPS	Effluent
Total number of samples	14	14	9
Number of detected samples	1	0	0
Range of concentration detected	1.03	--	--
Range of detection limit	0.498–0.62	0.496–0.91	0.497-0.543

PBDEs were sampled from the influent pump stations and effluent during nine events during 2012–14. The total PBDE concentrations are summarized in Figures 2-5 and 2-6 and Table 2-6. The total PBDE concentrations presented in this section represent the sum of 46 compounds. The total PBDE concentrations do not include estimated concentrations of compounds that fell below laboratory quantitation criteria, or congeners that were not detected at the reporting level. Figure 2-5 shows the total PBDE concentrations measured at influent trunk line and effluent sampling locations throughout the entire sampling period.

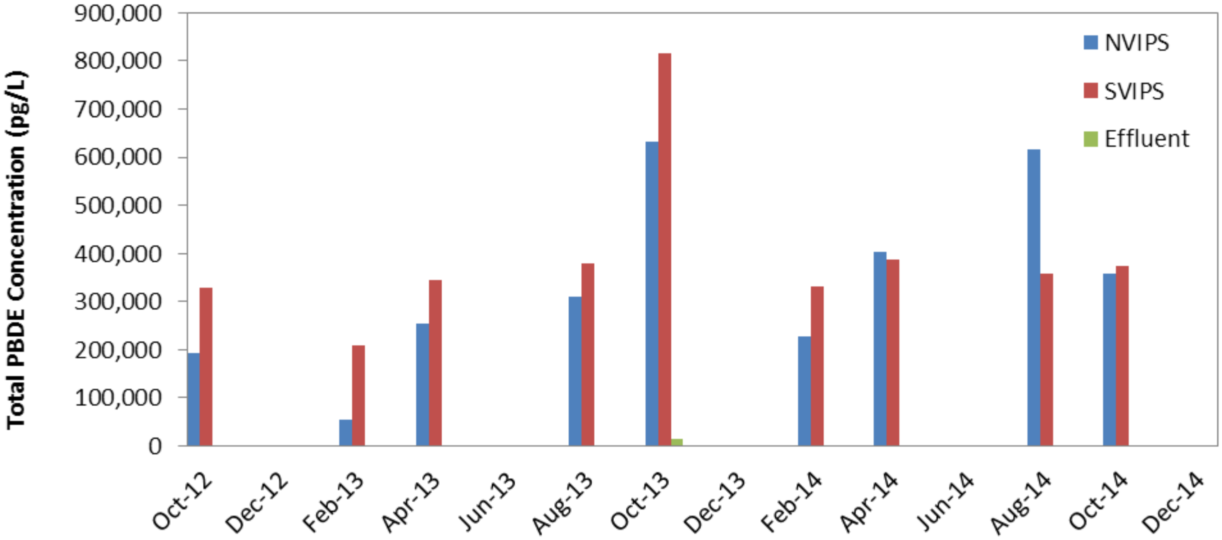

Figure 2-5. Total PBDE concentrations in influent trunk line and effluent samples, Oct. 2012–Dec. 2014

Figure 2-6 presents the same effluent sampling data shown in Figure 2-5, zoomed in on the y-axis to show the low levels of PBDEs in the effluent samples as compared to the influent samples.

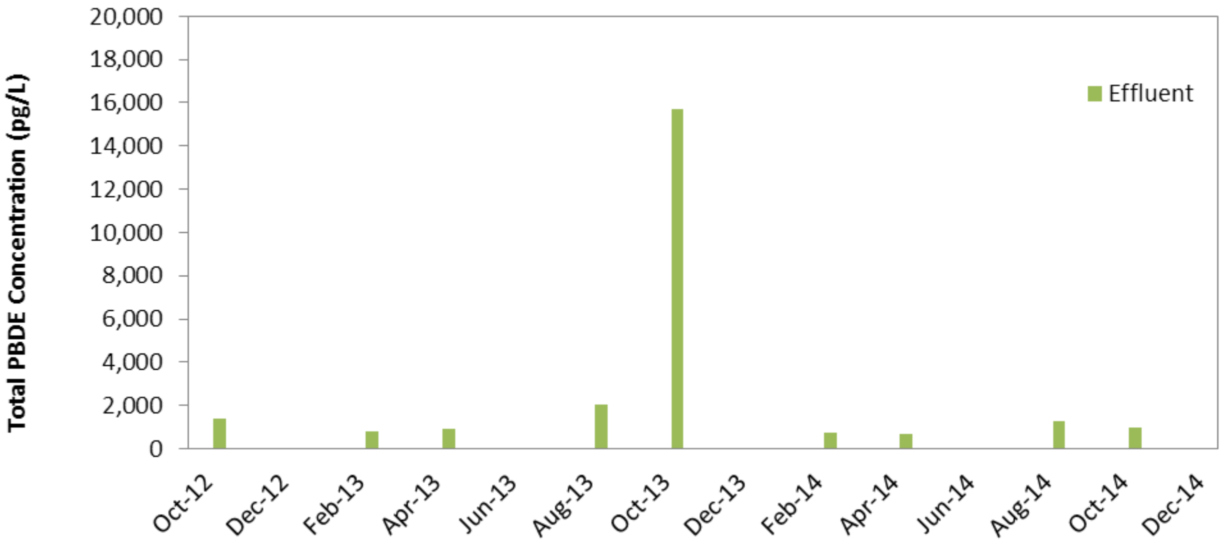

Figure 2-6. Total PBDE concentrations in effluent samples, Oct. 2012–Dec. 2014

Table 2-6. Total PBDE Concentrations (pg/L) and Statistics for 2012 – 2014

Statistics	NVIPS	SVIPS	Effluent
Number of Samples	9	9	9
Mean	338,300	392,200	2,730
Standard Deviation	190,900	167,300	4,900
Minimum	53,300	210,200	660
Maximum	631,600	815,600	15,700

The total PBDE concentration in the NVIPS and SVIPS samples ranged from 53,300 to 815,600 pg/L. Effluent PBDE concentrations ranged from 660 to 15,700 pg/L. In Figure 2-7, the box-whisker plot shows the median, first and third quartile, and minimum and maximum PBDE values for the influent and effluent samples. Based on the average flows and concentrations of PBDEs at the NVIPS, SVIPS, and effluent locations, the Facility removed greater than 99 percent of the PBDE mass entering the Facility.

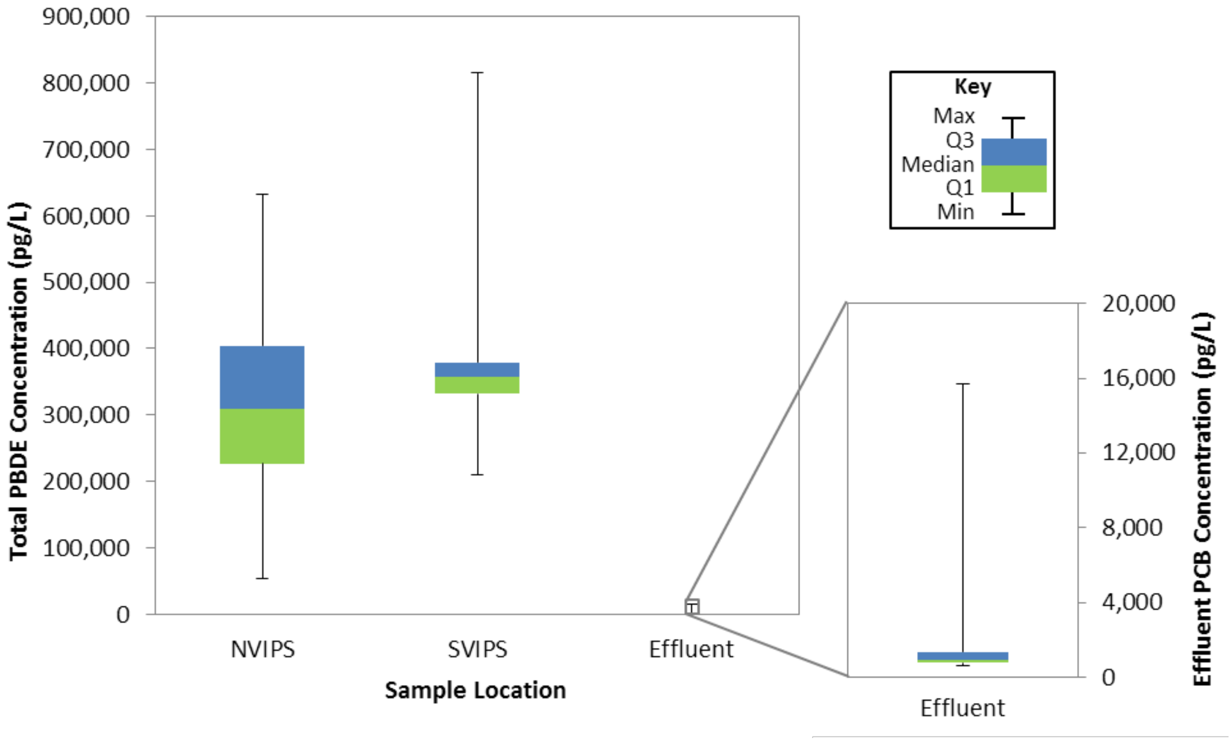

Figure 2-7. Box-whisker plot of total PBDE concentrations in influent trunk line and effluent samples

2.3.2 Collection System Track-Down Samples

The DMI basin was selected for further track-down based on the PCB concentrations measured in 2013–14 and reported in the 2014 Annual Report. As noted in section 2.1.2, there are multiple complicating factors in sampling subbasins including highly variable flows over a 24-hour period, traffic control requirements, and lack of power and security for automated equipment. Samples were taken as 40-minute composites at the approximate times listed in Table 2-7.

Table 2-7. Sampling Dates and Times for Track-Down Samples in 2014

Sampling Location	Date	Time	Date	Time
DMI MHA	6/23/2014	1:35 PM	12/8/2014	2:50 PM
DMI MHB	6/23/2014	12:32 PM	12/8/2014	1:30 PM
DMI MHC	6/24/2014	7:30 AM	12/9/2014	8:30 AM
DMI MHD	6/23/2014	3:15 PM	12/8/2014	11:48 AM
DMI MHE	8/12/2014	2:45 PM	10/20/2014	12:45 PM
DMI MHF	8/12/2014	1:00 PM	10/20/2014	8:40 AM
DMI MHG	8/13/2014	7:30 AM	10/20/2014	2:25 PM

DMI MH1, the manhole located at the outlet of the DMI basin, had an average PCB concentration of 20,090 pg/L in 2013. This was higher than the average concentrations measured at either influent pump station, or at the track-down locations upstream along the SVI and NVI.

The DMI basin splits near 28th Avenue, where one trunk line continues south along the Dishman-Mica Highway, and the other trunk line continues west. Sampling locations DMI MHA (west) and DMI MHB (south) cover each of these trunk lines.

Higher PCB concentrations were noted at DMI MHA on both sampling occasions. The average concentration at DMI MHA was approximately double that observed at DMI MHB. However, much of the difference is related to a high concentration in one sample collected at DMI MHA in June 2013 (33,000 pg/L).

Five more sampling locations were distributed throughout the DMI basin. These locations were intended to assess the importance of the year of housing construction to PCB observations. DMI MHC was located in a basin developed largely in the 1950s, DMI MHD was located in a basin developed largely in the 1970s, while the other three locations (DMI MHE, DMI MHF, and DMI MHG) were all located in basins developed in the past 10–20 years.

Data from the track-down sampling locations are summarized in Table 2-8 and Figure 2-8.

Table 2-8. Total PCB Concentrations (pg/L) and Statistics for Track-Down Samples in 2014

Statistics	DMI MHA	DMI MHB	DMI MHC	DMI MHD	DMI MHE	DMI MHF	DMI MHG
Sample 1	33,000	14,000	8,120	53,800	8,160	5,340	3,640
Sample 2	19,700	12,600	20,800	14,900	11,100	590	28,600
Average	26,300	13,300	14,500	34,400	9,600	2,970	16,100

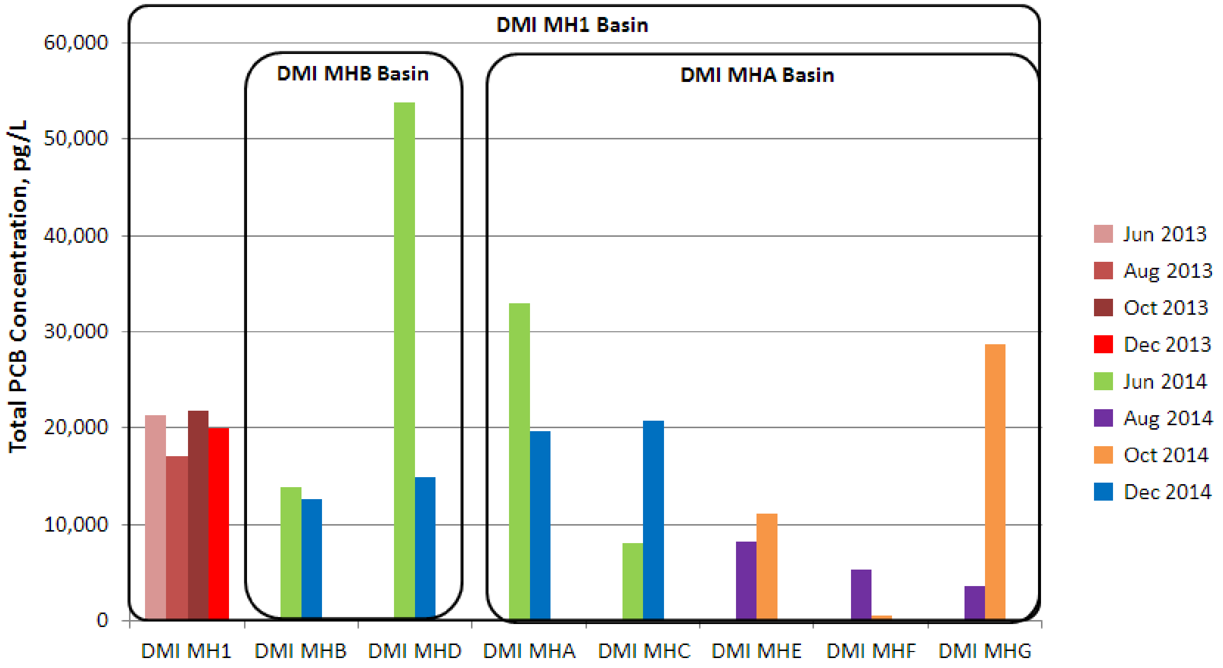

Figure 2-8. Total PCB concentrations at track-down locations within the DMI basin

The data at these locations (Figure 2-7) were difficult to compare, which may be related to the small number of observations (only two samples were taken at each location) at the time of this report's publication. DMI MHF, which covers a basin including new multifamily residential, as well as the trunk line to the Mica Landfill, had low PCB concentrations on both sampling events (5,340 and 590 pg/L). Relatively high PCB concentrations were noted during the June 2014 sampling event at DMI MHD (53,800 pg/L) and during the October 2014 sampling event at DMI MHG (28,600 pg/L).

The June 2014 loading at DMI MHD was not correlated with a high loading at downstream DMI MHA, which may indicate that the loading was of short duration. During the event, the wastewater sample at DMI MHD appeared unusually dark, with a relatively low pH and high solids (TSS) content (920 mg/L).There was low flow in the manhole during the event. The high solids loading may be associated with a flush of sediment because County maintenance crews have reported occasional grease plugging and subsequent flushing at that location. The relatively high PCB concentrations observed at DMI MHA, DMI MHD, and DMI MHG were noted only in one of the two samples taken at each site, limiting the conclusiveness of these data.

Given the limited number and duration of track-down samples, a correlation between the year of construction and the average PCB concentration in the downstream sewer could not be established. Aside from DMI MHF, which had consistently low PCB concentrations, none of the other subbasin sites demonstrated consistently noteworthy results. The DMI MHF subbasin has the highest proportion of new construction (only 4 percent homes built prior to 1980).

In summary, the track-down sampling conducted in Year 2 yielded the following results:

1. All sites were sampled two times during 2014, making it difficult to draw statistically relevant conclusions from the data. A third sampling event will be conducted at each of these sites, with results included in the 2016 Annual Report.
2. PCB concentrations at DMI MHA were consistently higher than those at DMI MHB.
3. PCB concentrations in the upstream basins demonstrated high variability compared to samples taken at the influent pump stations or the Year 1 track-down locations.
4. The site with the highest proportion of new construction had the lowest average PCB concentrations. Given the limited number and duration of track-down samples, a correlation between the year of construction and the average PCB concentration in the downstream sewer could not be established.

2.3.3 Pattern Analysis

PCBs and PBDEs are chemical groups comprising numerous individual congeners. Analyzing the pattern of congener concentrations within each sample can help identify relationships between samples and potential sources. This section presents pattern analysis for PCBs and PBDEs.

There are 209 PCB congeners, which can be sorted into homolog groups based on the number of chlorine atoms attached to the biphenyl ring. Congeners with a single chlorine atom are grouped into the monochlorobiphenyl homolog group (MoCB), congeners with two chlorine atoms are grouped into the dichlorobiphenyl homolog group (DiCB), and so on. The largest molecular weight congener is the decachlorobiphenyl homolog (DeCB) with ten chlorine atoms. Different PCB sources may comprise different levels of homolog groups. Analyzing the relative proportion of each homolog group within samples can demonstrate differences between the samples that may relate to potential different sources of PCBs.

Figure 2-9 presents the average proportion of each homolog group when compared to the average total PCB concentration for the influent trunk lines and effluent samples.

The homolog patterns for the NVIPS and SVIPS are similar to each other, while the Facility effluent appears to have a distinctly different homolog pattern compared to influent. NVIPS and SVIPS homolog patterns reflect a broad spectrum of all molecular weights of PCB congeners, and are mostly made up of tetra- through hexa-chlorinated biphenyl groups. The effluent contains primarily low-molecular weight PCB congeners (mono-chlorinated through tetra-chlorinated biphenyl groups), demonstrating the Facility's ability to filter out the higher molecular weight congeners that are present in the influent.

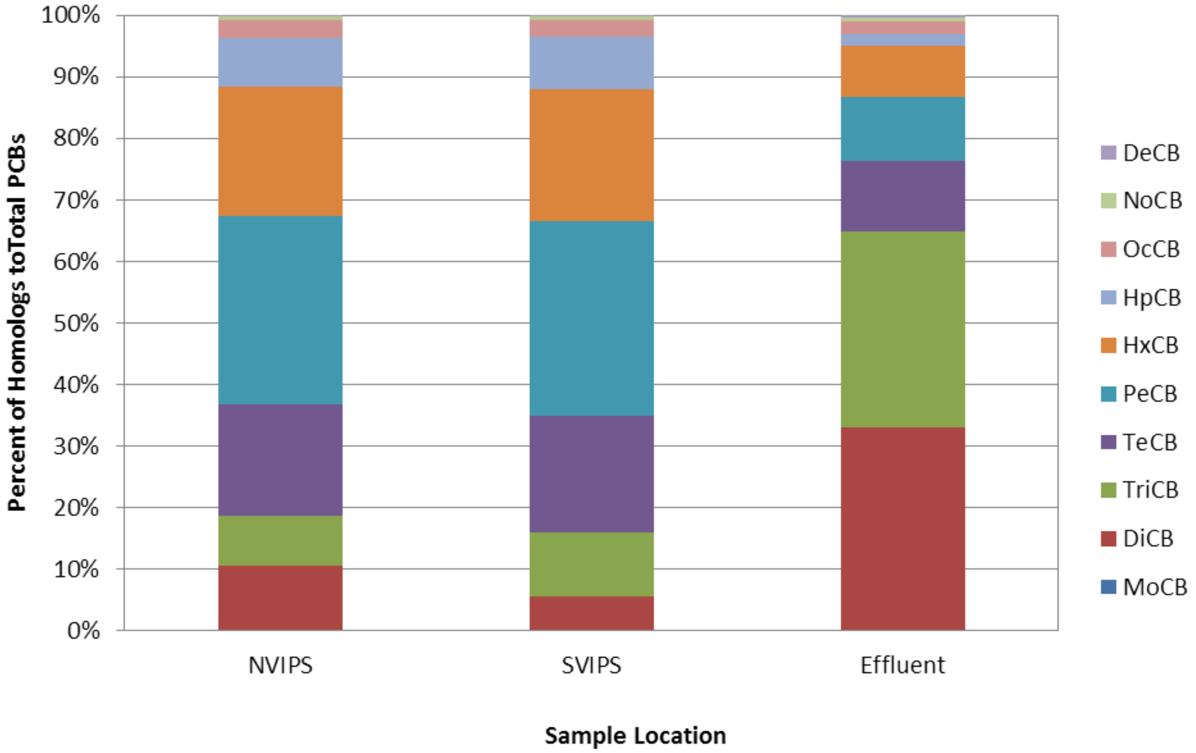

Figure 2-9. Comparison of PCB homolog composition for each sample type

The amount of each homolog was compared to the total PCB concentrations.

Figure 2-10 presents PCB homolog patterns for the track-down sampling locations. SVI MH1, NVI MH1 and DMI MH1 have very similar homolog proportions. The DMI MHB and DMI MHD, both in the DMI MHB subbasin, also have similar homolog proportions. More variability exists in the DMI MHA basin, which included five sampling locations. DMI MHE and DMI MHF have the highest proportion of low molecular weight congeners up to tetrachlorobiphenyls (TeCB) in that basin, much more than DMI MHA or DMI MHC. This variability in homolog pattern is evidence of different types of PCB sources in the sewershed.

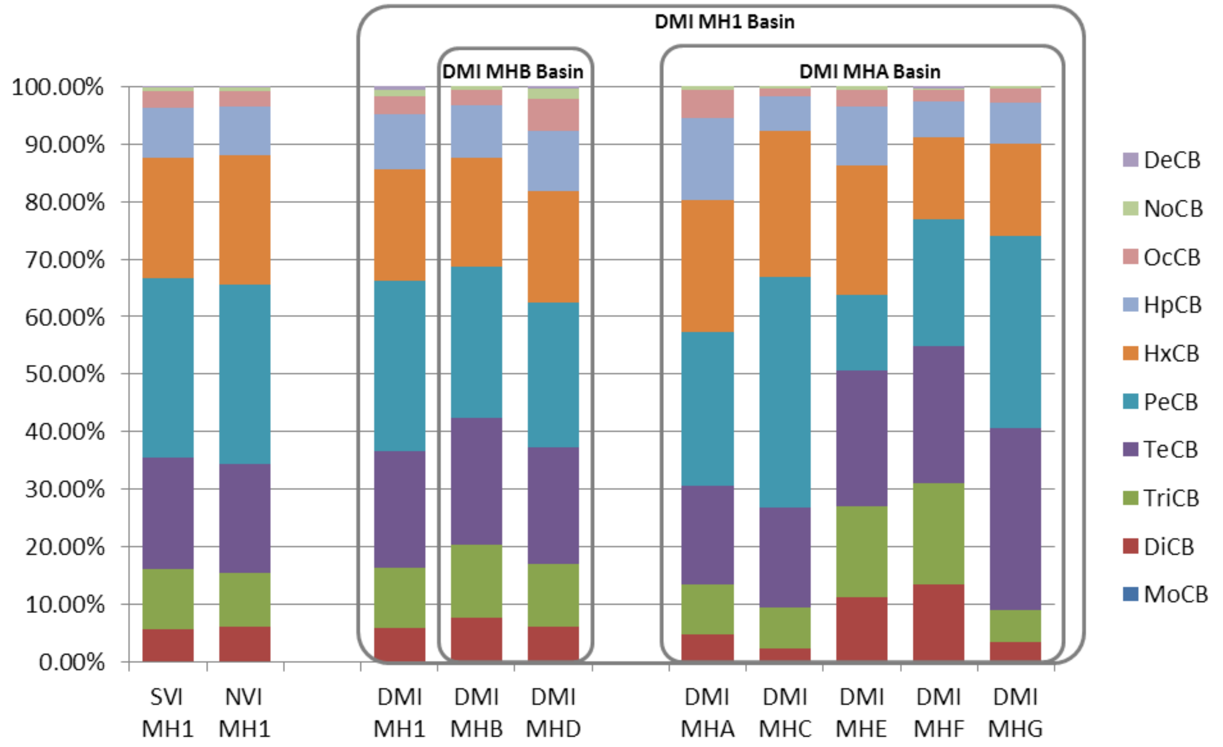

Figure 2-10. Comparison of PCB homolog composition for at track-down sampling locations

The amount of each homolog was compared to the total PCB concentrations.

Like PCBs, PBDEs may also be arranged into homolog groups. PBDEs are characterized by the number of bromine molecules attached to the diphenyl ether ring. Congeners with two bromine molecules compose the Dibromodiphenyl ether homolog group (DiBDE), congeners with three bromine molecules compose the Tribromodiphenyl ether homolog group (TriBDE), and so on. Figure 2-11 presents the composition of each homolog group when compared to the total brominated diphenyl ether concentration for the influent trunk lines, effluent, and track-down manholes. The percentages presented in Figure 2-10 are based on the average for each homolog group and the average total PBDE concentration for all of the data collected.

Tetrabromodiphenyl ether (TeBDE), pentabromodiphenyl ether (PeBDE), and decabromodiphenyl ether (DeBDE) compose the highest percentage of the influent trunk line samples. DeBDE is still produced in electronics, while the production of PeBDE has been phased out in the United States and most international markets (Ecology, 2006).

The effluent had high proportions of Nonabromodiphenyl ethers (NoBDE) and DeBDEs. However, this observation requires further discussion. The blank samples also typically registered relatively high concentrations of DeBDEs, specifically congener BDE-209. If the concentrations of PBDEs measured in the blanks are excluded, the majority of the effluent would be associated with the TeBDE and NoBDE homolog groups (specifically BDE-47, BDE-207, and BDE-208). However, congeners BDE-207 and BDE-208 were found only in two of the nine effluent samples. BDE-47 was found in all effluent samples, and this congener was not observed in high concentrations in the blanks.

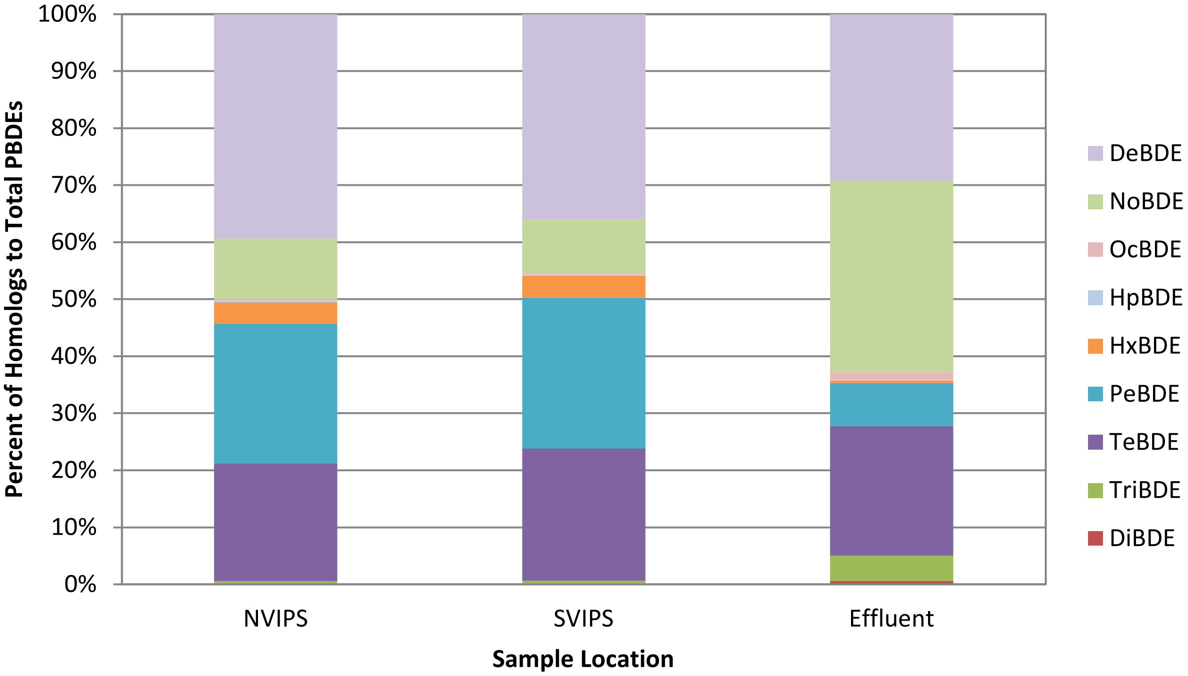

Figure 2-11. Comparison of PBDE homolog composition for each sample type

The amount of each homolog was compared to the total PBDE concentrations (excluding K flagged values).

The homolog group analysis demonstrates differences in homolog group levels in influent and track-down samples, but does not provide detailed evidence of potential PCB sources. To gain further insight into specific sources, differences between samples and sample locations can be analyzed at the congener level, using positive matrix factorization (PMF) as described in the following section.

2.3.4 Source Identification and Positive Matrix Factorization

The homolog evaluation was not able to discern potential sources. The County voluntarily performed an additional evaluation using Positive Matrix Factorization (PMF), an advanced source apportionment tool that has been used to identify PCB sources in water, sediment, and air. The PMF analysis was conducted to provide more definitive information on potential PCB and PBDE sources, even though this level of evaluation is not required by the Permit. This section describes the PMF analysis, which was performed by Dr. Lisa Rodenburg from Rutgers University.

2.3.4.1 PCB Positive Matrix Factorization

PMF is an advanced source apportionment tool developed by Paatero and Tapper (1994) that has been used to identify PCB sources in water, sediment, and air (Ding et al., 2013; Bzdusek et al., 2006a; Bzdusek et al., 2006b; Du et al., 2007; Du et al., 2008; Rodenburg et al., 2011; Qiu et al., 2012). The PMF2 software (YP-Tekniika KY Co., Helsinki, Finland) was used in this study.

PMF defines the sample matrix as a product of two unknown factor matrices with a residue matrix:

$$X = GF + E \qquad (1)$$

The sample matrix (X) is composed of n observed samples and m chemical species. F is a matrix of chemical profiles of p factors or sources. The G matrix describes the contribution of each factor to any given sample, while E is the matrix of residuals. The PMF solution, i.e., G and F matrices, are obtained by minimizing the objective function Q through the iterative algorithm:

$$Q = \sum_{i=1}^{n} \sum_{j=1}^{m} (e_{ij} / s_{ij})^2 \qquad (2)$$

Q is the sum of the squares of the difference (i.e., e_{ij}) between the observations (*X*) and the model (*GF*), weighted by the measurement uncertainties (s_{ij}).

PMF analysis requires three input matrices. The concentration matrix contains the concentrations of the *m* chemical species (in this case, PCB congeners) in the *n* samples. None of the concentrations in this matrix can be zero, so a non-zero value must be estimated for any result that is missing or below the detection limit. The uncertainty matrix contains an estimate of uncertainty for each data point in the concentration matrix. Finally, the limits of detection (LOD) matrix contains the LOD for every data point.

In general, matrices used for factor analysis should not have more analytes (*m*) than samples (*n*). The data set contained 71 samples. including duplicates, the duplicates were treated as samples and 71 congeners were chosen for the PMF analysis. The 71 congeners were chosen based on their abundance in the Aroclors and in the data set, with care taken to retain congeners that are abundant in the effluent, even if they are not particularly abundant in the influent. This approach meant that low molecular weight congeners were retained in the data matrix at the expense of some high molecular weight congeners. The 71 congeners account for approximately 90 percent of all of the PCB mass in all samples, and 87 percent of the PCB mass in the effluent samples.

Concentration matrix: A unique blank correction method tailored to the PMF was used for this analysis. Concentrations were blank corrected by subtracting the average concentration in the blanks (travel, lab, and rinsate blanks) for each congener. These averages were calculated by setting non-detect values to zero and excluding blanks in which the sum of PCBs was greater than 1,000 pg/L. After blank correction, concentration values that were less than or equal to zero were defined as “below detection limit.” Values below the detection limit composed 373 out of 5,041 data points in the concentration matrix (7.4 percent). These values were replaced with one-half of the analytical detection limit on a congener basis.

LOD matrix: The LOD matrix used the congener- and sample-specific LOD as provided. In the small number of cases where the LOD was missing, the LOD was estimated based on similarity to other samples in the data matrix.

Uncertainty matrix: As in other studies (Du et al., 2008; Rodenburg et al., 2008; Rodenburg et al., 2010a), uncertainty was estimated from the surrogate recoveries. The standard deviation of the recoveries of each surrogate was calculated and used as the uncertainty for each congener quantified against that surrogate. The uncertainty for the values below the detection limit was three times the uncertainty of the detected concentrations (i.e., the [x,3x] uncertainty matrix was used).

2.3.4.2 Non-Aroclor PCB Sources

PCB-11 was measured at relatively high concentrations (compared to other congeners) in both the influent and effluent. PCB-11 is the single most abundant congener in the effluent. . This is true with or without blank correction (see above for details on blank correction). PCB-11 concentrations in the effluent average 25 ± 7 pg/L (all concentrations are after blank correction unless stated otherwise). Concentrations of PCB-11 are significantly higher in the NVIPS samples (1,734 ± 1,791 pg/L) than the SVIPS samples (441 ± 76 pg/L) according to the two-tailed t-test assuming unequal variances ($p < 0.05$).

PCB-11 is virtually absent in the Aroclors. It is thought to enter the environment primarily from the use of diarylide yellow and other pigments in printing on paper and textiles (Rodenburg, 2010b). PCB-11 has a low K_{ow} and low molecular weight. Compared to other congeners, PCB-11’s physical/chemical properties cause it to partition to a lesser extent to particles. This may explain why PCB-11 was found in the effluent at higher concentrations than other, less soluble congeners. When the duplicate NVIPS samples collected on December 17, 2013, are excluded, PCB-11 (3,3'-dichloro) is strongly correlated with PCB-35 (3,3',4-trichloro; $R^2 = 0.73$) and somewhat correlated with PCB-77 (3,3',4,4'-tetrachloro; $R^2 = 0.27$). These structurally related congeners have all been reported as trace contaminants in diarylide yellow pigments (Litten et al., 2002; Anezaki and Nakano, 2014).

Other than PCB-11, there is no evidence that non-Aroclor PCB sources are impacting the influent and/or effluent of this Facility. For example, in the Delaware River, production of $TiCl_4$ (a precursor to titanium dioxide [TiO_2]) led to the extensive contamination of the sediment of the Delaware River with PCBs 206, 208, and 209. Nothing of that kind is observed in the County data.

2.3.4.3 PCB PMF Factors Analysis

A major challenge of factor analysis is to choose the "correct" number of factors that adequately describe the data matrix without over- or under-fitting. In the present case, seven factors were isolated from the 71 x 71 data matrix. For comparison, the 38 x 38 data matrix analyzed in 2014 yielded six factors. The 2015 factors were similar to the 2014 factors.

The seven-factor PMF solution did an excellent job of reproducing the data. The correlation coefficient (R^2) for the modeled versus measured data was greater than 0.9 for 62 of the 71 congeners. It was above 0.8 for another three congeners. The congeners with lower R^2 values were: PCB-3 ($R^2 = 0.64$), PCB-5 (0.797), PCB-9 (0.69), PCB-27 (0.75), PCB-198 (0.65), and PCB-203 (0.68).

To determine whether any of the factors represented mixtures of Aroclors, a multiple linear regression was performed in which a congener pattern (excluding PCB-11) was calculated that represented a linear combination of the four main Aroclors:

$$C_f = aC_{1242} + bC_{1248} + cC_{1254} + dC_{1260} \quad (1)$$

where C is concentration of the resolved factor (f) or individual Aroclor and a, b, c, and d are partial regression coefficients, which were constrained to be positive. Correlation coefficients (R^2) between this best-fit composite Aroclor congener pattern and the factor congener pattern were calculated. The resolved factors were compared with the congener patterns of the Aroclors (Rushneck et al., 2004) in an attempt to identify them (Table 2-9). Each factor's best-fit was also compared to a combination of Aroclors (Table 2-10). All factors were reasonably well described as a combination of Aroclors, although the correlation is worst for Factors 1 and 5, suggesting that they have undergone the most weathering.

Table 2-9. Correlation Coefficients (R^2) between Factors and Single Aroclors

Factor	1016	1242	1248	1254	1260
F1	**0.73**	0.60	0.11	0.01	0.06
F2	0.16	0.34	**0.78**	0.32	0.02
F3	0.40	0.59	**0.75**	0.14	0.02
F4	0.01	0.03	0.15	**0.57**	0.32
F5	0.00	0.07	**0.53**	0.36	0.01
F6	0.04	0.00	0.10	**0.98**	0.12
F7	0.07	0.07	0.01	0.12	**0.84**

The R^2 value is the correlation coefficient for the best-fit Aroclor versus the actual congener pattern. Factors with lower R^2 values have probably undergone more weathering. Note PCB-11 is excluded from these correlations.

Table 2-10. Coefficients for the Best-fit Description of Each Factor as a Mixture of the Four Most Common Aroclors

Factor	1242	1248	1254	1260	R^2
F1	0.83	0.00	0.00	0.01	0.60
F2	0.07	0.25	0.12	0.00	0.88
F3	0.42	0.39	0.18	0.02	0.88
F4	0.22	0.10	0.39	0.27	0.79
F5	0.00	0.71	0.42	0.00	0.69
F6	0.01	0.00	0.97	0.02	0.98
F7	0.00	0.05	0.24	0.65	0.90

The R2 value is the correlation coefficient for the best-fit Aroclor combination versus the actual congener pattern. Factors with lower R2 values have probably undergone more weathering. Note PCB-11 is excluded from these correlations.

The fingerprints of the seven resolved factors are shown in Figures 2-11 through 2-15. Factors 1 and 2 resembled Aroclors only when PCB-11 was removed from the correlation. Each of the factors was at least somewhat similar to one of the Aroclors (i.e., R^2 greater than about 0.45). Factors 3, 6, and 7 appear to represent relatively fresh or unweathered Aroclors 1248, 1254, and 1260, respectively. Factors 4 and 5 were similar to Aroclors 1254 and 1248, respectively, but appear to have undergone more substantial weathering, as indicated by lower R^2 values.

Factor 1, which is dominant in the effluent but barely present in the influent, is similar to the individual Aroclors 1016 and 1242, but even when expressed as a sum of the four main Aroclors, this factor does not well resemble any of these formulations. It is likely that Factor 1 represents the dissolved-phase PCB concentration that is not removed during the wastewater treatment process (see Figure 2-12). In order to determine whether the congener pattern of Factor 1 (excluding PCB-11) is similar to any of the other Aroclors when the water/particle partitioning is taken into account, the congener patterns (i.e., the abundance of each congener) of the Aroclors were divided by the congener's octanol-water partition coefficient (Hansen et al., 1999). The new "dissolved" congener pattern was compared to the congener pattern of Factor 1. The R^2 values for the comparison of Factor 1 (without PCB-11) and the "dissolved" Aroclors 1016, 1242, and 1248 were all between 0.5 and 0.7. In addition, the concentration of Factor 1 in the effluent is relatively constant at 116 ± 14 pg/L. Taken together, these two lines of evidence suggest that Factor 1 represents the dissolved phase of a variety of low molecular weight Aroclor formulations, plus the dissolved fraction of PCB-11.

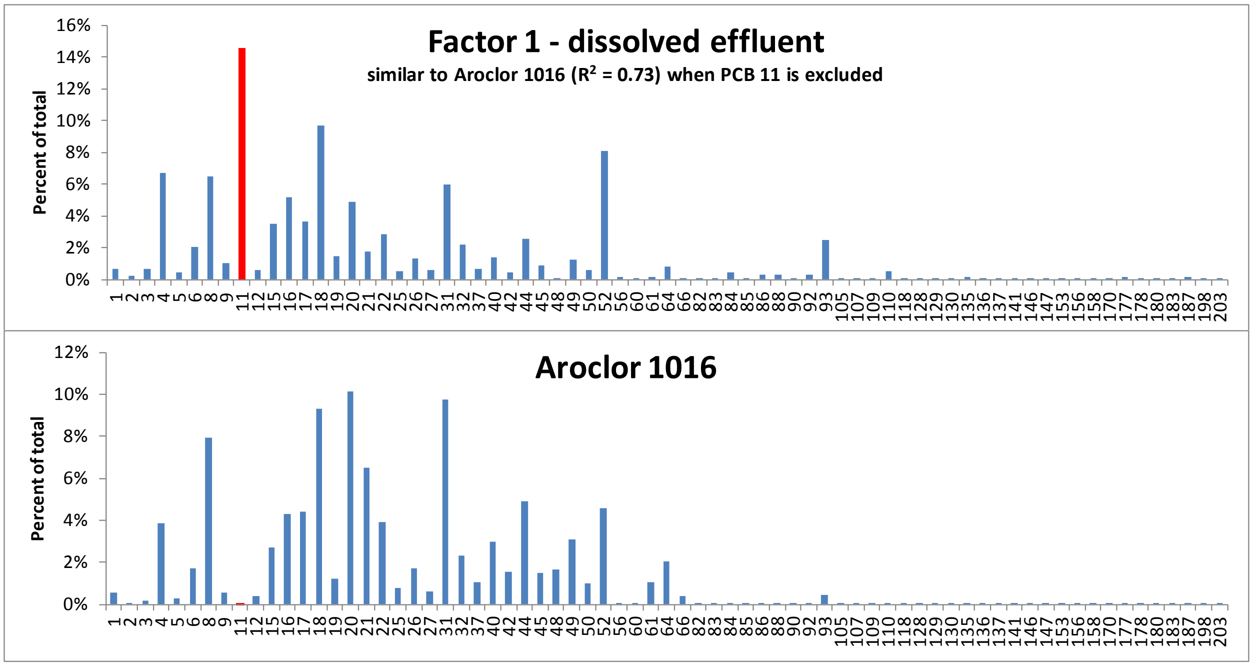

Figure 2-12. Fingerprint of Factor 1 compared to Aroclor 1016

Panel shows Factor 1 and each congener as percent of total mass in the data set.

Factor 2 is dominated by PCB-11 (Figure 2-13). When this congener is excluded, it resembles Aroclor 1248 (R^2 = 0.78). It is reasonably well described as a mixture of the four main Aroclors. As noted above, concentrations of this factor are significantly higher in NVIPS (1,845 ± 2,324 pg/L) than in SVIPS (589 ± 383 pg/L).

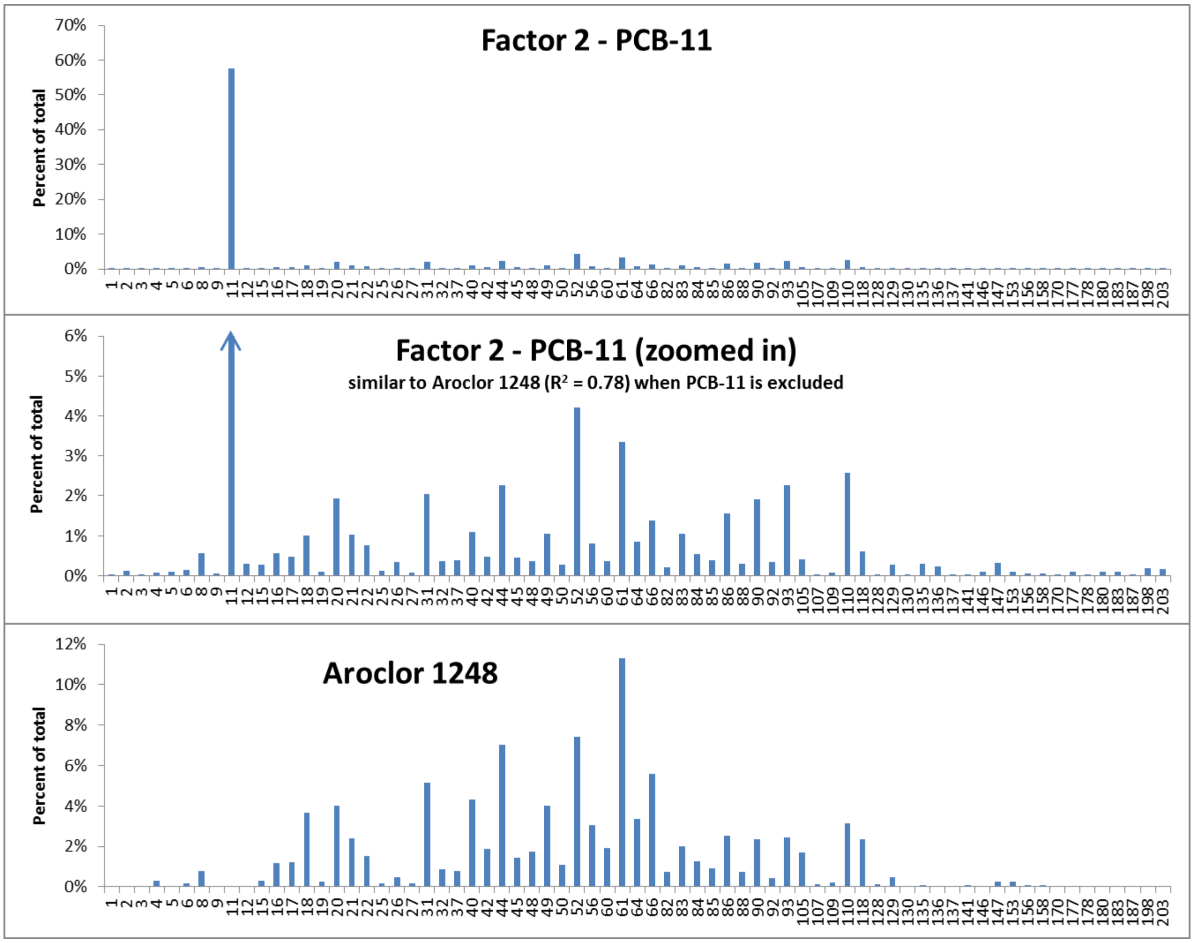

Figure 2-13. Fingerprint of Factor 2

Panel shows Factor 2 and each congener as percent of total mass in the data set. The bottom panel is the same fingerprint with the y-axis range modified to less than 6%.

Factor 3 is similar to Aroclor 1248 but, as Figure 2-14 shows, it contains a broader range of congeners at both the high and low MW ends of the spectrum. For this reason, Factor 3 is fairly well described as a mixture of the four main Aroclors. In contrast, Factor 5 also resembles Aroclor 1248, but it is “missing” congeners at both the high and low MW ends of the spectrum. It is similar to a mixture of Aroclors 1248 and 1254. Concentrations of Factor 3 are higher in SVIPS (3,268 ± 1,864 pg/L including track-down manholes, 2,827± 684 pg/L) than in NVIPS (1,815 ± 1,239 pg/L including track-down manhole samples, 1,854 ± 1,379 pg/L). Concentrations of Factor 5 are not different between NVIPS and SVIPS.

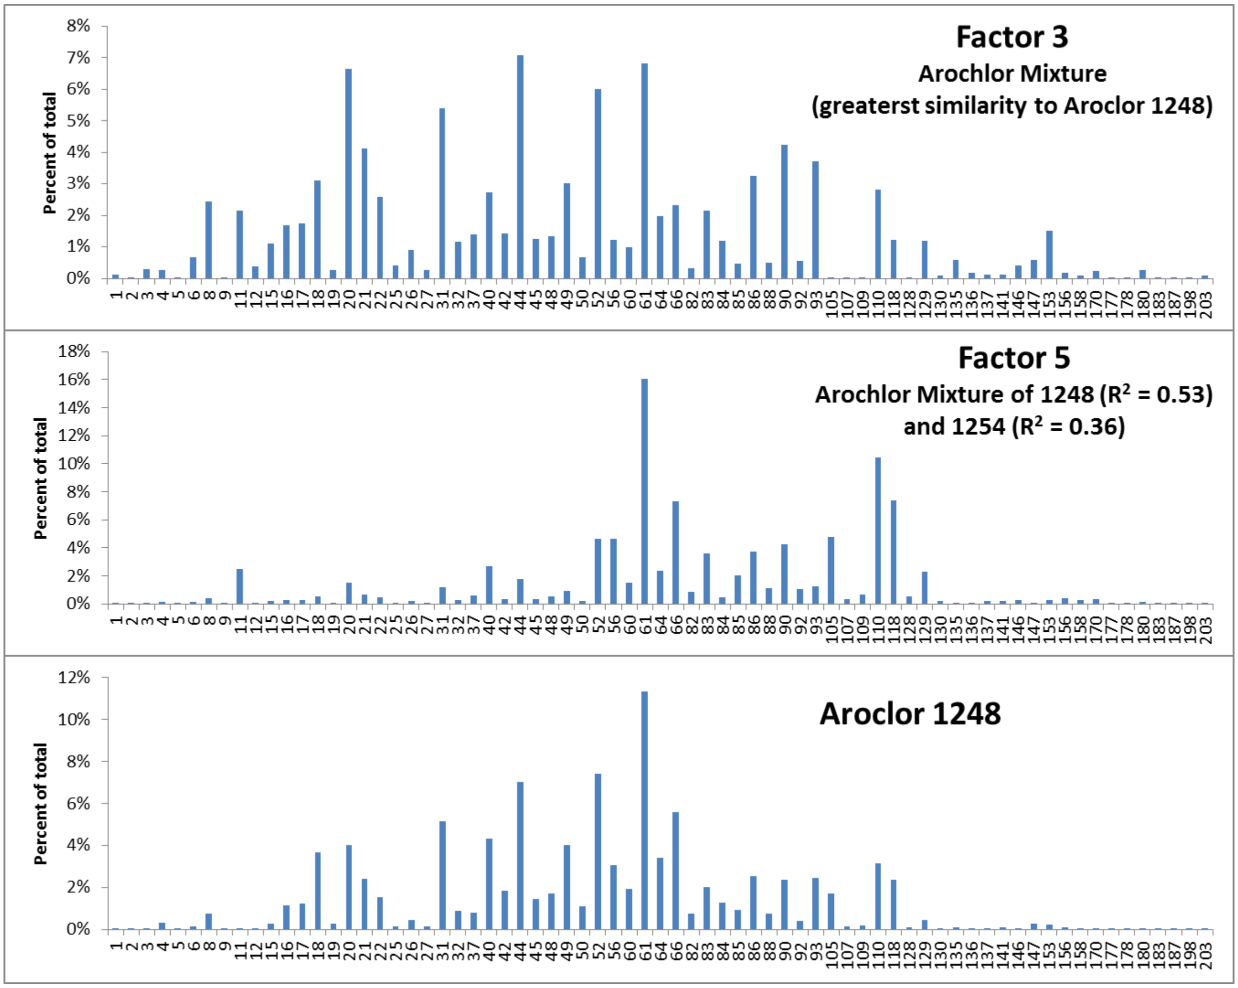

Figure 2-14. Fingerprints of Factors 3 and 5 compared to Aroclor 1248

Panel shows Factors 3 and 5, and each congener as percent of total mass in the data set.

Factor 4 resembles Aroclor 1254, but the correlation is not strong ($R^2 = 0.57$), and of all the factors, it is not well described as a mixture of Aroclors, indicating significant weathering. Concentrations of Factor 4 are not different between the NVIPS and SVIPS samples.

Factor 6 strongly resembles Aroclor 1254 ($R^2 = 0.98$). Such a strong resemblance implies virtually no weathering. Aroclor 1254 was the main Aroclor used in building materials such as caulk (Herrick et al., 2004). However, Aroclor 1254 was also used in a wide variety of other applications (Agency for Toxic Substances and Disease Registry [ATSDR], 2000). As noted in last year's report, this factor is particularly abundant in samples collected on August 20, 2013 at the NVIPS location. It is also abundant in the sample collected on December 9, 2014, at the DMI MHC location. Factors 4 and 6 are shown compared to Aroclor 1254 in Figure 2-15.

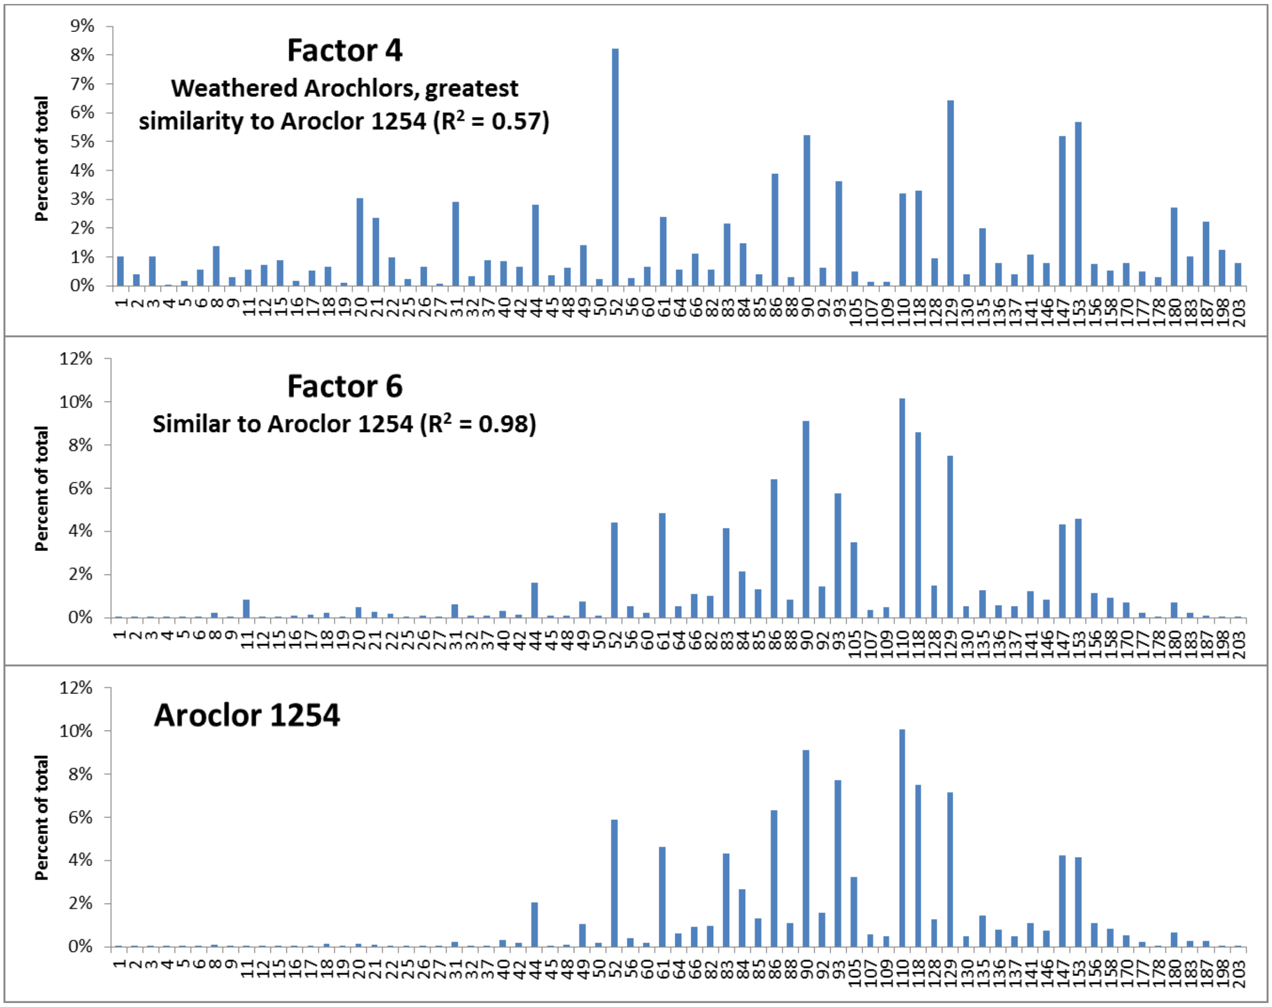

Figure 2-15. Fingerprints of Factors 4 and 6 compared to Aroclor 1254

Panel shows Factors 4 and 6, and each congener as percent of total mass in the data set.

Factor 7 somewhat resembles Aroclor 1260 (R^2 = 0.84), but contains more low molecular weight congeners (Figure 2-16). It is well described (R^2 = 0.90) as a mixture of Aroclors, especially Aroclors 1254 and 1260. Concentrations of Factor 7 are not different between NVIPS and SVIPS.

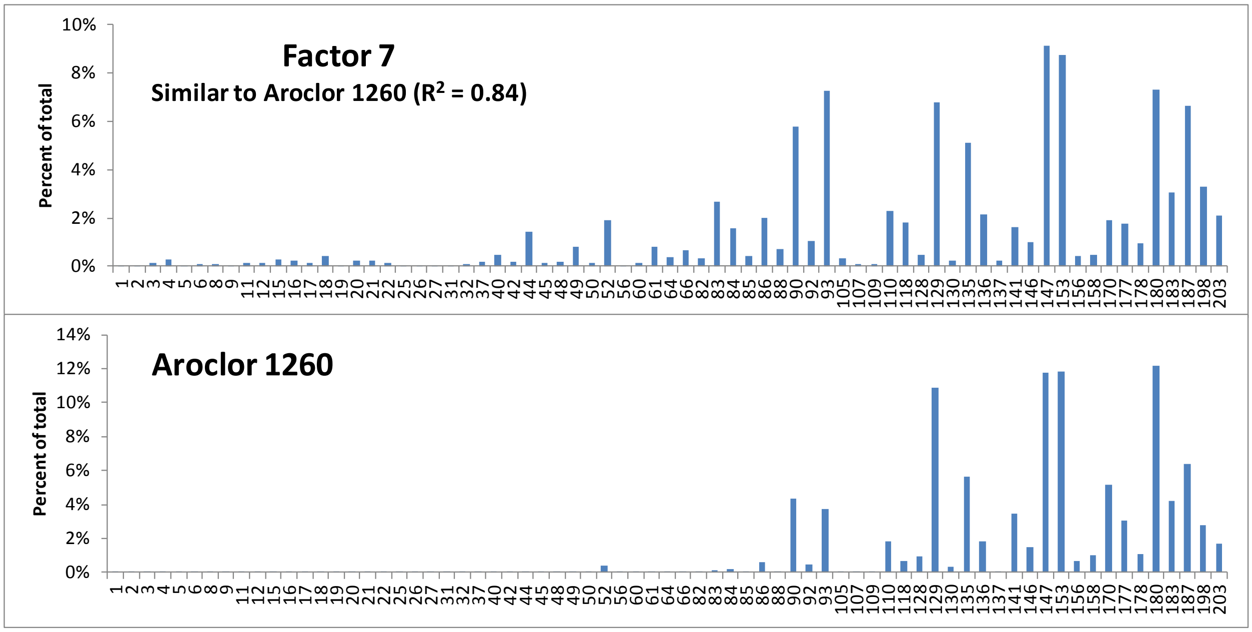

Figure 2-16. Fingerprint of Factor 7 compared to Aroclor 1260

Panel shows Factor 7 and each congener as percent of total mass in the data set.

The proportions of the seven factors in the influents (SVIPS and NVIPS) were similar to each other, but very different from the effluent. The following pie charts represent the average contribution of each factor to the total PCBs measured in selected samples. Figure 2-17 compares the factor profiles at the NVIPS and SVIPS. Factors 2 and 3 displayed significantly different concentrations in the NVIPS compared to the SVIPS samples. Concentrations of Factor 2 (which is dominated by PCB-11) were higher in the NVIPS samples, while concentrations of Factor 3 (which resembles Aroclor 1248) were higher in the SVIPS samples. This suggests that these two factors may be associated with specific contaminated locations, rather than regional background contamination. For this reason, these factors might be a priority for track-down. The Factor 3 concentration was noticeably elevated in the sample from DMI MHD collected on June 23, 2014.

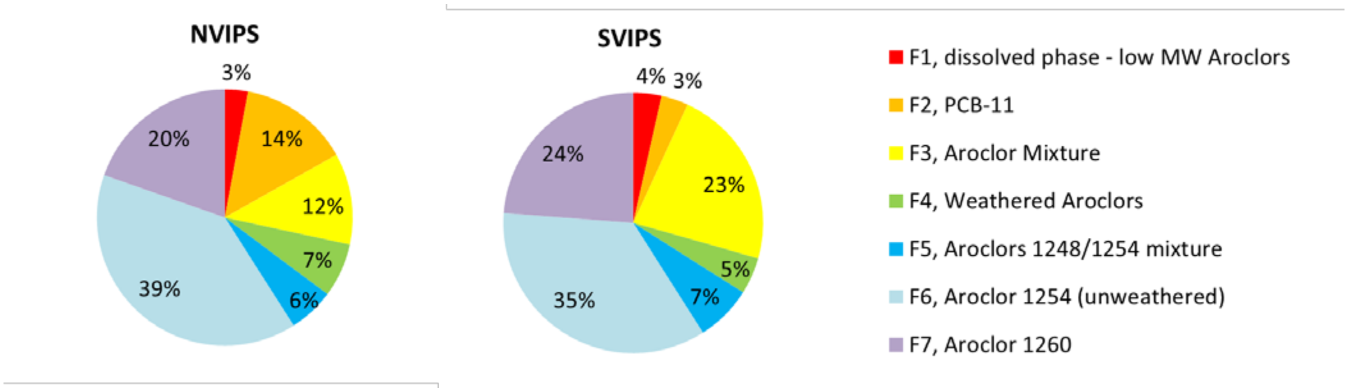

Figure 2-17. Contribution of each of the seven factors to the total PCB mass in the SVIPS and NVIPS

Figure 2-18 depicts the factor profiles in effluent samples. Factor 1, which correlates with dissolved phase low molecular weight Aroclors, is the most common factor. The other six factors are all present to varying degrees, with Factor 6 (unweathered Aroclor 1254) comprising the second-highest percentage. Factor 6 was the dominant factor at both influent locations.

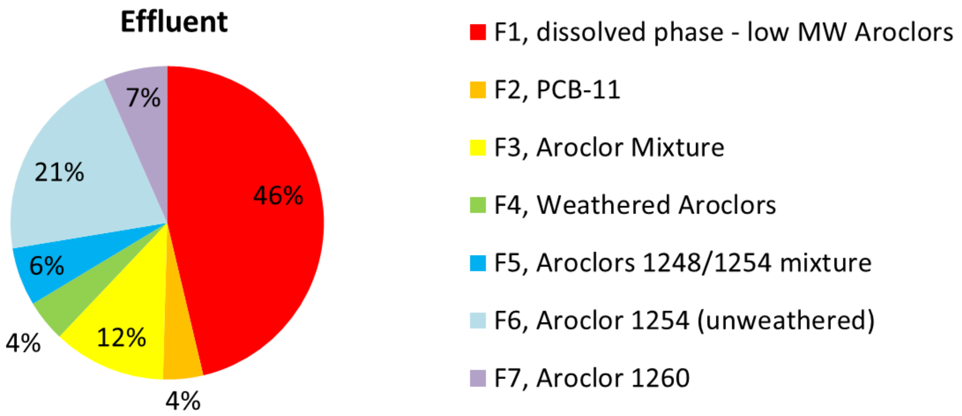

Figure 2-18. Contribution of each of the seven factors to the total PCB mass in the effluent

Figure 2-19 presents the factor profiles for the two highest total PCB concentrations observed to date: the August 2013 NVIPS sample (67,750 pg/L) and the June 2014 DMI MHD sample (53,900 pg/L). The August 2013 NVIPS sample is almost entirely comprised of Factors 6 and 7. Factor 6, which comprises 69 percent of the sample, correlates to a relatively pure (unweathered) profile of Aroclor 1254. This profile is consistent with an accidental point source discharge of one or two contaminated chemicals. In comparison, the June 2014 DMI MHD sample is much more varied, and resembles the overall profile observed at the downstream SVIPS and DMI MH1. A high TSS concentration was observed in this sample and this profile is consistent with a higher contamination due to the higher solids or sediment content.

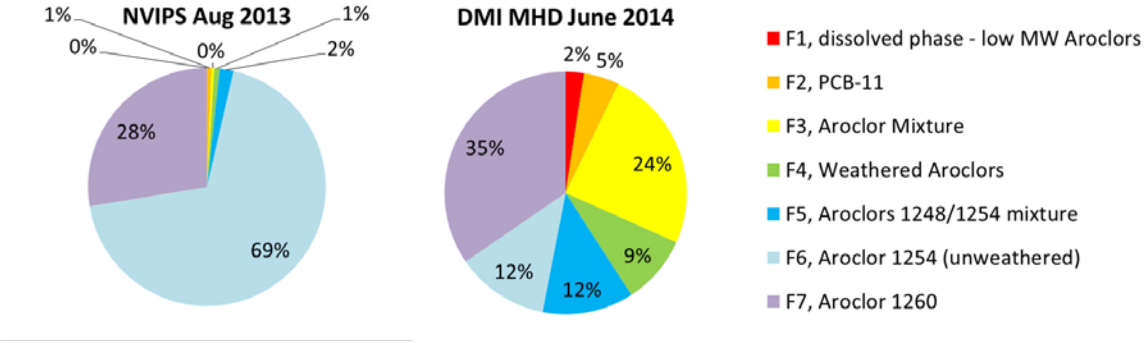

Figure 2-19. Contribution of each of the seven factors to the total PCB mass in the two most highly concentrated total PCB samples, to date

Figure 2-20 presents the factor profiles for the five track-down sampling locations in the DMI basin, which were selected on the basis of year of construction. Two samples from each DMI manhole location are presented in Figure 2-20. DMI-MHC, representing the oldest construction, shows a higher proportion of F6 (unweathered Aroclor 1254). Aroclor 1254 was commonly used in building materials, such as caulk and along with Aroclor 1260 were the main PCB mixtures used before 1950. DMI-MHD, representing homes built primarily in the 1960s and 1970s, has a profile similar to those observed at the influent pump stations and at the downstream DMI MH1. The three remaining sites, which represent newer developments, had varied profiles. DMI MHE had a high proportion of Factor 3, a mixture of four common Aroclors. DMI MHF, which represents the newest construction of all the sites, showed an even higher proportion of Factor 3, along with a relatively high proportion of Factor 2, which is associated with PCB-11. DMI MHG sampling results varied among the two samples taken. One sample from DMI MHG was dominated by Factor 5, which correlates to a mixture of Aroclors 1248 and 1254, with very little contribution from Factors 2 and 3. The DMI MHG profile is heavily influenced by the October 2014 event, with a total PCB concentration of 29,700 pg/L (compared to the August 2014 event which had a total PCB concentration of 3,670 pg/L). The October 2014 sample profile showed 66 percent Factor 5, and less than one percent of each of Factors 1, 2, 3, and 4.

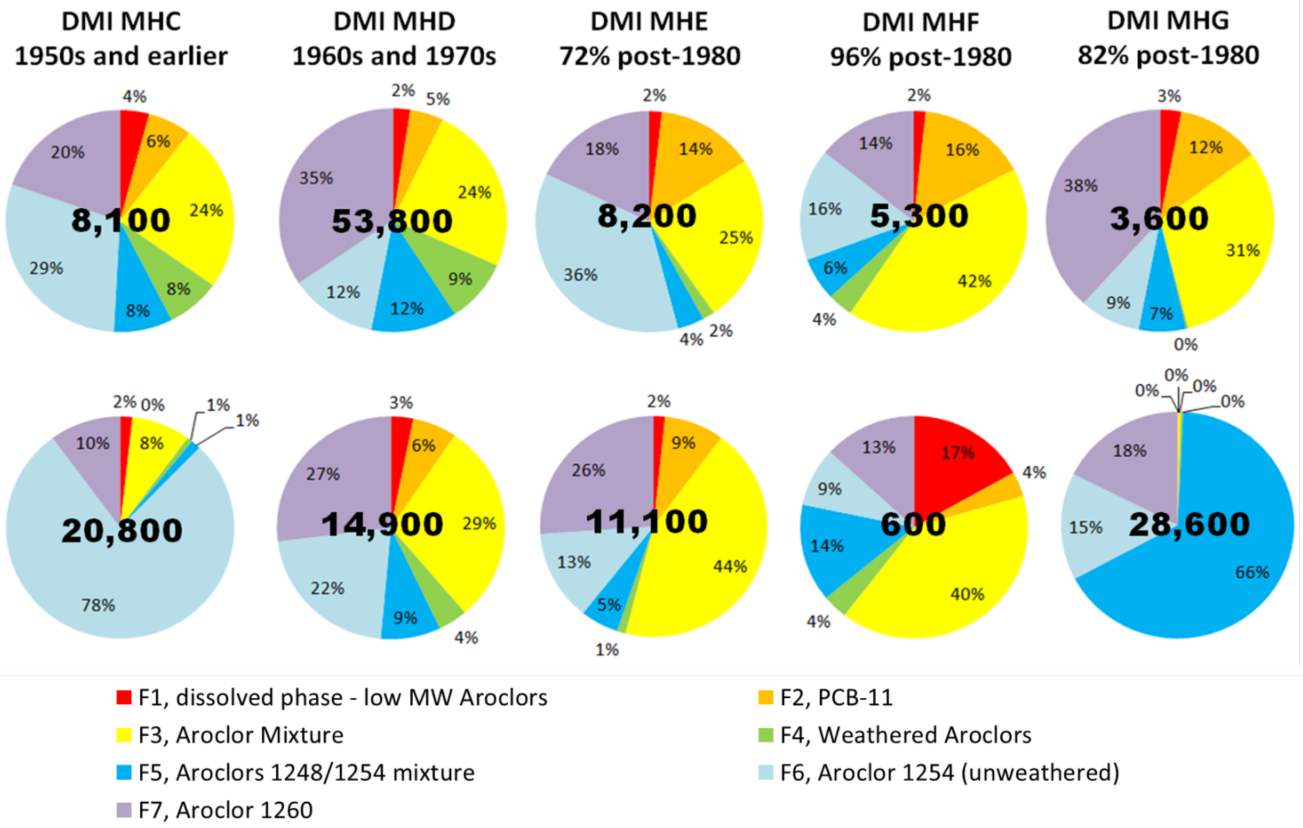

Figure 2-20. Contribution of each of the seven factors in the DMI subbasins

Note: the value bolded in black on each pie chart represents the total PCB concentration (pg/L) for each sample.

With only two samples per site in the 2014 DMI track-down, it is not possible to draw conclusions regarding the potential influence of year of construction. Impacts from individual or one-time point source discharges are amplified at sampling locations with small tributary areas. Events such as the October 2014 profile at DMI-MHG, dominated by 66 percent of Factor 5, and the December 2014 profile at DMI-MHC, which was 78 percent Factor 6, support this line of reasoning. Beyond that, the factor profiles suggest little correlation between the year of construction and the source of PCB contamination.

2.3.4.4 PCB PMF Summary and Conclusions

The PMF analysis yielded the following results and conclusions:

- The PMF analysis involved 71 congeners, totaling 90 percent of the total PCB mass across all samples.
- The seven-factor PMF solution did an excellent job of reproducing the data, based on congener correlation coefficients.
- Most of the factors are strongly correlated to Aroclors and Aroclor mixtures. The exception is Factor 2, which is mainly composed of PCB-11, which is often found in yellow dyes and pigments. Factor 2 was more prevalent at NVIPS than at SVIPS.
- Factor 1 comprised the majority of the effluent, and appears composed of dissolved-phase, low molecular weight Aroclors.
- Factor 6 appears similar to unweathered Aroclor 1254, which has been found in building materials such as caulk, and other applications. This factor was particularly abundant in the December 2014 sample at DMI MHC (20,900 pg/L total PCB concentration).
- Factor 3, which resembles a mixture of the four most common Aroclors, was much more prevalent in the SVIPS samples versus the NVIPS samples. It was also quite abundant in the June 2014 sample at DMI MHD (53,900 pg/L total PCB concentration).

2.3.4.5 PBDE Positive Matrix Factorization

PBDEs are produced and sold in three main types of formulations, the penta-, octa-, and deca-BDE formulations. Note that the name of the formulation does not necessarily correspond to the homologs of the BDEs that are present in the mixture. PeBDE is dominated by BDE-47, which is a TeBDE, as well as BDE-99 and BDE-100, which are both pentabromo congeners. Octa-BDE (OcBDE) contains primarily BDE-183 (hepta), although some octa formulations contain large amounts of BDE-206 and BDE-207 (nona), and BDE-209 (deca). DeBDE consists primarily of BDE-209.

The PBDE data set shows very little BDE-183; it is never more than 0.5 percent of the sum of BDEs in any sample. This may suggest that OcBDE was not used in significant quantities in this area.

Because BDEs in general have high octanol-water partition coefficients, they partition to the particulate matter in the water column to an even greater extent than PCBs. As a result, BDEs in general and especially the high molecular weight congeners are less likely to be found in the effluent because of the excellent solids removal of the Facility. Thus BDE-209 is undetectable in two of the nine effluent samples, despite its being the most abundant congener in many of the other samples (and in most environmental samples). Effluent BDE concentrations contain high proportions of TeBDEs, primarily BDE-47. BDE-47 is the dominant congener in the PeBDE commercial formulations, which include trade names such as DE-71 and 70-5DE, all sold under the name Bromkal.

BDE-28 and BDE-17 are also quite abundant in the effluent, composing up to 24 percent of the sum of BDEs. These two congeners are only very small contributors to the PeBDE technical mixtures. Bromkal DE-71 contains less than 0.1 percent BDE-17 and about 0.25 percent BDE-28 and BDE-33. Bromkal 70-5DE contains about 0.05 percent BDE-17 and 0.1 percent BDE-28. These two congeners are not detectable in the other commercial BDE formulations (La Guardia et al., 2006). Both of these congeners can be produced from the debromination of heavier BDE congeners. The photolysis of BDEs exhibits characteristic pathways and breakdown products (Wei et al., 2013; Fang et al., 2008; Sanchez-Prado et al., 2012; Sanchez-Prado et al., 2006). BDE-15 is a major photolysis product, with BDE-17 sometimes reported as a minor product (Wei et al., 2013; Sanchez-Prado et al., 2012). Several studies have noted that BDE-17 is a major product of microbial BDE debromination (Ding et al., 2013; La Guardia et al., 2007; Tokarz et al., 2008; Robrock et al., 2008). In contrast, Lee et al., 2011 studied the debromination of BDEs by a coculture consisting of Dehalococcoides and Desulfovibrio species, and found that debromination at the ortho position is preferred, with significant amounts of PBDE-15 formed.

Thus the abundance of BDE-17 and BDE-28 indicates that microbial debromination of BDEs is occurring in the system, most likely in the sewers (Rodenburg et al., 2010a and 2012a). The relative lack of BDE-15 suggests that photolysis is not important in this system.

PBDE PMF Analysis

The data set for PMF analysis included 27 of the 47 BDE congeners measured. The excluded congeners were below the detection limit in the majority of samples, so the data set included virtually 100 percent of the mass of all of the BDEs in the data set. As with the PCB PMF analysis, the BDE analysis was performed on blank corrected data and included the duplicates as separate samples. In the future when more samples are collected, duplicates can be excluded. The final matrix contained 27 congeners measured in 47 samples.

Concentration matrix: Values below detection limit composed 209 out of 1,269 data points in the concentration matrix (16 percent). These values were replaced with one-half of the detection limit. Blank correction was performed by subtracting the average concentration of each congener across all blanks from each sample.

LOD matrix: The LOD matrix used the congener- and sample-specific LOD as provided.

Uncertainty matrix: As in other studies (Du et al., 2008; Rodenburg et al., 2008; Rodenburg et al., 2010a), uncertainty was estimated from the surrogate recoveries. The standard deviation of the recoveries of each surrogate was calculated and used as the uncertainty for each congener quantified against that surrogate. For congeners that were quantified relative to more than one surrogate, the uncertainty was propagated for the average surrogate recovery (i.e., the uncertainty was the square root of the sum of the squared uncertainties of all surrogates used). The uncertainty for the values below the detection limit was three times the uncertainty of the detected concentrations (i.e., the [x,3x] uncertainty matrix was used).

PBDE PMF Results

Three factors were resolved from this data matrix. The three-factor model gave the best agreement between the nine seed runs (i.e., the relative standard deviation [RSD] of the G matrix was 1.4 percent) and the agreement between the modeled and measured concentrations was excellent. The correlation coefficient (R^2) for the measured vs. modeled concentrations was greater than 0.80 for 21 of the 27 congeners. The remaining congeners (BDEs 7, 8, 37, 71, 75, 199, and 183) had R^2 values greater than 0.85 when one to six of these outliers were removed from the correlation. The congener patterns for the three factors are shown in Figure 2-21.

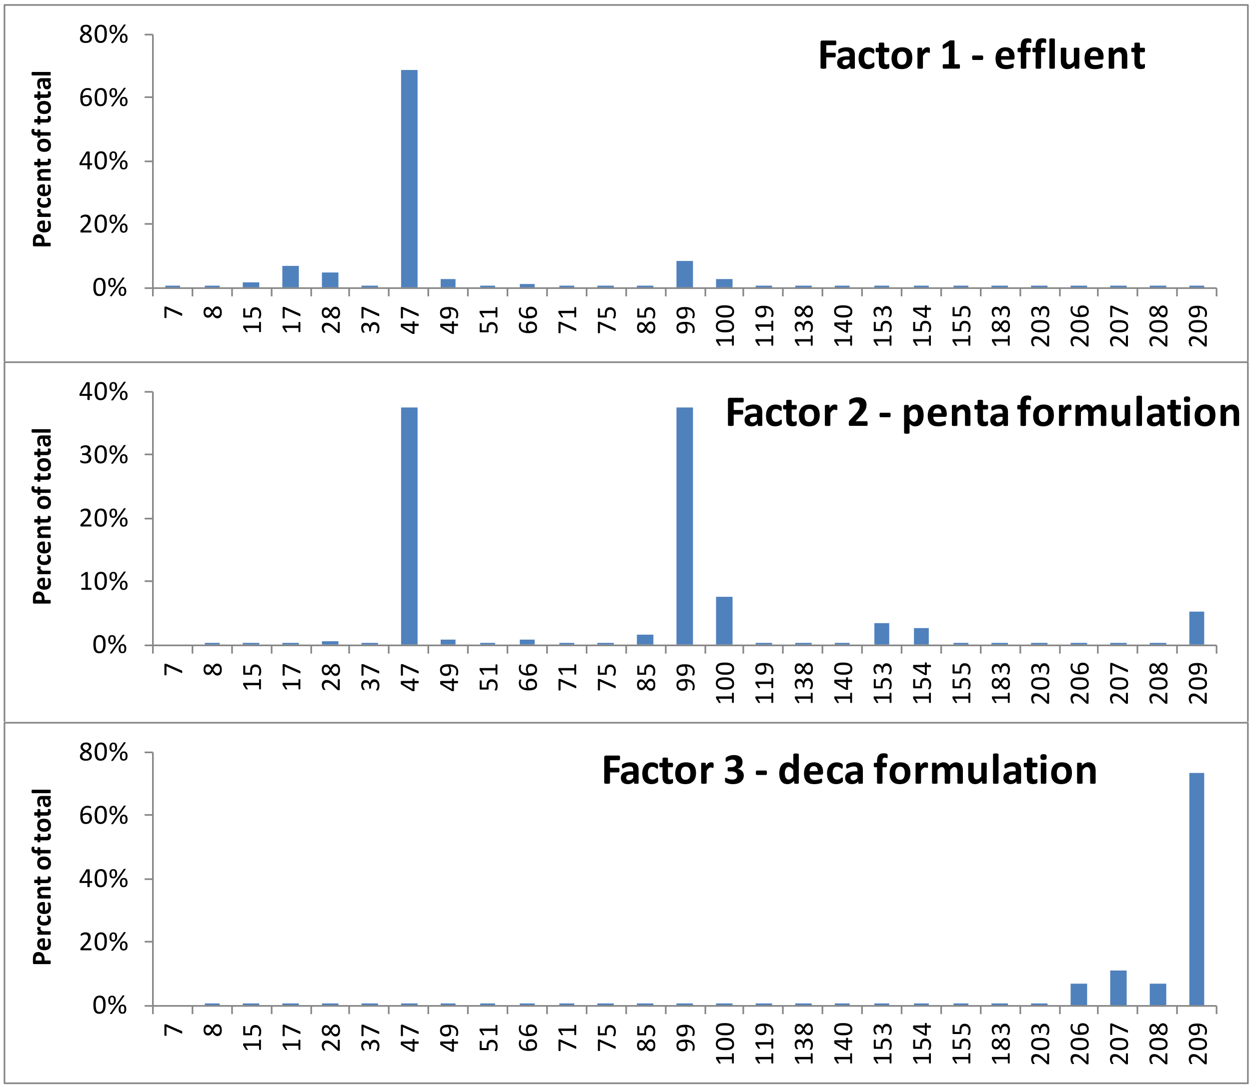

Figure 2-21. Fingerprints of the three resolved BDE factors

Numbers in parentheses are the percent contribution of each factor to the total mass in the data set.

Factor 1 does not strongly resemble any of the technical BDE formulations. Because it contains a relatively high amount (6.9 percent) of BDE-17 and the highest proportions of BDE-7 and BDE-8, it may represent debromination of higher molecular weight BDE congeners. It accounts for only 1 percent of the total mass in the data set, but it is the dominant factor in eight out of the nine effluent samples (Figure 2-19). In the effluent, concentrations of this factor are relatively constant averaging 689 ± 242 pg/L. In this sense, Factor BDE-1 is similar to Factor 1 of the PCB solution. Both appear to represent the dissolved phase. Factor 1 concentrations are significantly higher in SVIPS (4,714 ± 1,459 pg/L) than in NVIPS (2,679 ± 1,136 pg/L). This difference probably arises because Factor 2 is also higher in the SVIPS samples (see below) and Factor 1 represents the fraction of Factor 2 that partitions into the dissolved phase. This interpretation is supported by the fact that concentrations of Factor 1 are strongly correlated with concentrations of Factor 2 ($R^2 = 0.78$).

Factor 2 accounts for 62 percent of the mass in the NVIPS and SVIPS and represents the PeBDE formulations. Concentrations of this factor are significantly higher in SVIPS (273 ± 88 nanograms per liter [ng/L]) than in NVIPS (174 ± 53 ng/L). Note the change in units from pg/L to ng/L. Factor 2 is at low concentrations in the effluent and is removed by the Facility.

Factor 3 is dominated by high MW BDE congeners such as BDEs 206, 207, 208, and 209. It represents the deca-BDE formulation. Concentrations of this factor are not different between SVIPS and NVIPS. This factor is present only occasionally in the effluent, suggesting virtually complete removal

Figure 2-22 shows the contribution of each BDE factor compared to the total BDE mass of the NVIPS, SVIPS, and effluent samples. The PMF results suggest that the commercial PeBDE and DeBDE formulations are the dominant sources of BDEs to the influent.

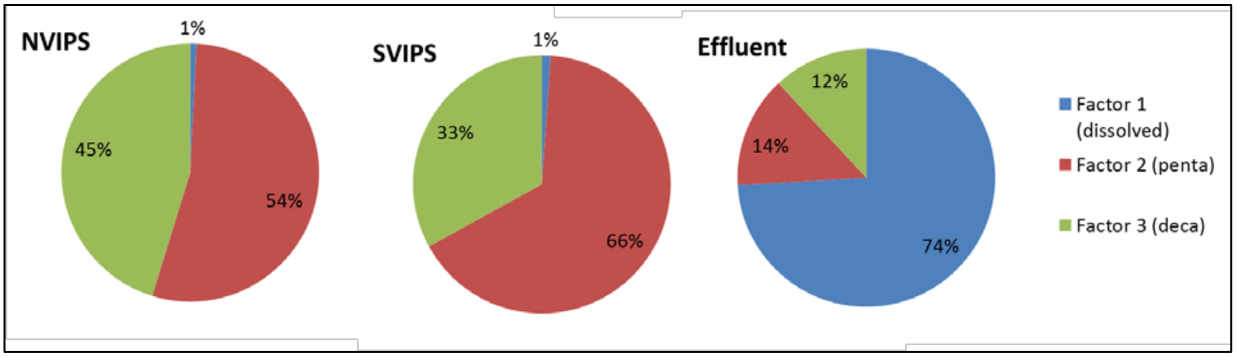

Figure 2-22. Contribution of each BDE factor to the total BDE mass in the NVIPS, SVIPS, and effluent samples

One effluent sample with high BDE-209 concentration was excluded.

PBDE PMF Conclusions

The BDE PMF accounted for nearly 100 percent of the PBDE mass found in the samples. The main source of PBDE is from commercial formulations, such as Bromkal. The 2014 results are similar to those of 2013; therefore, continued monitoring for PBDEs is unlikely to significantly improve the understanding of PBDE sources or management measures.

2.4 Source Assessment

This section discusses potential sources of PCB, Dioxin, and PBDE that could affect Spokane County's wastewater collection system. Potential PCB sources include legacy products, current products, and dispersed sources. These sources are described in the following sections.

Dioxin can be created as a by-product of certain industrial processes involving halogenated substances, such as herbicide or paper production. It can also be produced by combustion of municipal waste and other materials. As noted in Section 2.3, Dioxin has been detected only once in the samples collected to date, at a concentration close to the detection limit.

PBDEs have been used as flame retardants in a variety of household products. Because they are not chemically bound to plastic, foam, fabrics, and other products in which they are used, PBDEs can leach out of those products. There are no water quality or fish tissue standards for PBDEs. The manufacture and import of PeBDEs and OcBDEs were banned in the United States in 2004. The County is not aware of any industrial sources of PBDE within its service area. Ecology (2012) found that wastewater samples from new residential areas contained higher PBDE concentrations than wastewater samples collected from industrial or older residential areas in the Liberty Lake, Washington, study area. Based on the Liberty Lake pilot study, Ecology recommended that efforts to reduce PBDEs in wastewater focus on education of residents and businesses associated with residential work, such as carpet cleaners, laundromats, furniture shops, and re-upholsterers (Fernandez, 2012).

2.4.1 Legacy Products

PCBs are man-made compounds with no natural sources. PCBs were commercially produced in the United States as standard mixtures bearing the brand name Aroclor (Belton et al., 2007). Aroclors were produced from about 1929 until 1979, when EPA banned PCB manufacturing, distribution, and use. Because of the long service life of many PCB-containing items and the use of PCBs in some durable products, Aroclors are still found in some equipment and materials currently in use (Munoz, 2007).

Aroclors were used in a wide range of products, as summarized in Table 2-11 below. Specific Aroclors are defined by a four-digit number. The first two digits refer to the number of carbon atoms in the phenyl ring (for PCBs, this number is 12). The second two digits refer to the percentage of chlorine by mass in the mixture, except for Aroclor 1016, which has 12 carbon atoms but 42 percent chlorine by mass.

Table 2-11. Common Uses of Aroclors

Common uses	Aroclor						
	1016	1221	1232	1242	1248	1254	1260

Sources: Nagpal (1992), ATSDR (2000).

Table 2-11 indicates the wide range of historical application of Aroclor products. The three Aroclors found in the samples could have originated from sources such as electrical transformers, capacitors, hydraulic fluids, rubber products, varnishes, and a variety of other products. Some of these products can be found in commercial or residential areas as well as industrial areas.

A land use map for the Facility's service area is presented in Figure 2-23. While there are areas of industrial use, at present the data are insufficient to link any of these areas with toxics entering the County's sanitary sewer system.

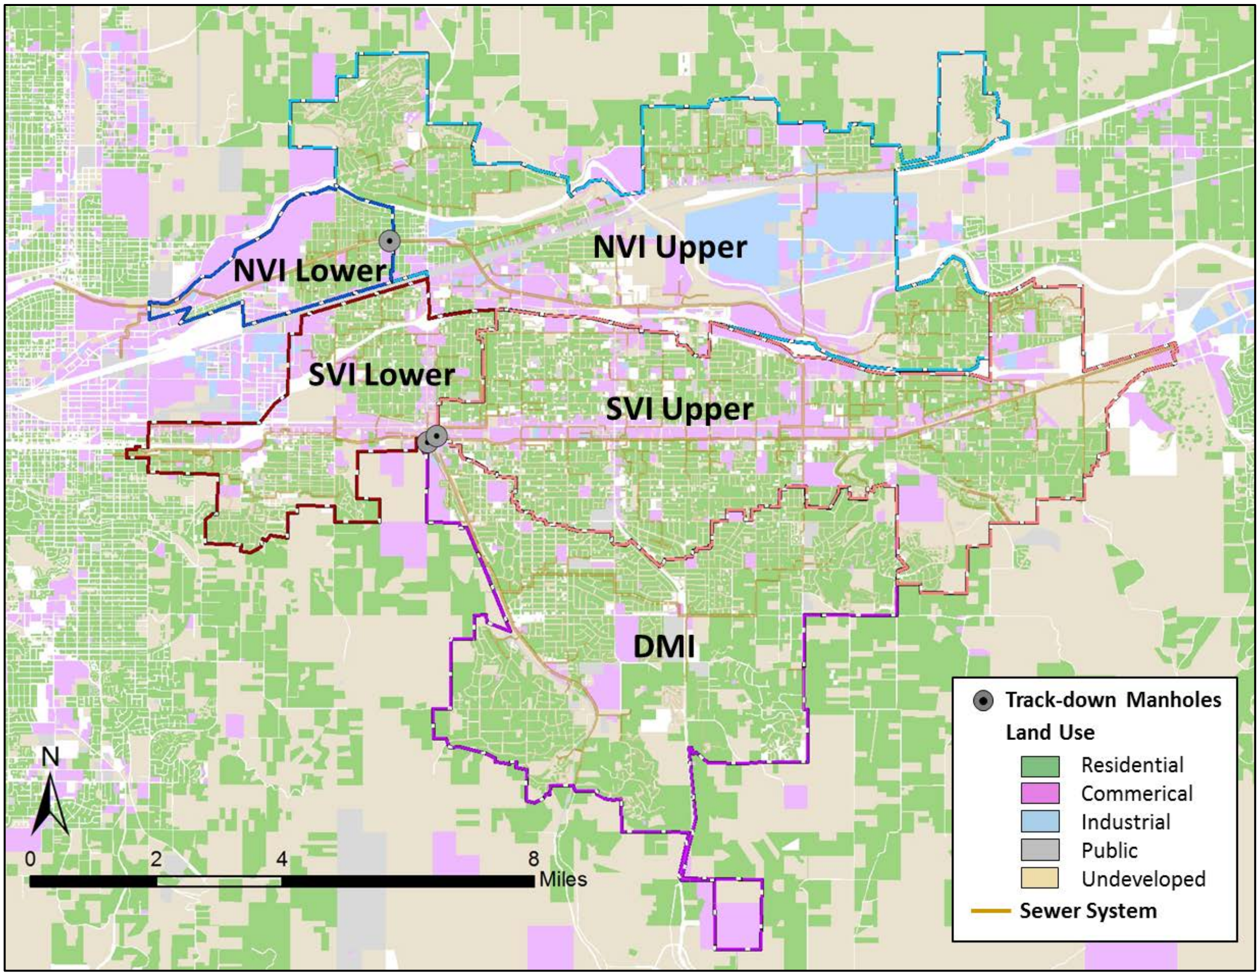

Figure 2-23. Land use in Facility service area

2.4.2 Current Products

Chemical processes involving carbon, chlorine, and high temperatures can inadvertently produce PCBs as by-products. For example, synthesis of diarylide yellow pigment, titanium dioxide white pigment, and silicone rubber tubing have the potential to generate PCB by-products (Rodenburg, 2012b). More than 200 chemical processes can generate PCBs as by-products (Munoz, 2007). The Toxic Substances Control Act (TSCA) allows concentrations of 5 to 50 parts per million (ppm) as manufacturing by-products.

2.4.3 Dispersed Sources

PCBs can enter the air through volatilization and combustion and be deposited on land or water via precipitation or dry deposition (NJDEP, 2009). Precipitation can contain significant concentrations of PCBs (Franz and Eisenreich, 1993; Gregor and Gummer, 1989; Los Alamos National Laboratory, 2012; Offenberg and Baker, 1997). PCBs in precipitation could enter the sewer system via stormwater inflow or groundwater infiltration. PCBs in dry deposition could enter the sewer system via hand-washing, washing of fruits and vegetables, laundry, or other domestic activities.

PCBs can be present in fatty fish and other foods. Some of the ingested PCBs are excreted in fecal matter (Juan et al., 2002; Harrad et al., 2003).

2.4.4 Potential Pathways

PCBs from the potential sources listed above could enter the County's collection system in a variety of ways:

- wastewater discharge from residential, commercial, or industrial land uses
- storm flow runoff that enters the wastewater system via cross-connections or leaky manholes
- groundwater that enters the wastewater system via cracks or leaks

The County's sewer system is relatively new (much of the pipe is less than 10–20 years old) and constructed in accordance with modern sewer codes designed to minimize inflow and infiltration. As a result, flows in the two influent trunk lines do not increase very much during wet weather. Flow and rainfall data were compared for 2012. On the days with the nine largest precipitation events (0.5 to 1.2 inches per day), the observed increase in flow to the Facility ranged from 1 to 11 percent. Larger flow increases were sometimes observed on days without rainfall. These flow and rainfall data suggest that stormwater runoff and groundwater infiltration volumes are relatively minor and are probably minor pathways for PCBs to enter the County's wastewater collection system.

2.4.5 Source Assessment Summary

No specific sources of toxic constituents were identified in 2014. While relatively high PCB concentrations were noted at several track-down sampling locations, those findings were not consistent over the two sampling events this year. As one moves upstream within the collection system toward a PCB source, one would expect the PCB concentration to increase as the sewage flow decreases. The DMI basin comprises approximately 10,000 parcels. Subbasin DMI MHD, which observed the highest PCB concentration recorded in 2014 (53,900 pg/L), comprises approximately 500 parcels. In order to account for the difference in PCB concentrations between the DMI basin (20,375 pg/L) and the other 2013 track-down locations (12,630 pg/L at NVI MH1 and 15,425 pg/L at SVI MH1), the DMI MHD subbasin would need to generate an average PCB concentration of over 120,000 pg/L on a consistent basis. This was not observed, nor was it observed in any of the other track-down subbasins within the DMI sewer basin. The evidence suggests that PCB contamination is more generalized, with a large number of small sources, rather than a small number of large sources, contributing to the influent loading from this basin.

If PCB contamination is from a large number of small sources, a reasonable approach to source assessment would be to group the County customers and assess whether certain groups are discharging disproportionately large amounts of PCBs in the sewage. With the 2014 track-down sampling, customers have been grouped according to the year of structure construction. The basis of this grouping was the supposition that structures built prior to PCB regulations in the late 1970s could discharge relatively more PCB contaminants through leaching from pipe and caulking material, or collection from paint, dust, and other surfaces through the collection and disposal of washwater. With one or two sampling events per track-down location completed to date, the data are inconclusive. The basin with the smallest proportion of older (pre-1980) construction has demonstrated very low levels of PCB contamination (average concentration of 3,940 pg/L at DMI MHF). However, relatively high concentrations have been observed in one basin dominated by homes built in the 1960s and 1970s (53,900 at DMI MHD) as well as in one basin dominated by homes built in the 1980s and 1990s (29,700 pg/L at DMI MHG).

Further track-down efforts will be directed at both stepwise track-down and customer grouping, with an emphasis on customer grouping based on the results observed to date.

The PMF and congener analysis showed that PCB-11 and four of the Aroclors (1242, 1248, 1254, and 1260) compose the bulk of the influent. PCB-11 is found as a manufacturing by-product in diarylide yellow and other pigments used in printing on paper and textiles (Rodenburg, 2011). The abundance of PCB-11 may be linked to dispersed sources (such as household laundries) or active sources. Examples of active sources could include paper and printing industries, textile and apparel manufacturers, paint manufacturers, chemical manufacturers, or manufacturing of miscellaneous materials where dyes or pigments may be used. Figure 2-24 presents a map of all industries in the service area that fit into these categories. The prevalence of such industries is similar in the SVI and NVI basins, with few such industries located in the DMI basin. The four printing locations within the DMI basin are all home-based businesses, and are unlikely to represent major sources of PCB contamination. The upcoming track-down effort will include directed sampling of areas with higher densities of such customers.

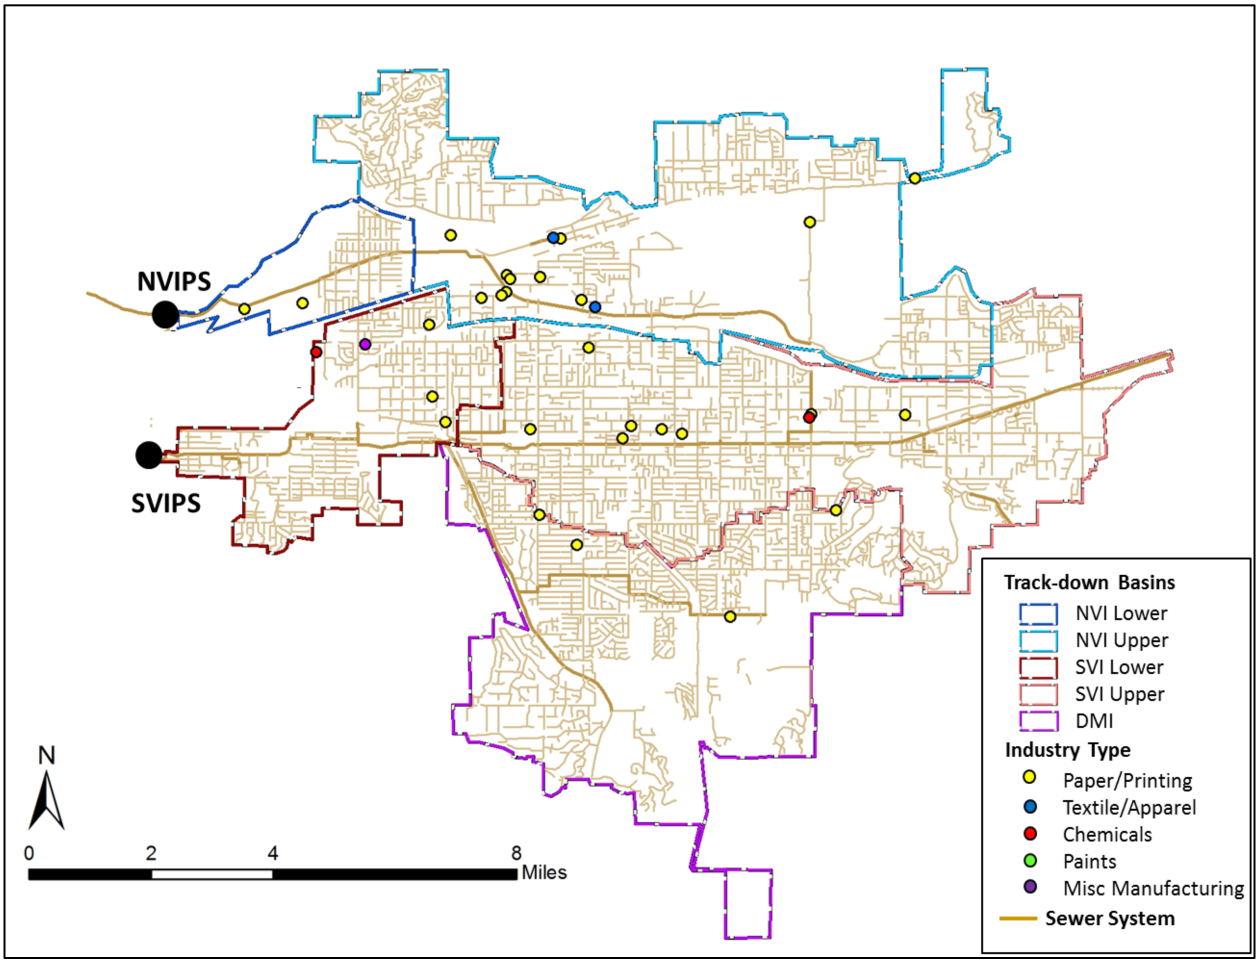

Figure 2-24. Industries that may use or produce dye or pigment

Ongoing collection system track-down sampling suggests that multiple small sources, rather than few large sources, are responsible for the bulk of PCB contamination in the influent. The Toxics Management Action Plan, presented in Section 3 of this Report, describes how Spokane County intends to move forward during the next 2 years to investigate, identify, and mitigate sources of pollutants.

Section 3

Toxics Management Action Plan

This section describes Spokane County's proposed Toxics Management Action Plan for reducing toxics entering the County's wastewater collection system. The County's 4-year plan includes the activities listed below:

1. Source investigation and identification
2. Remediation and/or mitigation of individual sources
3. Application of best management practices (BMPs) to all County sewer customers
4. Application of pretreatment regulations to industrial users

Section 3.1 describes the overall approach. Sections 3.2 through 3.4 describe the proposed activities for the remainder of the Permit term. Toxics Management Action Plans prepared for each subsequent year will be refined based on the increasing body of knowledge.

3.1 4-Year Program Approach

As discussed in Section 2 above, the pollutants targeted in this Toxics Management Action Plan could enter the sewer either via active disposal or passive transport.

<u>Sources of active disposal of toxic compounds of concern could include:</u>

- Industrial, commercial, and residential sites where products or equipment manufactured before 1979 that contain PCBs are still in use, such as older mechanical machinery, electrical equipment and components, and construction material content such as paints and caulking.
- Industrial, commercial, and residential sites with products containing inadvertently produced or unregulated levels of PCBs, such as inks, dyes, soaps, and cleaners from foreign as well as domestic manufacturers. As noted above, TSCA allows concentrations of 5 to 50 ppm as manufacturing by-products.
- Industrial sites where active manufacturing processes are inadvertently generating PCBs below the TSCA limits.

<u>Sources of passive entry of pollutants into the sewer via stormwater runoff, inflow, or infiltration could include</u>:

- locations where legacy products or equipment are still in use and exposed to rainfall or runoff: industrial sites, commercial locations, and private residences
- locations where legacy products have been discarded or disposed-of: vacant lots, open spaces, landfills, and junk yards
- locations where legacy products have been used in the past, and where leakage or spills may have taken place: industrial sites, commercial locations, private residences, vacant lots, and open spaces
- locations where products containing inadvertently produced or unregulated levels of pollutants are used, stored, disposed, or otherwise exposed to rainfall or runoff: industrial sites, commercial locations, and private residences
- locations where pollutants conveyed in the atmosphere or rainfall could enter sewers via inflow or infiltration

Based on the data collected to date, Aroclors 1242, 1248, 1252, and 1260, as well as PCB-11, appear to be potential sources of PCBs to the Facility. As noted in Table 2-11 above, these Aroclors were used in a wide range of commercial products before PCB production was banned in 1979. PCB-11 is virtually absent in Aroclor products, but occurs as a manufacturing by-product in diarylide yellow and other pigments in printing on paper and textiles. Notably, PCB-11 was the most abundant congener found in the effluent samples. It is possible that the most substantive long-term action to reduce PCB-11 loads may be an industry-wide product reformulation on a national or international scale, rather than local source control actions.

The data collected to date suggest that commercial formulations, such as Bromkal, may be important sources of PBDEs to the Facility (see Section 2.3.4.5). Industry-wide product reformulation may be the most effective long-term action to reduce PBDE loads to the Facility.

The County's toxics management program takes a systematic approach to source identification, with an investigative emphasis on tracking down sources of toxic compounds through sampling, and identification of potential products and activities through chemical fingerprinting. Other activities will be directed at remediation and/or mitigation of identified individual sources, and application of BMPs throughout the community.

3.1.1 Source Investigation and Identification

The 4-year approach to source investigation and identification is summarized on Figure 3-1. This approach features a track-down sampling program and chemical fingerprint analysis that is described in detail in the next two sections. This approach was first introduced in the 2013 Annual Toxics Management Report and the implementation of this continued approach is described in this section.

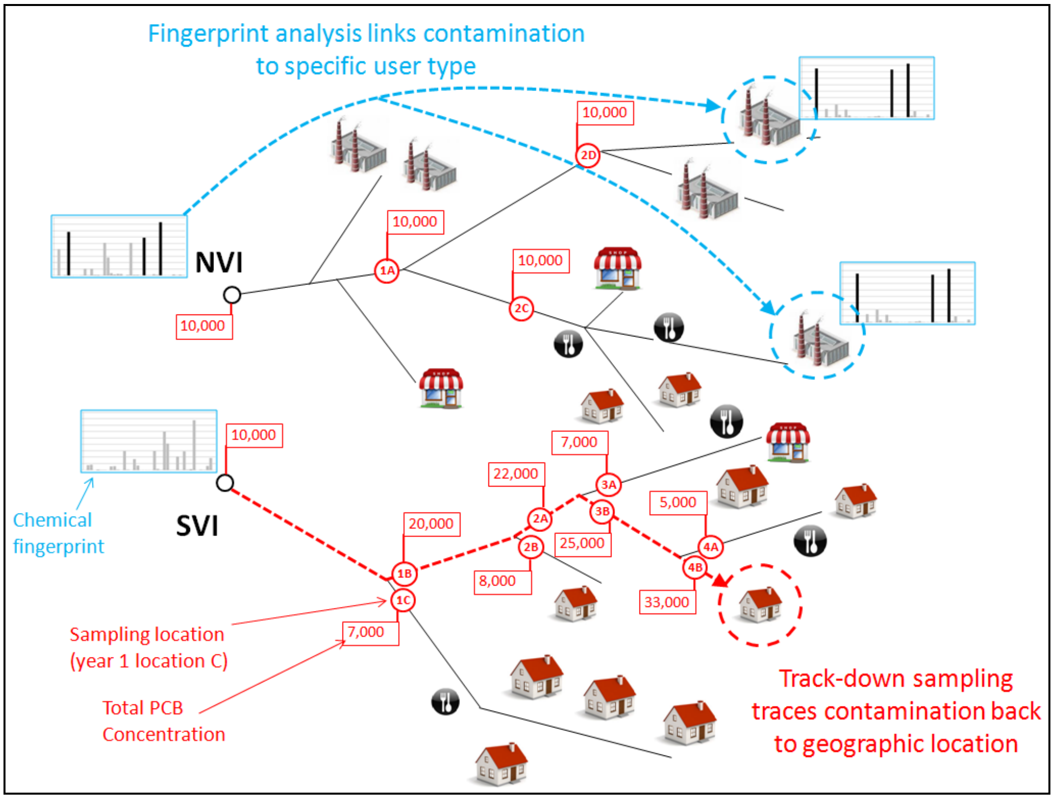

Figure 3-1. Approach to source investigation and identification

Locations, concentrations, and fingerprints on figure are conceptual and have no relation to actual data.

3.1.1.1 Track-Down Sampling

In addition to the ongoing sampling at the NVIPS and SVIPS, the County will collect samples at locations upstream in each interceptor. Each year, sampling locations will move farther upstream and investigate certain hypotheses to help identify potential sources of toxics (Figure 3-1). By tracing relative concentrations upstream and evaluating specific hypotheses related to user type or land use, the program aims to track down sources of toxic compounds and to inform public education programs.

Track-down sampling results will be evaluated during preparation of each annual report. Sampling parameters, locations, and frequency maybe adjusted based on the results.

The track-down sampling was first implemented in 2013. The 2013 sampling divided the service area into five basins. The 2013 track-down sampling focused on PCBs and PBDEs because Dioxin had been detected in only one influent sample since October 2012.

In 2014, track-down sampling was focused on PCBs in the DMI basin. PBDE track-down sampling was completed in 2013, as the PMF analysis accounted for nearly 100 percent of the mass. Section 3.2.2 describes the proposed 2015 track-down sampling.

At this time, the County envisions that 2015 track-down sampling will focus on PCBs in the NVI basin, as discussed in Section 3.3 below.

3.1.1.2 Chemical Fingerprinting and Positive Matrix Factorization

PCBs and PBDEs are groups of chemicals comprising hundreds of individual congeners. By comparing the relative concentrations of congeners in samples against legacy products and other pollutant-containing products, it may be possible to identify specific sources. For example, if samples taken at the NVIPS show a consistent pattern that relates to a specific product or industry, this would allow the targeting of specific sites for further assessment. The fingerprinting analysis could potentially lead to identification of individual sources, as depicted on Figure 3-1. It could also help focus application of BMPs if, for example, the fingerprint analysis indicated that a common construction material, such as paint or caulking, was a likely source.

Chemical fingerprinting was continued for this 2015 Annual Toxics Management Report following the initial analysis in the 2014 Annual Toxics Management Report. The PMF data for PCBs suggest a combination of legacy sources (Aroclors 1016, 1242, 1248, 1252, and 1260) and PCB-11, which is associated with pigments, and is the single most abundant congener in the effluent. The PMF results for PBDEs accounted for nearly 100 percent of the mass and suggest that commercial formulations such as Bromkal are contributing PBDEs to the Facility.

3.1.2 Remediation and/or Mitigation of Individual Sources

If the track-down sampling program or chemical fingerprinting identifies potential individual sources, the County will sample wastewater discharge from the potential source area. If the focused sampling confirms that the source area wastewater PCB concentrations are substantially elevated compared to the NVIPS or SVIPS sample concentrations, the County will notify the property owner about the issue and provide guidance for the property owner to remediate or mitigate the source (depending on the nature of the source [e.g., active process, passive runoff, soil contamination etc.]). Guidance will be based on standards provided by appropriate regulatory agencies and in coordination with the SRRTTF. This may involve educating the property owner about legacy sources (e.g., products containing Aroclors manufactured before 1979), as well as current products that can contain inadvertently produced PCBs (e.g., yellow pigment). Engagement with property owners may be done under the County's Industrial Pretreatment Program and related ordinances (Spokane County Code [SCC] 8.03A) for industrial sources and/or via the County's sewer ordinance (SCC 8.03) for domestic and commercial sources.

3.1.3 Application of Best Management Practices

The County used the track-down sampling and PMF results to help refine and focus its toxic management activities proposed in this Report for upcoming work.

Spokane County's accomplishments during 2014 included public education, participation in the SRRTTF, and other activities as follows:

- Public education on toxics management: Public education is a critical component of the County's ongoing efforts to reduce toxic pollutant loadings to the Facility. The County is an active participant in the SRRTTF and is developing a targeted, regional public education program in coordination with the SRRTTF. In 2014, the County began a targeted, multimedia public outreach program for residential and commercial/industrial sewer customers. The program identifies commonly used products known to contain PCBs and informs customers about the existing health advisories, effects of PCBs on public health, and measures that they can take to reduce PCB releases to the environment. The education program also promotes proper handling and disposal practices of materials that are known to contain PCBs. Information has been disseminated via various mailings and utilities billings inserts, the Spokane County Utilities Web site, and public events at the Spokane County Water Resource Center. Product-specific information is limited but is developed and disseminated when appropriate and reliable information is available. The following specific activities were accomplished by Spokane County in the past year:
  - Hired a water resources communications specialist to implement outreach and education and to participate on the SRRTTF
  - Updated County web presence to include PCB information
  - Developed and mailed a PCB primer to all County wastewater treatment customers, both commercial/industrial and residential (about 40,000 customers)
  - Developed a PCB informational poster for display in the Water Resource Center and other venues
  - Coordinated an Open House event at the Water Resource Center, including PCB information, in November 2014
  - Coordinated a meeting with other regional municipal wastewater treatment entities to discuss coordinated and consistent outreach to commercial and pretreatment customers
  - Prepared and sent a letter to County pretreatment customers requesting individual meetings to provide PCB information
  - Presented at several area conferences regarding the results thus far of the track-down sampling and treatment efficiency
  - Provided input to the Washington Legislature regarding the Toxics Management Act
  - Provided in-kind and financial support to the local EnviroStars program, a local source control/waste minimization program aimed at businesses
  - Provided financial support for PCB monitoring and education by the SRRTTF.
- Played an active role in the SRRTTF including financial support for administrative and technical tasks
- Supported industry-wide reformulation of products that can contain elevated concentrations of PCB-11 (e.g., diarylide yellow and other pigments used in printing and textiles), as well as commercial products that contain elevated PBDE concentrations (e.g., Bromkal).
- Elimination of older, County-owned, mechanical and electrical machinery: The County removed all known PCB-containing light ballasts and transformers from County-owned facilities in 1993 and 1995. The County Facilities Department will continue to remove and dispose of the remaining PCB-

containing materials and equipment as they are encountered. These materials are profiled and disposed of during annual hazardous waste identification and disposal activities.

- Regional clearinghouse: The County continued to contribute data on observed PCB concentrations and patterns from the County's monitoring program to the SRRTTF's regional clearinghouse. The County data, in combination with data submitted by others, will increase understanding of the potential sources of PCBs in the region and help focus regional management efforts.
- Procurement policies: The County supported the SRRTTF in identifying commercial products that could contain inadvertently produced PCBs. This past year the County passed a revised procurement practices ordinance that allows for PCB testing of products and preferential purchasing of non-PCB equivalents within cost controls, similar to the City of Spokane and State of Washington. The newly passed purchasing ordinance now allows the County to minimize purchase of PCB-containing products.

3.2 Toxics Management Action Plan for 2015

This section summarizes the sampling and analysis to be conducted from April 2015 through March 2016. The purpose of proposed actions for 2015 includes continued compliance with the Permit and continued systematic analysis and track-down of toxics in subbasins of the Facility's sewersheds. Actions to be conducted prior to the next annual report include the following:

- Continued sampling of the two influent trunk lines (NVIPS and SVIPS) and the Facility effluent per the terms of the Permit
- Year 3 of track-down sampling in the NVI collection system for PCBs only
- Continued chemical fingerprinting analysis
- Conducting initial source control measures

These actions were chosen as next steps in the continued systematic analysis and track-down approach and are described further in the following sections.

3.2.1 Continued Sampling at Influent Trunk Lines and Facility Effluent

NPDES-mandated sampling of the NVIPS, SVIPS, and Facility effluent will continue per the terms of the Permit. By the publication of the April 2016 annual report, the following data will have been collected during the period of study:

- 20 samples of PCB and Dioxin data at each influent trunk line (i.e., NVIPS and SVIPS), for a total of 80 samples
- 13 samples of PCB, Dioxin, and PBDE data at the Facility effluent, for a total of 39 samples
- 13 samples of PBDE at the NVIPS and SVIPS, for a total of 26 samples
- QA/QC samples per the approved QAPP

The additional data should allow for an assessment of variability over time. Continuing fingerprinting analysis of the PCB and PBDE congener data will also be performed in order to assess similarities and differences in the PCB makeup of the wastewater in each influent trunk line. These analyses may assist with point source identification and continuing track-down analysis. They may also provide guidance with respect to application of BMPs or industrial pretreatment regulations.

3.2.2 Year 3 of Track-Down Sampling (2015)

The County evaluated the first 2 years of track-down results in order to develop its strategy for future track-down sampling. The 2013 sampling plan focused on manholes upstream of the NVIPS and SVIPS locations, NVI MH1, SVI MH1, and DMI MH1.

The following bullets summarize the findings from the 2013 track-down sampling:

- PCB concentrations were higher at the DMI track-down location (DMI MH1) than at either of the other two track-down locations (SVI MH1 or NVI MH1) or at the SVIPS.
- PCB concentrations at the NVIPS appeared higher than those observed at NVI MH1, suggesting potential PCB sources between these two locations.
- The PCB PMF results identified six factors. The PMF was able to account for about 60 percent of the mass of PCBs.
- PBDE concentrations were more varied than PCB concentrations, and the differences between sites were less notable.
- The PMF results for PBDEs suggest dispersed sources related to commercial products that are still in widespread use. The PMF was able to account for nearly 100 percent of the PBDE mass.
- Based on the 2013 results, the County focusedits 2014 track-down sampling on PCBs in the DMI basin in 2014. The following bullets summarize the findings from the 2014 track-down sampling.The PCB PMF results identified seven factors. The PMF was able to account for about 90 percent of the mass of PCBs.
- Most of the factors are strongly correlated to Aroclors and Aroclor mixtures. The exception is Factor 2, which is mainly composed of PCB-11, which is often found in yellow dyes and pigments. Factor 2 was more prevalent at NVIPS than at SVIPS.
- Upstream sampling within the DMI noted relatively high variability in PCB concentrations over time and space, but the limited number of sampling events limits the statistical relevance of the findings. None of the track-down locations registered PCB concentrations high enough to independently account for the relatively high average concentration noted at the DMI MH1 in 2013. Rather, the high concentration appears more likely the result of moderately elevated concentrations from multiple sources.
- Track-down sampling efforts aimed to differentiate PCB contamination by the age of construction within the DMI subbasins. While the lowest overall concentrations were observed in the basin most dominated by new construction, no statistically relevant trend was observed in the other basins given the limited data.

Based on the 2013 and 2014 results, year 3 track-down sampling will wrap up analysis of the DMI basin and then focus on the NVI basin. Track-down sampling will have three directives:

1. Confirm the diffuse nature of PCBs in the DMI subbasins. The 2014 sampling developed a limited dataset for the DMI subbasins. A further round of sampling in these subbasins will be completed to support the evidence that PCBs are ubiquitous at relatively low levels in the DMI subbasins.
2. Sample the NVI Lower basin—the basin located between the NVIPS and NVI MH1. In 2013, PCB concentrations were consistently higher at the NVIPS than at the upstream NVI MH1, suggesting a relatively higher contribution of PCBs between the two sampling locations. Notably, the highest PCB concentration noted to date (67,600 pg/L) was noted at NVIPS, during an event where the PCB concentration at the upstream NVI MH1 was only 16,000 pg/L.
3. An attempt to discern relationships between customer type and average PCB concentration. The NVI basin has a relatively large industrial customer component. Track-down efforts will focus on industrial and light industrial zones. The data may be compared against residential sampling in the DMI basin in 2014 to determine whether the user class may be applied as an indicator or predictor of PCB contamination in the sewage. As part of this effort, areas with multiple textile and paper industries will be investigated throughout the NVI basin (Figure 2-24).

In line with these efforts, six potential sites have been identified for track-down sampling within the NVI basin (Figure 3-2). Two of these sites are located in the NVI Lower basin (NVI L-MHA and NVI L-MHB), while the others are located in the NVI Upper basin.

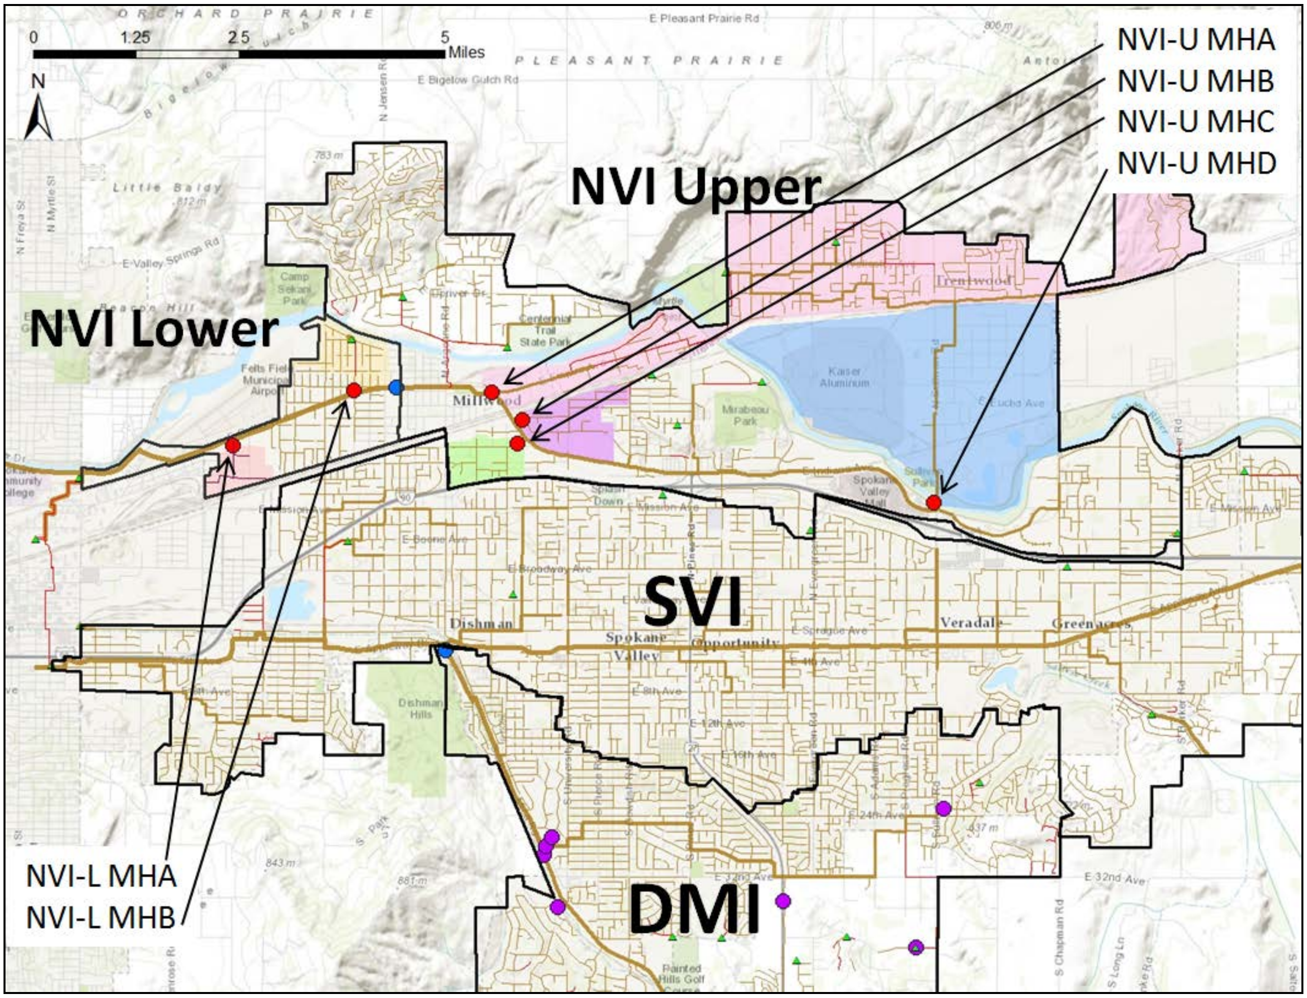

Figure 3-2. Potential sampling locations for track-down analysis for 2014

Based on field conditions, the number of sites sampled and the locations may be adjusted. The 2014 track-down sampling locations will be described in further detail in the 2015 revised QAPP. Additionally, an adaptive monitoring approach will be used based on the results from the sampling analysis to determine how many subsequent samples are taken at each proposed manhole location.

The QAPP will be amended to reflect the new track-down sampling approach. QA/QC samples will be collected in accordance with the approved QAPP. Each sample will be tested for PCBs. This sampling will allow for these upstream samples to be compared to the samples collected from the two influent trunk lines (i.e., at the NVIPS and SVIPS).

Track-down sampling will be evaluated during preparation of each annual report. Sampling locations and frequency may be adjusted based on the results.

3.2.3 Chemical Fingerprinting Analysis

Chemical fingerprinting analysis will be expanded to include the Year 3 (2015) track-down sampling locations. With each year, the database of results will increase, and the accuracy of the fingerprinting analysis will improve. With an increased number of sampling locations, the fingerprinting analysis may help to establish relationships between sources of toxics and specific locations within the collection system, and specific user characteristics.

3.2.4 Source Control Measures

The County will continue to apply the BMPs summarized in Section 3.1.3. These actions include active participation in the SRRTTF, development of a targeted public education program, ongoing removal of PCB-containing equipment and machinery, and revision of County procurement practices. Depending upon the results of chemical fingerprinting and track-down analysis, initial source control measures may extend to individual source remediation and/or mitigation, if individual sources are identified.

The County plans to expand its public education program. Planned education activities for 2015 include:

- Spring and fall open houses at the Water Resource Center
- Increase collaboration with non-dischargers to disseminate toxics management information (e.g., Spokane Riverkeeper)Provide updates as warranted to wastewater treatment customers regarding new and useful PCB information that can provide consumer guidance
- Updates to PCB information on the County website
- Meet with pretreatment customers to review latest information on PCBs
- Presentations at area conferences and to citizen groups
- Provide input to the Legislature regarding impending legislation regarding PCBs
- Continue in-kind and financial support to the local EnviroStars program

Additionally, Spokane County plans to:

- Support industry-wide reformulation of products that can contain elevated concentrations of PCB-11 as well as commercial products that contain elevated PBDE concentrations (e.g., Bromkal)
- Continue to contribute data on PCB concentrations and sources to the SRRTTF's regional clearinghouse to help increase understanding of the potential sources and to help regional management efforts
- Continue to play an active role in the SRRTTF including financial support for administrative and technical tasks
- Continue to support the SRRTTF in identifying commercial products that could contain inadvertently produced PCBs
- Continue to review the County wastewater customer database in light of the ongoing chemical fingerprinting analysis, and perform follow-up actions as appropriate.

3.3 Toxics Management Action Plan for 2016

In March and April 2016, the County will evaluate the results of the NVIPS and SVIPS sampling and track-down sampling conducted during 2015. The evaluation will look for differences in PCB concentrations related to land use and year of construction to discern potential sources. Chemical fingerprinting analyses will continue and expand to identify the types of products that could account for the observed PCB patterns. The analytical data and evaluation of potential sources will be presented in the April 2016 Annual Toxics Management Report.

At this time, it is envisioned that the 2016 track-down sampling will focus on the SVI sewersheds.

The April 2016 Toxics Management Action Plan will describe the proposed track-down sampling, source investigations, and focused control measures to be implemented in 2016 (if sources are identified). The County will update the QAPP as needed to guide the track-down sampling and source investigations.

The April 2016 Toxics Management Action Plan will also update the County's proposed BMPs for reducing use of products that could contain PCBs. The County will work with the SRRTTF to refine these BMPs and develop new BMPs based on the lessons learned during 2015.

3.4 Annual Toxics Management Report for 2016

The County will prepare the April 2016 Annual Toxics Management Report to summarize the County's toxic source control program, actions completed, BMPs implemented, and source identification results. In addition, the 2016 document will include a summary of all of the toxics sampling and laboratory results completed by the County under the current NPDES Permit.

Comment/Action Record

CLIENT:	County of Spokane, WA
PROJECT NAME:	Spokane County PCB Study
PROJECT NUMBER:	142892

Laboratory report prepared by: AXYS Analytical Services
Laboratory analysis type: Polychlorinated Biphenyl (PCB)
Laboratory report checked by: Valerie Fuchs

Batch Date: 3/14/2014
Batch ID: WG46535
Check Date: 4/14/2014

DESCRIPTION:
QA/QC was performed on the AXYS laboratory data based on the measurement quality objectives detailed in the QAPP. All data and data quality checks met the requirements of the QAPP.

Laboratory check/spiked samples were within the percent recovery range required in the QAPP.

ADDITIONAL REMARKS / COMMENTS:

AXYS Comments	**BC Response**
1. Data are considered final. 2. Data are not blank corrected.	None.

Laboratory analysis type: Polychlorinated Biphenyl (PCB)
Laboratory report checked by: Valerie Fuchs

Batch Date: 5/21/2014
Batch ID: WG47248
Check Date: 5/28/2014

DESCRIPTION:
QA/QC was performed on the AXYS laboratory data based on the measurement quality objectives detailed in the QAPP. All data and data quality checks met the requirements of the QAPP.

Laboratory check/spiked samples were within the percent recovery range required in the QAPP.

ADDITIONAL REMARKS / COMMENTS:

AXYS Comments	**BC Response**
Revised 21-May-14: 1. Revised the EDD to include omitted Homologue Totals and TEQ data. Please discard previously submitted data and accept this data as final. 2. Data are considered final. 3. Data are not blank corrected.	No action necessary.
4. A disturbance of the mass ion used to monitor instrument performance (lock-mass) greater than method specifications was observed in sample ‘SVIPS PCB’ (AXYS ID:L21382-7) near the retention time corresponding to PCB 197/200 and in the Laboratory Blank (AXYS ID: WG47248-102) near the retention time corresponding to PCB 2 and these targets have been flagged with a ‘G’. PCB 197/200 and PCB 2 are not major contributors to the total concentration of PCB in these samples, respectively, and data are not considered significantly affected.	None of the G-flagged data account for more than 2% percent of the total PCB concentration reported for the respective sample. The data are accepted, but G flags will be retained for future reference.

PROJECT NUMBER:	142892

Laboratory report prepared by: AXYS Analytical Services
Laboratory analysis type: Polychlorinated Biphenyl (PCB)
Laboratory report checked by: Valerie Fuchs

Batch Date: 7/24/2014
Batch ID: WG47904
Check Date: 8/6/2014

DESCRIPTION:

QA/QC was performed on the AXYS laboratory data based on the measurement quality objectives detailed in the QAPP. All data and data quality checks met the requirements of the QAPP.

The total concentrations of the duplicate (split) sample were within 12% of each other, meeting the QAPP requirement of equal to or less than 50% relative percent difference.

Laboratory check/spiked samples were within the percent recovery range required in the QAPP.

ADDITIONAL REMARKS / COMMENTS:

AXYS Comments	**BC Response**
1. Data are considered final. 2. Data are not blank corrected.	No action necessary.
3. The recovery of different 13C-labelled PCB congeners in different samples did not meet the method criteria; these compounds are flagged with a 'V'. As the isotope dilution method of quantification produces data that are recovery corrected, the slight variances from the method acceptance criteria are deemed not to affect the quantification of the analytes.	TBD. SVIPS and the Lab Blank both had 77% passing; all other samples were greater than 95%. The spiked matrix had 87% passing. All of the V-flagged congeners were below the 25% recovery acceptance limit. Most were between 20-25%. Congeners with recovery less than 20% are as follows: for the lab blank 104L was 18% and 155L was 16.3%. For DMI-MHA, 155L was 18.2% and 209L was 18.5%. The data are accepted, but V flags will be retained.

QA/QC was performed on the AXYS laboratory data based on the measurement quality objectives detailed in the QAPP. All data and data quality checks met the requirements of the QAPP.

Laboratory check/spiked samples were within the percent recovery range required in the QAPP.

ADDITIONAL REMARKS / COMMENTS:

AXYS Comments	**BC Response**
1. Data are considered final. 2. Data are not blank corrected.	None.
3. The recovery of 13C-labeled-2,3,7,8-TCDD in sample Travel Blank TCDD (AXYS ID L21009-2) is slightly outside the method acceptance criteria; this compound has been flagged with a 'V'. As the isotope dilution method of quantification produces data that are recovery corrected, the slight variances from the method acceptance criteria are deemed not to affect the quantification of these analytes. Percent surrogate recoveries are used as general method performance indicator only.	Recovery of 13C-labeled-2,3,7,8-TCDD was 36% (target 35%); does not appear to be outside of acceptance criteria. This congener is not flagged in the data file. 37CL-labeled-2,3,7,8-TCDD is flagged with V but also does not appear to be outside of acceptance criteria. The data are accepted but V flags are retained.

Appendix B: Laboratory Results from AXYS and Anatek

Submitted electronically

This page left blank intentionally.

Draft response to downstream waters comments

Comments paraphrased:

Comments from tribes, enviro groups, public: The new HHC will not protect the consumption uses of downstream tribal waters, usual and accustomed waters, and waters shared with other states.

Comments from EPA: explain how narrative provision protects downstream waters - provide rationale detailing how use of a narrative downstream protection criterion alone will protect Oregon's more stringent water quality standards.

Also from EPA:

> *"...most of Washington's rivers are in the Columbia River basin and are, therefore, upstream of Oregon's portion of the Columbia River. In addition, the Columbia River creates most ofthe Washington-Oregon border. Since approximately 90% ofWA's proposed human health criteria are higher than Oregon's EPA-approved criteria for the same pollutants, the EPA strongly encourages Ecology to consider adopting numeric criteria (either in addition to or instead of narrative criteria) that ensure the attainment and maintenance of Oregon's downstream WQS, or to provide additional rationale detailing how the use of a narrative downstream protection criterion alone will protect Oregon's more stringent WQS. For waters flowing into Oregon, criteria that are equally stringent or more stringent than Oregon's human health criteria would better ensure the attainment and maintenance of Oregon's downstream WQS consistent with 40 CFR 131.10(b). This aligns with the EPA's previous statements regarding a desire for regional consistency in human health criteria among Region 10 states."*

RESPONSE STARTS BELOW

Responses to comments on protection of downstream waters are addressed in the discussion below:

What are the requirements on downstream waters protection that are in the federal water quality standards regulation (40CFR131)?

The federal regulations specify how states are to address downstream waters in development of state water quality standards. These two requirements are found in 40 CFR 131.10 as follows:

> *"Subpart B—Establishment of Water Quality Standards*
> *§ 131.10 Designation of uses.*
> *(b) In designating uses of a water body and the appropriate criteria for those uses, the State shall take into consideration the water quality standards of downstream waters and shall ensure that its water quality standards provide for the attainment and maintenance of the water quality standards of downstream waters."*

These requirements are broken out as:

- ...the State shall take into consideration the water quality standards of downstream waters
- ...the State... shall ensure that its water quality standards provide for the attainment and maintenance of the water quality standards of downstream waters.

These two specific requirements of states are addressed more fully below.

Has Ecology fulfilled the federal requirements? Yes, as explained in 1 and 2 below.

1. …the State shall take into consideration the water quality standards of downstream waters

Washington formally took into consideration the water quality standards of downstream waters by (1) placing language requiring protection of downstream waters in the draft rule and (2) by considering all public comments that were received during the public comment period, regarding downstream waters protection, as the final rule was developed.

2. …the State… shall ensure that its water quality standards provide for the attainment and maintenance of the water quality standards of downstream waters.

Rule narrative language in WAC 173-201A ensures that Washington's water quality standards provide for attainment and maintenance of the water quality standards of downstream waters as follows (relevant section in boldface):

Washington water quality standard from WAC 173-201A-260 that provides for attainment and maintenance of the water quality standards of downstream waters	What does this language mean?
New language: WAC 173-201A-240 Toxic substances. (b) Human health protection. The following provisions *apply to the human health criteria in Table 240. All waters shall maintain a level of water quality when entering downstream waters that provides for the attainment and maintenance of the water quality standards of those downstream waters, including the waters of another state.*	This language explicitly requires upstream water quality to provide for attainment and maintenance of downstream water quality standards. This language was taken from EPA's *Templates for Narrative Downstream Protection Criteria in State Water Quality Standards* (EPA 2014, 820-F-14-002) at http://water.epa.gov/scitech/swguidance/standards/narrative.cfm .
WAC 173-201A-260 Natural conditions and other water quality criteria and applications. (3) Procedures for applying water quality criteria. *In applying the appropriate water quality*	This language allows for case-by-case establishment of additional requirements to fully support designated and existing uses.

criteria for a water body, the department will use the following procedure: *(a) The department will establish water quality requirements for water bodies, in addition* *to those specifically listed in this chapter, on a case-specific basis where determined* *necessary to provide full support for designated and existing uses.*	
WAC 173-201A-260 Natural conditions and other water quality criteria and applications. (3) Procedures for applying water quality criteria. *In applying the appropriate water quality* *criteria for a water body, the department will use the following procedure:* *(b) Upstream actions must be conducted in manners that meet downstream water body* *criteria....*	This language directs that upstream actions (such as discharges into waters) must be conducted in a manner to meet downstream criteria.

Does Ecology's approach align with federal guidance and federal precedent?

Federal Guidance: Ecology did not follow the approach to downstream waters protection that is the focus of the EPA 2014 guidance FAQ. The language in EPA's downstream guidance FAQ, which is not a rule and is thus not binding on states, addresses the uses and criteria sections of the water quality standards (and acknowledges the antidegradation section), but does not mention or take into account the General Provisions portions of the standards, described in EPA's Water Quality Standards Handbook (Chapter 1: General Provisions (40 CFR 131.1-131.6; http://water.epa.gov/scitech/swguidance/standards/handbook/chapter01.cfm) as follows:

> *"WQS consist of the following elements:*
>
> - *Designated use or uses such as "supporting aquatic life" or "recreation" (which are described in Chapter 2 of this Handbook).*
> - *Water quality criteria necessary to protect the designated uses (which are described in Chapter 3 of this Handbook).*
> - *Antidegradation requirements (which are described in Chapter 4 of this Handbook).*
> - *General policies affecting the application and implementation of WQS that states and authorized tribes may include at their discretion (e.g., mixing zone, variance, and critical low-flow policies, which are described in Chapter 5 of this Handbook)."*

The downstream waters protection approach that is used in the Washington standards (language in table above) is best described by language developed by EPA (2004; http://water.epa.gov/scitech/swguidance/standards/upload/Sierra-Club-Petition-Response-signed-2004-06-25.pdf) in its decision on how to address a settlement agreement petition: *"Decision on petition for rulemaking to publish water quality standards for the Mississippi and Missouri Rivers within Arkansas, Illinois,* *Iowa, Kansas, Kentucky, Missouri, Nebraska and Tennessee."* The language from that document addresses a situation where, because of issues surrounding downstream waters protection, EPA was petitioned by the Ozark Chapter of the Sierra Club to *"publish water quality standards for the Mississippi and Missouri Rivers within the petition area states. Such standards should be: 1) Consistent among the states on each river, such that no state impairs the ability of any other affected state (whether across-stream or downstream) to achieve its water quality standards; and..."* (EPA 2014).

EPA's response to that petition includes:

> *Protection of Downstream Uses*
> *The federal regulations state, "In designating uses of a water body and the appropriate criteria for those uses, the State shall take into consideration the water quality standards of downstream waters and shall ensure that its water quality standards provide for the attainment and maintenance of the water quality standards of downstream waters." 40 C.F.R. §131.10(b).* ***The regulations do not compel states to adopt the same criteria and uses, nor do they suggest that this is the only way a state can meet these requirements. The water quality program is structured to provide states with flexibility to determine the best way to meet their obligations under § 131.10(b).***
>
> *Under the NPDES permitting regulations, no permit may be issued "when the imposition of conditions cannot ensure compliance with applicable water quality requirements of all affected States[.]" 40 C.F.R. §122.4(d). To obtain approval of a state NPDES program, the CWA requires the state to have the authority to notify other affected states of applications for permits and provide an opportunity for a hearing. CWA section 402(b)(3). Further, the state must allow any state whose waters may be affected by the discharge to submit recommendations. If the permitting state rejects the recommendations, it must notify the affected state and EPA Administrator. CWA section 402(b)(5). Where EPA determines the permitting state rejected the recommendations for inadequate reasons, EPA may exercise its discretionary authority to object to the permit. If the objection is not resolved, EPA may issue a federal permit. 40 C.F.R. §123.44(c)(2).*
> *(Page 4, EPA 2004)*

In this response EPA states that the federal regulations do not compel states to adopt the same criteria and uses, or even suggest that this is the only way a state can meet the requirements to protect downstream waters, and that the federal water quality program is structured to provide states with flexibility to determine the best way to meet their obligations under § 131.10(b). The Washington water quality standards contain the combination of a direct statement on downstream protection (new proposed language), an allowance for additional requirements, and requirements for upstream actions implemented under various CWA permitting programs.

What about the general comment that water quality standards upstream should be as stringent as the downstream standards in order to protect downstream uses, especially with regard to the risk levels used in criteria calculations?

This is best responded to by language developed by EPA (2004; http://water.epa.gov/scitech/swguidance/standards/upload/Sierra-Club-Petition-Response-signed-2004-06-25.pdf) in its decision on how to address a settlement agreement petition: *"Decision on petition for rulemaking to publish water quality standards for the Mississippi and Missouri Rivers within Arkansas, Illinois, Iowa, Kansas, Kentucky, Missouri, Nebraska and Tennessee."* The language from that document addresses a situation where, because of issues surrounding downstream waters protection, EPA was petitioned by the Ozark Chapter of the Sierra Club to *"publish water quality standards for the Mississippi and Missouri Rivers within the petition area states. Such standards should be: 1) Consistent among the states on each river, such that no state impairs the ability of any other affected state (whether across-stream or downstream) to achieve its water quality standards; and..."* (EPA 2014).

The states along the Mississippi River have differing risk levels (PCB example given):

> *"EPA acknowledges there are variations in the numeric PCB criteria adopted by the petition states. There are four legitimate reasons why the numeric PCB criteria vary within the petition area:...*
>
> *...(3) As discussed in the "Statutory and Regulatory Background" section, EPA publishes section 304(a) criteria based on a 10–6 risk level for carcinogens; states may select a specific risk level based on their own risk management decisions. EPA believes that adoption of criteria within a risk level of 10–6 (one in a million incremental risk for cancer) or 10–5 (one in one hundred thousand incremental risk for cancer) represents an acceptable range of risk management discretion for states and tribes.[24] Within the petition states, each state adopts criteria to protect human health based on risk management decisions. Iowa, Arkansas, Tennessee, and Nebraska have adopted PCB criteria based on a 10-5 risk level; Illinois, Kentucky and Missouri have adopted PCB criteria based on a 10-6 risk level; and Kansas chose to adopt a PCB criterion to protect human health at a 10-7 risk level.*
>
> *[24] U.S. Environmental Protection Agency. Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000). Office of Water. Washington, D.C. EPA-822-B-00-004. <http://www.epa.gov/waterscience/humanhealth/method > October 2000."*
>
> *(Pages 17-18, EPA 2004)*

The human health criteria differed among states for a number of valid reasons, among them the differing risk levels. EPA language for PCBs is below:

> *"As discussed above, Iowa and Missouri adopted a numeric PCB criterion to protect human health based on the toxicity information available in IRIS that was updated in 1989. With regard to the Sierra Club's specific concern about Iowa's PCB criterion as compared to Missouri's criterion, EPA found that Iowa's criterion is an order of magnitude greater than Missouri's because Iowa has chosen to protect human health at a 10-5 risk level while Missouri protects human health at a 10-6 risk level. With regard to the Sierra Club's specific concern about Nebraska's PCB criterion as compared to Missouri, EPA found that Nebraska adopted a numeric PCB criterion to protect human health based on EPA's section 304(a) criteria recommendations published in 1999 (Missouri used the updated 1999 IRIS data), but chose a 10-5 risk level. As a result, Nebraska's PCB criterion is greater than Missouri's criterion."*
>
> *(Page 18, EPA 2004)*

These differences in criteria were not found to be cause for EPA to promulgate consistent criteria across the states:

> *"…the regulations do not compel states to adopt the same criteria and uses in order to provide for attainment and maintenance of downstream water quality standards (40 C.F.R. §131.10(b)), nor do the regulations suggest that this is the only way a state can meet the requirements under § 131.10(b). The water quality program is structured to provide states with flexibility to determine the best way to protect their designated uses and meet their obligations under § 131.10(b)."*
>
> *(Page 19, EPA 2004)*

How does Ecology protect downstream uses as it implements the water quality standards?

Ecology implements the standards in its permitting and certification processes, as well as in its Water Clean-up (Total Maximum Daily Load) program. The requirements for downstream protection (as per WAC 173-201A-260) apply to all criteria, including toxic and conventional pollutants. An example for each are below.

Example 1 – NPDES permit – Human health criteria pollutants (XXX Have Vince fill in table)	
NPDES permit reissuance	Weyerhaeuser permit and number and date
Receiving water (shared with Oregon)	Columbia River
Human health criteria pollutants found in discharge	PCBs
Reasonable potential determination	
Effluent limits	
Verification that Oregon standards would be met	

Example 2 – TMDL – conventional pollutants (nutrients)	
TMDL	*Spokane River and Lake Spokane Dissolved Oxygen Total Maximum Daily Load: Water Quality Improvement Report* (2007, as revised in 2010)
Receiving water	Discharges to Spokane River. Downstream impacts occurring in Long lake
Conventional pollutants found in point and non-point source discharges	Nutrients causing downstream dissolved oxygen depletion
Basis of allowable loading of phosphorus and nitrogen	The allowable loads to the Spokane River were based on meeting the dissolved oxygen criteria in downstream Long Lake
Effluent limits	Based on meeting the load allocations in the TMDL
Verification that downstream standards will be met	The TMDL and effluent limits are based on meeting dissolved oxygen standards in Long Lake. Effectiveness monitoring will verify improvements in water quality over time.

Abstract To better understand the dynamics of contaminant uptake in outmigrant juvenile salmon in the Pacific Northwest, concentrations of polychlorinated biphenyls (PCBs), DDTs, polycylic aromatic hydrocarbons (PAHs) and organochlorine pesticides were measured in tissues and prey of juvenile chinook and coho salmon from several estuaries and hatcheries in the US Pacific Northwest. PCBs, DDTs, and PAHs were found in tissues (whole bodies or bile) and stomach contents of chinook and coho salmon sampled from all estuaries, as well as in chinook salmon from hatcheries. Organochlorine pesticides were detected less frequently. Of the two species sampled, chinook salmon had the highest whole body contaminant concentrations, typically 2–5 times higher than coho salmon from the same sites. In comparison to estuarine chinook salmon, body burdens of PCBs and DDTs in hatchery chinook were relatively high, in part because of the high lipid content of the hatchery fish. Concentrations of PCBs were highest in chinook salmon from the Duwamish Estuary, the Columbia River and Yaquina Bay, exceeding the NOAA Fisheries' estimated threshold for adverse health effects of 2400 ng/g lipid. Concentrations of DDTs were especially high in juvenile chinook salmon from the Columbia River and Nisqually Estuary; concentrations of PAH metabolites in bile were highest in chinook salmon from the Duwamish Estuary and Grays Harbor. Juvenile chinook salmon are likely absorbing some contaminants during estuarine residence through their prey, as PCBs, PAHs, and DDTs were consistently present in stomach contents, at concentrations significantly correlated with contaminant body burdens in fish from the same sites.

1 Introduction

Estuaries are important habitats for salmon during the juvenile stage of their life cycle, when they make the transition from freshwater to the ocean (Healey, 1982). Estuaries provide outmigrating juvenile salmon with a refuge from predators, a rich food supply that supports rapid growth, and appropriate conditions for the physiological adaptation to saltwater (Dorcey *et al.*, 1978; Simenstad *et al.*, 1982). However, urban and industrial development may impair the quality of estuarine habitats. Estuaries located near urban centers often receive inputs of toxic contaminants from municipal and industrial activities (Brown *et al.*, 1998; USEPA,

[1] Environmental Monitoring and Assessment

1997), which may be taken up by juvenile salmon and their prey. Because juvenile salmon are in a period of rapid development, and undergoing many physiological changes during their residence in estuarine environments, they may be especially vulnerable to the deleterious effects of toxic chemicals.

The well-documented presence of chemically contaminated sediments in Puget Sound urban estuaries (e.g., Malins *et al*., 1982) prompted a series of studies to examine the degree to which juvenile salmon were exposed to toxic chemicals during estuarine residence (McCain *et al*., 1990; Varanasi *et al*., 1993; Stein *et al*., 1995; Stehr *et al*., 2000). Juvenile salmon (primarily chinook and coho, *Onchorhynchus tshawytscha* and *O. kisutch)* were sampled from several urban and non-urban estuaries in Puget Sound including the Green River/Duwamish Estuary system in Seattle, the Puyallup River/Hylebos Waterway system in Tacoma, and the more rural Snohomish River and Nisqually River Estuaries. Juvenile chinook salmon from hatcheries associated with sampled estuaries were also collected and whole bodies and stomach contents were analyzed for chemical concentrations. Results of these surveys showed that outmigrating juvenile chinook salmon from the Duwamish and Hylebos Waterways exhibited consistent evidence of exposure to contaminants. Juvenile chinook salmon from the Snohomish Estuary, which has some urban development, also appeared to be exposed to contaminants, but to a much lesser degree than salmon from the Duwamish and Hylebos Waterways. In addition, when held in tanks with flow-through seawater for a period of several months, juvenile salmon from the Duwamish Estuary exhibited reduced growth and reduced disease resistance when compared to salmon from either the Green River Hatchery (the primary source of salmon for the Duwamish Estuary) or to salmon from the nonurban Nisqually system (Arkoosh *et al*., 1998; Casillas *et al*., 1995). Similar effects were observed for juvenile salmon from the Hylebos Waterway (Arkoosh *et al*., 2001; Casillas *et al*., 1998). Chemical contaminant exposure in the estuary appeared to place additional stresses on juvenile chinook salmon that could affect their long-term health and survival as they enter the marine environment.

To increase our knowledge of concentrations of chemical contaminants in outmigrant salmon in the Pacific Northwest, we carried out an expanded study from 1996–2001 in which juvenile coho and chinook salmon were collected for contaminant analyses from a number estuaries in Washington and Oregon. Classified by the overall level of development and channel alteration in each estuary (Cortright *et al*., 1987), the sampling areas included: five deep draft estuaries, with the maximum level channel alteration and urban development (Duwamish Estuary, Columbia River, Grays Harbor, Yaquina Bay, and Coos Bay); two shallow draft estuaries with less extensive channel alteration and some urban and industrial development (Tillamook Bay and Coquille River), four conservation estuaries, where channel alteration is minimal and development is limited (Skokomish Estuary, Nisqually Estuary, Willapa Bay and Alsea Bay); and two natural estuaries, which are largely undeveloped for residential, commercial or industrial uses (Elk River and Salmon River). Predominantly wild fish were collected in the estuaries, although some fish of hatchery origin may have been sampled due to incomplete marking of hatchery fish. Juvenile chinook salmon were also sampled from regional hatcheries to evaluate contaminant uptake during rearing but prior to release. Our results indicate that exposure to chemical contaminants is widespread in outmigrant juvenile chinook and coho salmon, and concentrations in tissues of chinook salmon from several estuaries are high enough to pose a potential threat to their health and survival.

2 Materials and methods

2.1 Collecting juvenile salmon

Juvenile, subyearling chinook salmon were collected from a number of Washington and Oregon estuaries over a 6-year period (1996–2001; Fig. 1; Table 1). The Washington estuaries included: Skokomish and Nisqually Estuaries; Duwamish Estuary, and Grays Harbor and Willapa Bay. The Oregon estuaries included the Columbia, Salmon, Coquille, and Elk Rivers; and Yaquina, Alsea, and Coos Bays. Juvenile coho were also collected from Grays Harbor and Willapa, Yaquina, Alsea, and Coos Bays during 1998 (Fig. 1; Table 1). Due to the pattern of salmon movement in the estuaries, we generally sampled on early morning outgoing tides. Salmon were caught with a beach seine net 36.6 meters in length. The wings of

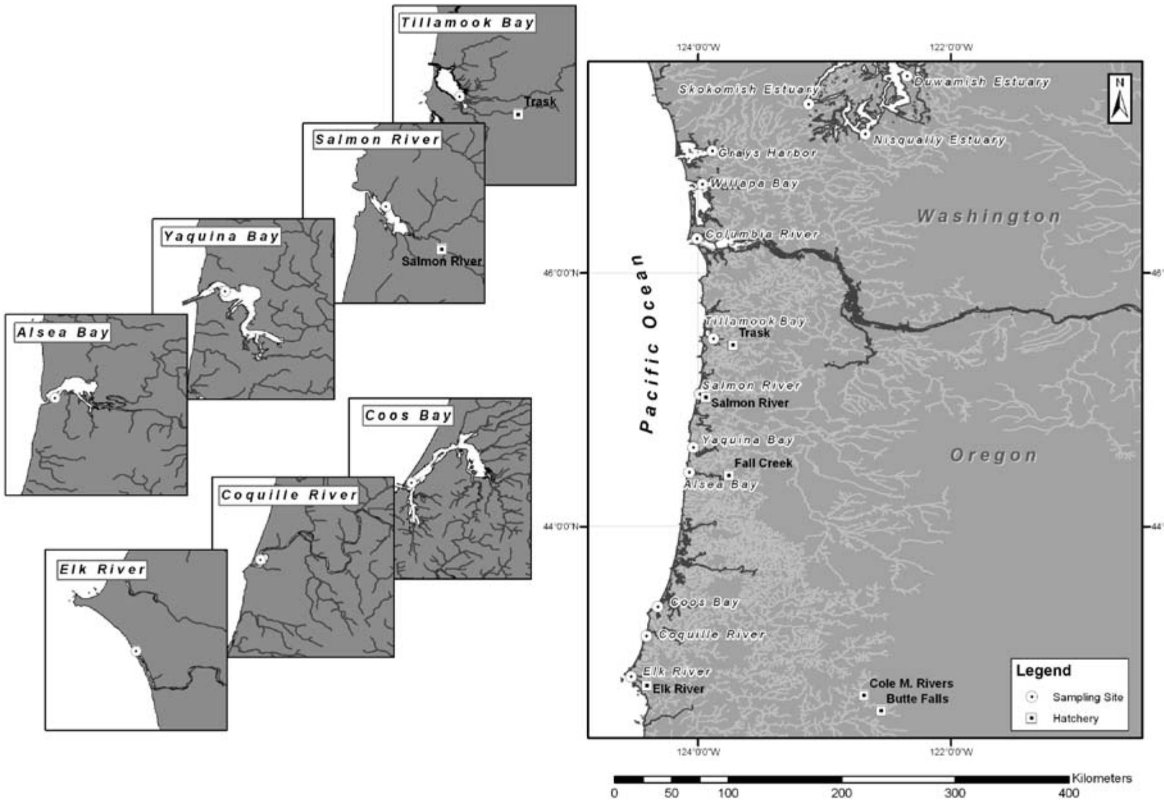

Fig. 1 Locations of hatcheries and estuaries where juvenile coho and chinook salmon were collected

the net were 18 meters long by 2.3 meters deep with 0.6 cm mesh.

Appropriate sampling permits were obtained from the National Marine Fisheries Service (NMFS), and the Oregon and Washington Departments of Fish & Wildlife prior to sampling. To ensure sampling of wild fish instead of hatchery-reared fish we attempted to collect fish from field sites prior to releases from hatcheries or other programs (such as the Salmon and Trout Enhancement Program or STEP). Although a few fin-clipped hatchery fish were collected and sampled, we did not include these fish in our analyses. Once target salmonids were removed from the net they were placed in insulated aerated tanks and transported live to the nearest laboratory, either the Hatfield Marine Science Center in Newport, Oregon; the University of Oregon's Oregon Institute of Marine Biology in Charleston, Oregon; the U.S. Fish and Wildlife's Olympia Fish Health Center in Olympia, Washington, the Point Adams Field Station in Hammond, Oregon or the Northwest Fisheries Science Center in Seattle, Washington, where they were necropsied within a few hours of collection. Juvenile chinook salmon were also obtained directly from several hatcheries (Fall Creek, Butte Falls, Cole M. Rivers, Elk River, Salmon River, and Trask; see Fig. 1 for locations) to evaluate contaminant uptake during hatchery rearing. Juvenile hatchery coho salmon were not available for sampling at the time of the survey.

Fish to be necropsied were measured (to the nearest mm) and weighed (to the nearest 0.1 g), then sacrificed by a blow to the head. Bile and stomach contents were removed, and composites of 10–15 fish each were generated. Whole gutted bodies from 10 fish were also collected and composited. Bile and stomach contents samples were frozen and stored at −80 °C and whole body samples were frozen and stored at −20 °C until chemical analyses were performed. Sampling sites, dates, and sample types collected are listed in Table 1. Because of limitations associated with fish availability and tissue requirements for analysis, not all samples types could be collected each year from all sites.

2.2 Sample analyses

2.2.1 *Organochlorine and aromatic hydrocarbon analyses of composite whole body and stomach content samples*

Samples in this study were analyzed using a performance-based measurement system (Telliard, 1999), described in detail by Sloan *et al*. (1993) and updated in Sloan *et al*. (2005). Briefly, after the addition of surrogate standards, samples of up to 3 g were extracted with dichloromethane either by homogenizing in the presence of sodium sulfate (Sloan *et al*., 1993) or utilizing accelerated solvent extraction (Sloan *et al*., 2005). For composite whole body samples, a portion of the extract was taken for gravimetric lipid determination. The portion of the extract to be analyzed underwent initial cleanup by filtering through silica gel and neutral alumina, followed by the addition of a recovery standard to determine the fraction of the total extract analyzed. After further sample cleanup using high-performance liquid chromatography with size-exclusion chromatography, the sample fraction containing organochlorines (OCs) and 2–6 ring aromatic hydrocarbons was collected. The fraction was reduced in volume, a GC standard was added, and the sample was analyzed using high-resolution gas chromatography coupled with electron capture detection (samples analyzed for OCs 1996–1998; Sloan *et al*., 1993) or mass spectrometry with selected-ion monitoring (samples analyzed for OCs 1999–2001; Sloan *et al*., 2005) with 5–10 levels of calibration standards. Concentrations of aromatic hydrocarbons (stomach contents samples only) were analyzed in all sampling years by high-resolution gas chromatography with mass spectrometry using selected ion monitoring and 5–6 levels of calibration standards. Quality assurance measures included analysis of a certified reference material and a laboratory blank with each batch of samples. Performance criteria were met for all samples and sample batches.

Analyses for OCs included individual PCB (polychlorinated biphenyl) congeners, DDTs, chlordanes, lindane, aldrin, dieldrin and mirex. PCBs measured over all years included a standard list of 17 congeners (IUPAC numbers 18, 28, 44, 52, 95, 101, 105, 118, 128, 138, 153, 170, 180, 187, 195, 206, and 209). Total PCBs was calculated by summing the concentrations of these individual congeners and multiplying the result by two. This formula provides a good estimate of the total PCBs in a typical environmental sample of sediments or animals feeding on lower trophic levels, where a mixture of Aroclors 1254 and 1260 is the predominant pattern (Lauenstein *et al.*, 1993). Summed DDTs (ΣDDTs) levels were calculated by summing the concentrations of o,p'- and p,p'-DDD, o,p'- and p,p'-DDE, and o,p'- and p,p'-DDT. Summed chlordanes (ΣCHLDs) were calculated by summing the concentrations of heptachlor, heptachlor epoxide, γ-chlordane, α-chlordane, oxychlordane, *cis*-nonachlor, *trans*-nonachlor and nonachlor III. Summed low molecular weight aromatic hydrocarbons (ΣLAHs) were determined by adding the concentrations of biphenyl, naphthalene, 1-methylnaphthalene, 2-methylnaphthalene, 2,6-dimethylnapthalene, acenaphthene, fluorene, phenanthrene; 1-methylphenanthrene, and anthracene. Summed high molecular weight aromatic hydrocarbons (ΣHAHs) were calculated by adding the concentrations of fluoranthene, pyrene, benz[a]anthracene, chrysene, benzo[a]pyrene, benzo[e]pyrene, perylene, dibenz[a,h]anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, indenopyrene, and benzo[ghi]perylene. Summed total aromatic hydrocarbons (ΣAHs) were calculated by adding ΣHAHs and ΣLAHs.

2.2.2 PAH metabolites in bile

Composite samples of bile were analyzed by high-performance liquid chromatography with fluorescence detection (HPLC/uvf) for aromatic hydrocarbon (AH) metabolites as described in Krahn *et al.* (1986). In brief, bile was injected directly onto a C18 reverse-phase column (Phenomenex Synergi Hydro) and eluted with a linear gradient from 100% water (containing a trace amount of acetic acid) to 100% methanol at a flow of 1.0 mL/min. Chromatograms were recorded at the following wavelength pairs: 1) 260/380 nm where several 3–4 ring compounds (e.g., phenanthrene) fluoresce and 2) 380/430 nm where 4–5 ring compounds (e.g., benzo[a]pyrene) fluoresce. Peaks eluting after 5 minutes were integrated and the areas of these peaks were summed. The concentrations of fluorescent AHs in bile were determined using phenanthrene (PHN) and benzo[a]pyrene (BaP) as external standards and converting the fluorescence response of bile to phenanthrene (ng PHN equivalents/g bile), and benzo[a]pyrene (ng BaP equivalents/g bile) equivalents. Bile metabolites fluorescing at phenanthrene wavelengths were considered an indicator of exposure to low molecular weight PAHs, while metabolites fluorescing at benzo[a]pyrene (BaP) wavelengths were considered as an indicator of exposure to high molecular weight PAHs.

2.2.3 Statistical methods

Statistical analyses were conducted with the Statview©statistical software package (SAS Institute, Inc., Cary, NC, USA). Temporal and intersite differences in tissue, stomach contents, and bile contaminant concentrations were determined by ANOVA. Data were log-transformed as necessary to achieve a normal distribution. The significance level for all analyses was set at $\alpha = 0.05$.

3 Results

3.1 Lipid content in whole bodies

Lipid content (as total extractable organics) in bodies of chinook salmon collected from the estuaries varied from 0.8% in fish from Tillamook Bay to 3.5% in fish from Coquille River, with an average concentration of 2.4% (Fig. 2; Table 2). Lipid levels in juvenile coho salmon were slightly lower, with an average concentration of 1.2% (Fig. 2; Table 2), but not significantly different than levels in estuarine chinook salmon (ANOVA, $p = 0.08$). Lipid concentrations in hatchery chinook salmon were significantly higher than in estuary chinook (ANOVA, $p = 0.001$), with an average concentration of 7.9% (Fig. 2; Table 2). The number of samples collected (typically one composite per site or hatchery) was too small for intersite or interhatchery differences to be meaningfully evaluated,

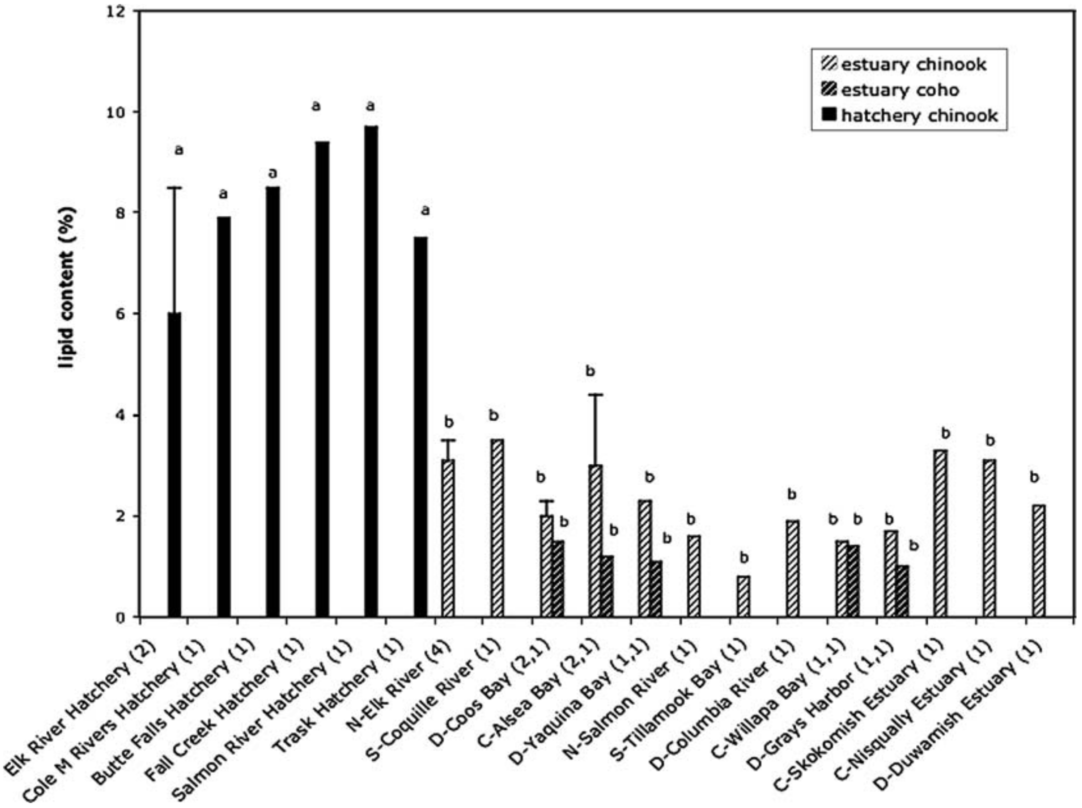

Fig. 2 Mean lipid content (%, as total extractable organics, ± SE) in whole bodies of chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from associated hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

but concentrations tended to be fairly uniform within the sampling groups (i.e, estuarine chinook, estuarine coho, and hatchery chinook).

3.2 Organochlorine contaminants in whole bodies

Concentrations of PCBs in whole bodies of estuarine chinook salmon (Fig. 3, Tables 2 and 3) were quite variable, ranging from ∼500 ng/g lipid weight (lw) in salmon from Elk River and Coquille Estuaries to 3100 ng/g lw in salmon from the Duwamish Estuary in Seattle (or from 3.6 ng/g wet weight (ww) at Salmon River to 103 ng/g ww at Duwamish). The lowest concentrations of PCBs were found in chinook salmon from Elk River Estuary, Coquille River, Alsea Bay Estuary, Salmon River, and Tillamook Bay; wet weight PCB concentrations were less than 20 ng/g ww at all these sites, and lipid weight PCB concentrations were below 600 ng/g lw in chinook from Elk River Estuary, Coquille River, and Tillamook. The highest PCB concentrations (2500–3100 ng/g lw or 45–103 ng/g ww) were found in salmon from Yaquina Bay, the Columbia River, and the Duwamish Estuary.

Concentrations of PCBs in juvenile coho salmon (Fig. 3, Tables 2 and 3) tended to be lower than those in chinook salmon. At sites where both species were collected, the mean PCB concentration overall was significantly lower in coho than in chinook on both a lipid weight and wet weight basis (1030 vs. 1650 ng/g lw, $p = 0.018$; 10 vs. 30 ng/g ww; $p = 0.0026$). No significant differences were observed in PCB concentrations in coho salmon from different sampling sites, but the number of samples was very small.

The mean concentration of PCBs in juvenile chinook salmon from hatcheries (Fig. 3, Tables 2 and 3) was relatively low on a lipid weight basis (620 ng/g lw),

Table 2 Contaminant concentration mean values (± SE), ranges, and sites where high and low values were observed in juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from Pacific Northwest hatcheries. Values with different superscripts are significantly different (ANOVA, $p = 0.05$) in estuarine chinook, estuarine coho, and hatchery chinook

comparable to concentrations observed in estuary chinook and coho salmon from rural estuaries (e.g., Elk River, Coquille River, Alsea Bay). On a wet weight basis, however, the mean PCB concentration in hatchery chinook was quite high (47 ng/g ww), comparable to concentrations in moderately to heavily urbanized estuaries (Table 3).

Concentrations of ΣDDTs in estuarine chinook salmon bodies ranged from 62 ng/g lw at Tillamook Bay to 2280 ng/g lw in the Columbia River (or from below 0.5 ng/g ww in fish from Tillamook Bay to 41 ng/g ww in fish from the Columbia River) (Fig. 4, Tables 2 and 3), with a mean concentration of 550 ng/g lw or 13 n/g ww (Fig. 4; Tables 2 and 3). Concentrations

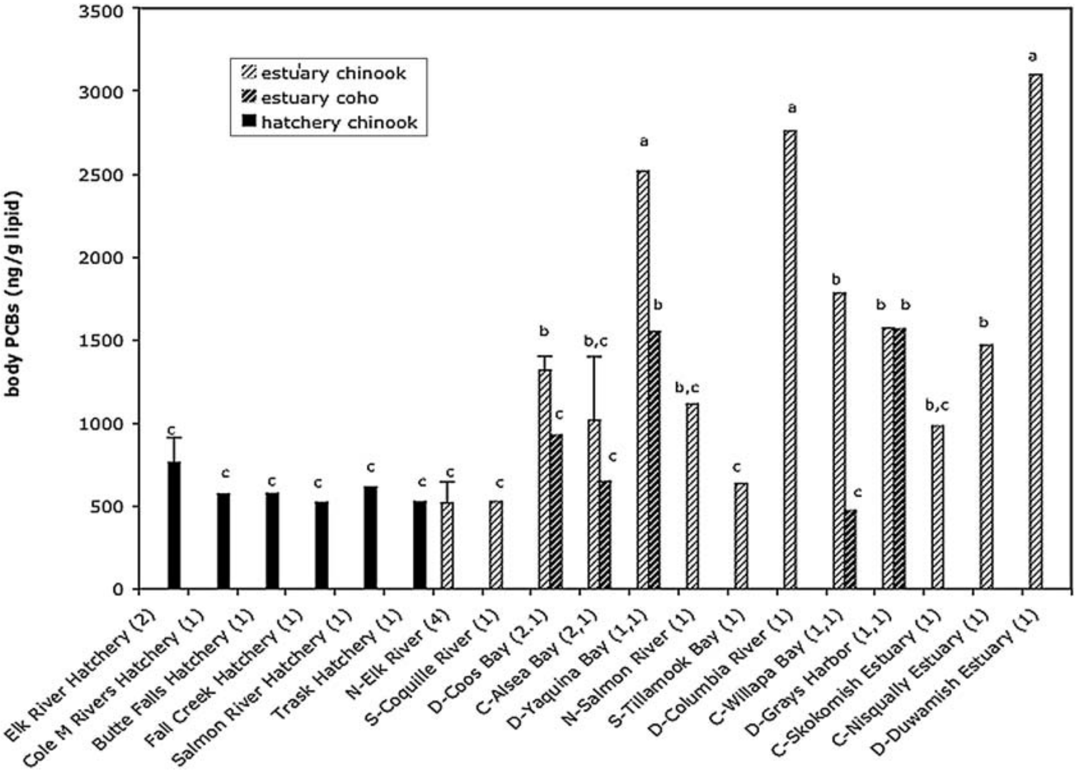

Fig. 3 Mean concentrations of ΣPCBs (ng/g lipid, ± SE) in whole bodies of juvenile chinook and coho salmon from Pacific Northwest Estuaries and juvenile chinook salmon from associated hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

of ΣDDTs were low in fish from Tillamook Bay, Alsea Bay, and Elk River on both a wet wt and lipid wt basis (below 250 ng/g lw and 5 ng/g ww); at Coquille River lipid wt DDT concentrations were comparable but wet wt concentrations were higher, while the reverse was true for chinook from Salmon River. Concentrations of ΣDDTs were relatively high (over 1000 ng/g lw or 25 ng/g ww) in fish from the Nisqually, Duwamish, and Columbia River Estuaries. Fish with the highest ΣDDT concentrations were from the Columbia River, where levels were over 2200 ng/g lw or 40 ng/g ww.

In juvenile coho salmon, the maximum ΣDDT concentration was 333 ng/g lw or 3.4 n/g ww in fish from Grays Harbor (Fig. 4; Tables 2 and 3), while the mean concentration was 140 ng/g lw or 1.7 ng/g ww. When coho and chinook salmon collected from the same sites were compared, ΣDDT concentrations were much lower in coho salmon (1.7 ± 0.3 ng/g ww vs. 8.8 ng/g ww, $p = 0.0026$; or 137 ng/g lw vs. 551 ± 95 ng/g lw, $p \leq 0.001$).

On a wet weight basis, concentrations of ΣDDTs in whole bodies of juvenile Chinook collected from the hatcheries were fairly high, with the mean concentrations for all hatcheries significantly above the mean concentrations measured in estuarine chinook and coho (Tables 2 and 3). However, because of the high lipid content of the hatchery fish, their whole body ΣDDT concentrations on a lipid weight basis were more moderate (400–500 ng/g lw), and did not differ significantly from mean concentrations in estuarine salmon (Fig. 4; Tables 2 and 3).

Of the six DDTs measured in salmon whole bodies, *p,p′*-DDE predominated in whole bodies of both coho and chinook salmon from all estuaries and hatcheries sampled, accounting for 75–100% of DDTs measured (Fig. 5; Table 3). The second most prominent DDT was *p,p′*-DDD; it accounted for 10–20% of DDTs measured in chinook and coho salmon from most sites. Additionally, *p,p′*-DDT was present at several sites, accounting for 3–6% of total DDTs in chinook salmon

Table 3 Mean concentrations ($\pm$ SE) in ng/g, wet wt of ΣPCBs, ΣDDTs, and DDT isomers in whole bodies of juvenile chinook and coho salmon collected from Pacific Northwest estuaries and juvenile chinook salmon from Pacific Northwest hatcheries. Compounds were measured by GC/ECD in samples collected from 1996–1998 and by GC/MS in samples collected from 1999–2001. Values with different letter superscripts are significantly different (ANOVA, $p \leq 0.05$)

from the Columbia River, Yaquina Bay, Grays Harbor, and Salmon River, 4% of total DDTs in juvenile coho from Grays Harbor, and 13% of total DDTs in coho from Willapa Bay. In hatchery chinook salmon, *p,p′*-DDT accounted for an average of 5% of total DDTs. Concentrations of estrogenic *o,p′*-DDT, *o,p′*-DDD, and *o,p′*-DDE (Fig. 6) were below detection limits in all coho and many chinook salmon sampled, but were present at concentrations above 0.1 ng/g ww or 10 n/g lw in chinook salmon from the Columbia, Nisqually, Duwamish and Yaquina Bay Estuaries. As with ΣDDTs, concentrations of the *o,p′* isomers were highest in chinook from the Columbia River. In hatchery chinook salmon, they averaged 8 ng/g lw.

We calculated the ΣDDTs/ΣPCBs ratios in whole body samples of chinook and coho salmon to identify groups of fish with distinct contaminant profiles (Fig. 7). In coho salmon, the mean ΣDDTs/ΣPCBs ratio was 0.2, and in estuarine chinook salmon, the mean ratio was 0.4. In both coho and chinook salmon from most of the sites we sampled (Nisqually, Skokomish, Coos Bay, Alsea Bay Estuary, Salmon River Estuary, Willapa Bay, Elk River Estuary, Duwamish Estuary, Tillamook Bay, Yaquina Bay), ΣDDT/ΣPCB ratios were 0.5 or lower. This was not true, however, of chinook salmon from the Columbia River, whose ΣDDTs/ΣPCBs ratios were 1.0–1.1. In hatchery chinook, the mean ΣDDTs/ΣPCBs ratio was ~0.7.

In addition to PCBs and DDTs, chlordanes, hexachlorobenzene, and dieldrin were detected in whole bodies of estuarine chinook and coho salmon from one or more sampling sites, but at much lower concentrations than PCBs or DDTs (mean concentrations ranging from <1 ng/g ww to 4 ng/g ww; Table 4). Of the

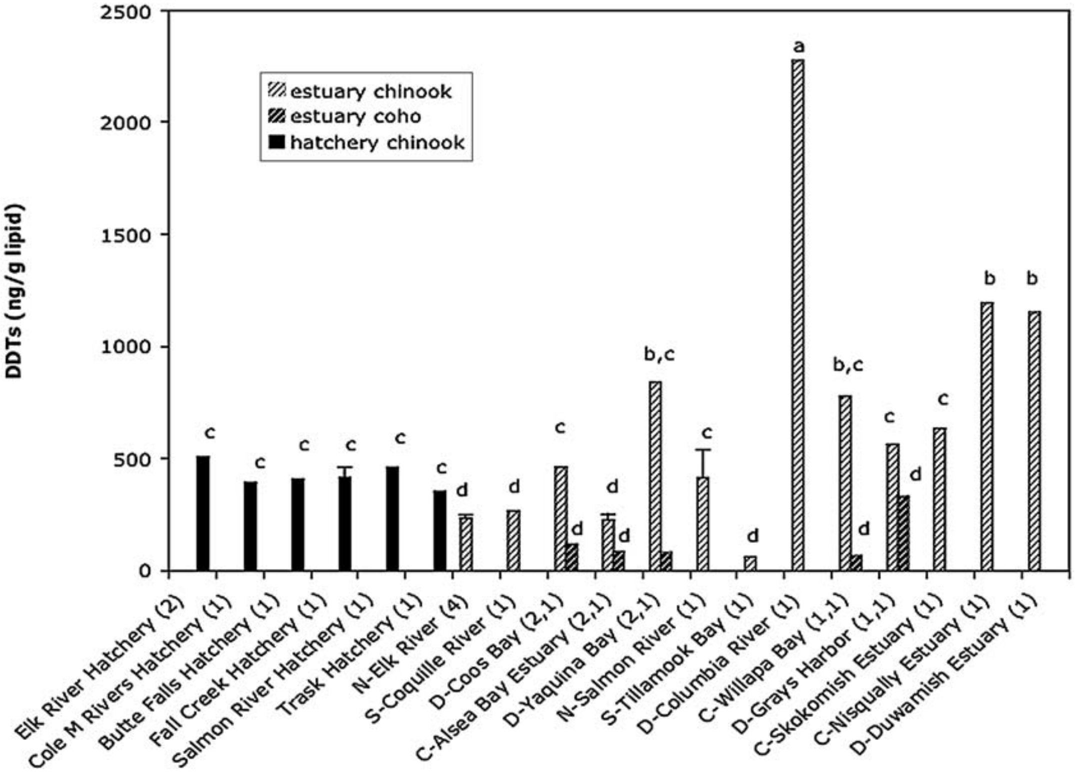

Fig. 4 Mean concentrations of ΣDDTs (ng/g lipid, ± SE) in whole bodies of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from associated hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

pesticides detected, chlordanes were generally found at the highest concentrations. Other OC pesticides (i.e., lindane, mirex and aldrin) were below the limits of detection (generally <0.5 ng/g ww) in all samples. Dieldrin, chlordanes, and HCB were detected in whole bodies of juvenile chinook from all sampled hatcheries, typically at concentrations in the 1–5 ng/g ww range. Concentrations were comparable to the highest levels reported in estuarine chinook and coho (Table 4).

3.3 Bile metabolites

Levels of high molecular weight AH metabolites in bile (FACs-BaP) were low to moderate (100–400 ng/g bile) in juvenile fall chinook and coho salmon collected from most of the estuaries sampled along the Washington and Oregon Coast (Fig. 8). Concentrations in chinook salmon from the Duwamish Estuary (~1930 ng BaP equiv/g bile) were significantly higher than in fish from any other sites. FAC-BaP levels were also somewhat elevated (350–500 ng/g bile) in chinook salmon from the Columbia River, Skokomish Estuary, Grays Harbor, and Willapa Bay, and in coho salmon from Grays Harbor. Lowest concentrations were observed in chinook and coho salmon from Elk River Estuary, Yaquina Bay Estuary, and Alsea Bay Estuary. At 100–200 ng BaP equiv/g bile, concentrations of FACs-BaP in fish at these sites were significantly lower than in chinook salmon from the Columbia, Skokomish, Willapa Bay, and Duwamish sites, and in chinook and coho salmon from Grays Harbor.

Concentrations of metabolites of low molecular weight PAHs (FAC-PHN; Fig. 8) were also significantly higher in chinook salmon from the Duwamish Estuary (359,000 ng PHN equiv/g bile) than in fish from any other sites. Concentrations in chinook salmon from Grays Harbor, Coos Bay, and the Columbia River (60,000–70,000 ng PHN equiv/g bile) were much lower than in the Duwamish chinook, but significantly above levels in either coho or

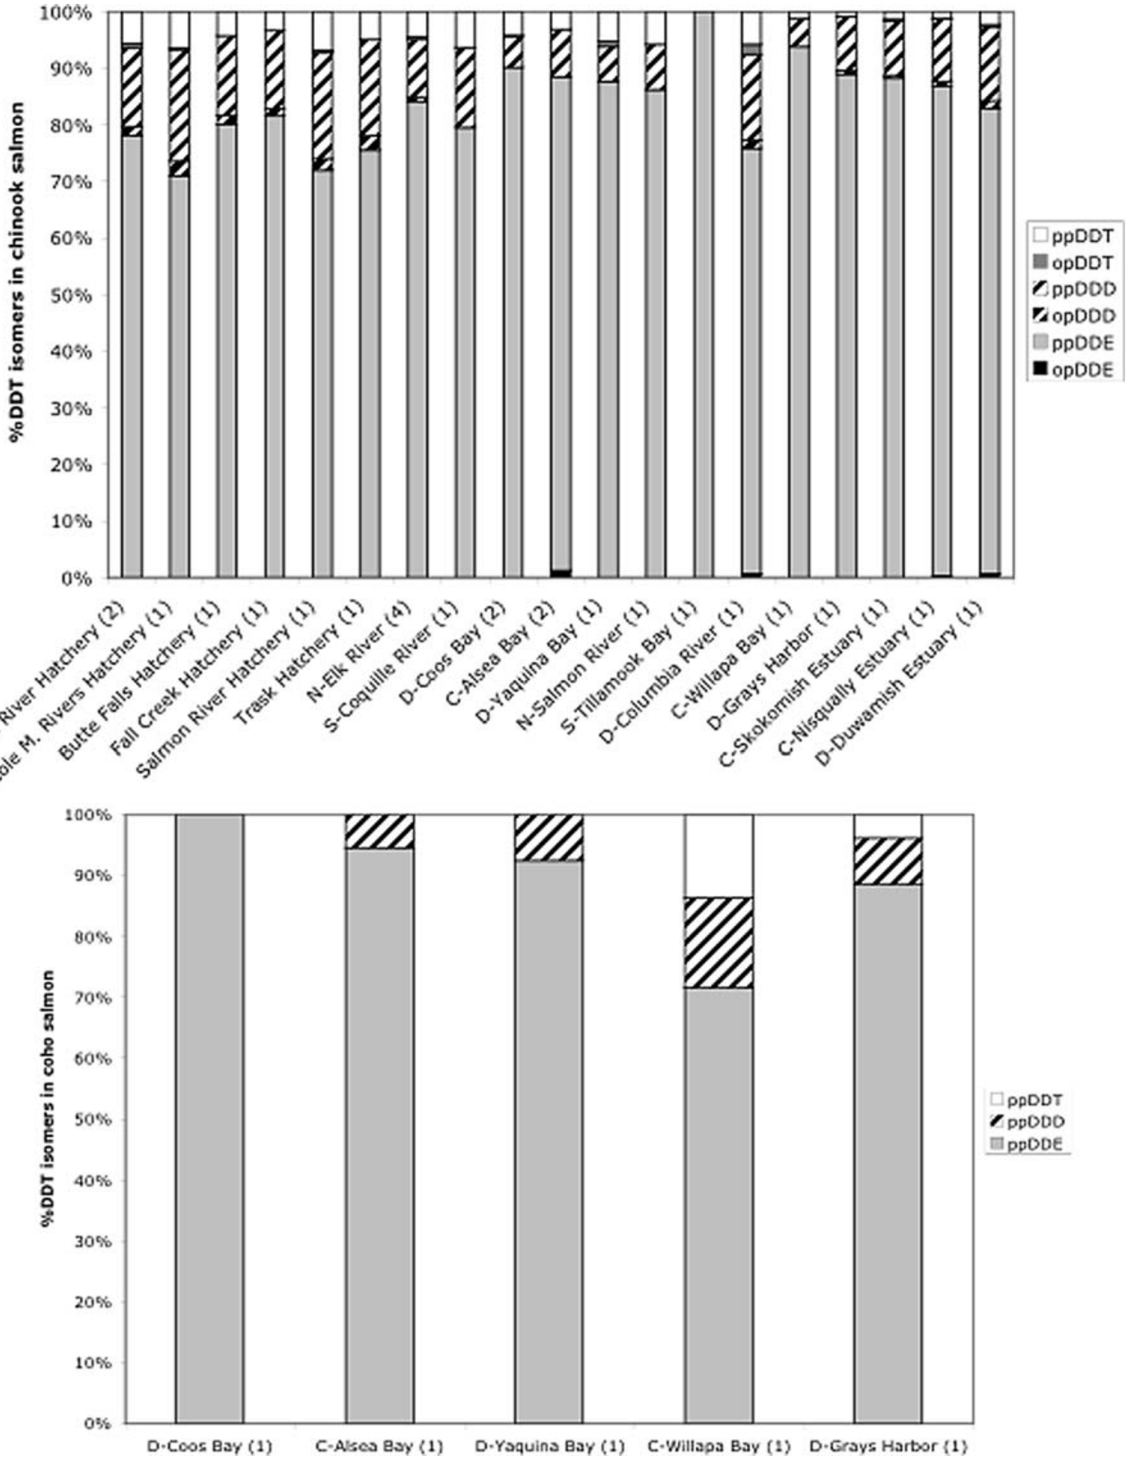

Fig. 5 Proportions of various DDTs in composite whole body samples of juvenile chinook and coho salmon collected from Pacific Northwest estuaries and hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group

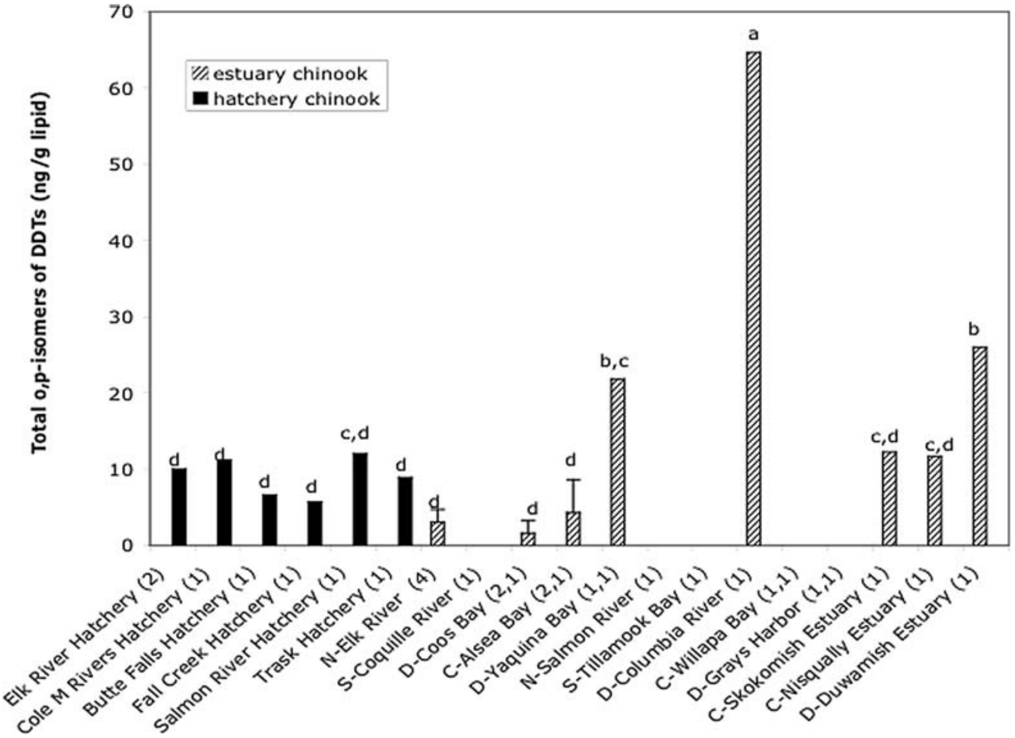

Fig. 6 Mean concentrations of $\Sigma o, p'$-isomers of DDTs (ng/g lipid, ± SE) in whole bodies of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from associated hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$). Values were below detection limits for coho from all sites where they were sampled, and for chinook from Coquille River

chinook salmon from the other sampling sites, whose biliary FACs-PHN concentrations were 30,000 ng PHN equiv/g bile or less. Bile sample could not be collected from chinook salmon at the hatcheries.

3.4 Contaminants in stomach contents

Several classes of contaminants, including PCBs, DDTs, and low and high molecular weight PAHs, were present at detectable concentrations in stomach contents of outmigrant juvenile chinook and coho salmon. Concentrations of ΣLAHs in stomach contents of estuarine chinook salmon (Fig. 9; Table 2) ranged from 12 ng/g ww at the Elk River Estuary to 8000 ng/g ww at the Duwamish Estuary. Concentrations of ΣLAHs were also fairly high in fish from Willapa Bay, Yaquina Bay, and Grays Harbor in comparison to other sites, ranging from 350 to 1400 ng/g ww. Concentrations of ΣLAHs in stomach contents of chinook and coho salmon from all other sites were <100 ng/g ww (Fig. 9; Table 2). At sites where both species were collected, average ΣLAH concentrations in stomach contents of chinook salmon were higher than in coho salmon (920 ng/g ww vs. 5 ng/g ww). In chinook salmon from Elk River Hatchery, the concentration of ΣLAHs in stomach contents was 28 ng/g ww (Fig. 9; Table 2).

Concentrations of ΣHAHs in stomach contents of juvenile chinook salmon (Fig. 9, Table 2) were highest in fish from the Duwamish Estuary and Willapa Bay (6000–6300 ng/g ww). Concentrations of ΣHAHs at Grays Harbor and Yaquina Bay (330–340 ng/g ww) were also relatively high in comparison to other sites, where concentrations were ~20 ng/g ww and below. The lowest levels ΣHAHs (1–2 ng/g ww) were observed in chinook from Salmon River and Elk River Estuary sites. In coho salmon (Fig. 9; Table 2) concentrations of ΣHAHs in stomach contents were ~10 ng/g ww or below in fish from all sites; at sites where both species were collected, ΣHAH concentrations were higher in chinook salmon than in coho salmon (323 ng/g ww vs. 40 ng/g ww). In chinook and coho salmon from most sampling sites, HAHs accounted for

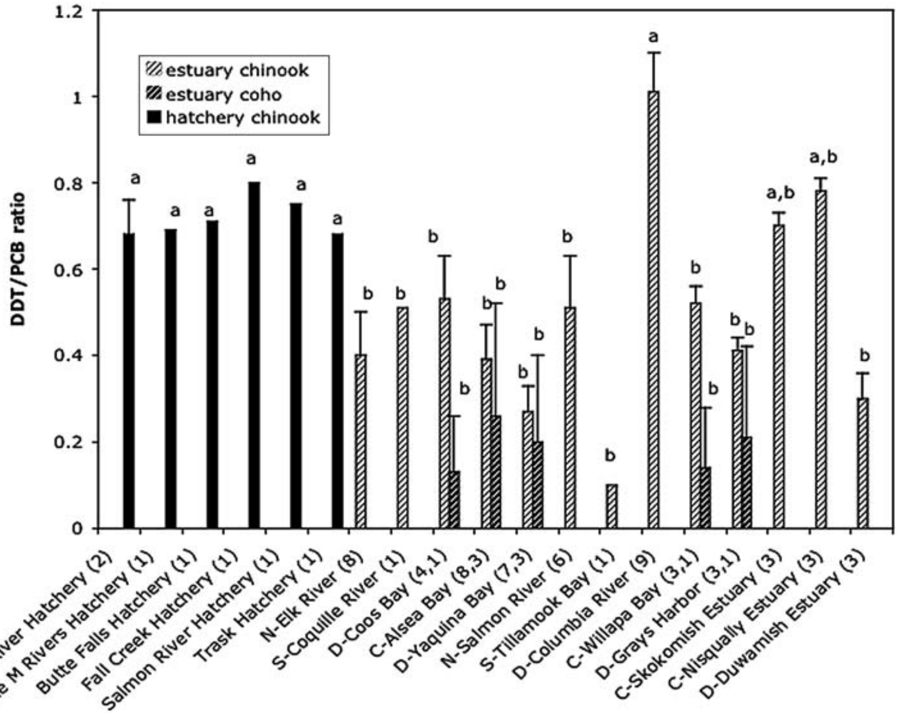

Fig. 7 Mean ΣDDT/ΣPCB ratios (± SE) in whole bodies of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from associated hatcheries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

10–20% of total AHs. However, in chinook salmon from the Duwamish, Grays Harbor, Yaquina Bay, and Willapa Bay, HAHs were more predominant, accounting for 30–70% of total AHs. In chinook salmon from the Elk River Hatchery (Fig. 9), ΣHAH concentrations were relatively low (5 ng/g ww) and accounted for about 15% of total AHs.

Concentrations of ΣPCBs in stomach contents of estuarine chinook salmon (Fig. 10; Table 2) ranged from 5 ng/g ww in fish from the Salmon River Estuary to 200 ng/g ww in fish from the Duwamish Estuary. Concentrations of PCBs in salmon from the Columbia River and Grays Harbor were about 40 ng/g ww, and concentrations were about 20 ng/g ww or less at all other sampling sites. Lowest levels (5–10 ng/g ww) were observed at Yaquina Bay, Alsea Bay, Coos Bay, Elk River, and Salmon River Estuaries. In coho salmon (Fig. 10, Table 2), PCB concentrations in stomach contents ranged from 5 ng/g ww in fish from Alsea Bay Estuary to 22 ng/g ww in fish from Willapa Bay. At sites where both species were collected, PCB concentrations were similar in stomach contents of chinook salmon and coho salmon, 14 ng/g ww vs. 12 ng/g ww. At the Elk River Hatchery, PCB concentrations in stomach contents were 13 ng/g ww, comparable to levels in estuarine chinook salmon from non-urban sites (Fig. 10; Table 2).

Concentrations of ΣDDTs in stomach contents of estuarine chinook salmon (Fig. 11; Table 2) were highest in fish from Grays Harbor (45 ng/g ww) and the Columbia River (39 ng/g ww), significantly higher than in fish from all other sites. In stomach contents of chinook from all sampling sites except for the Columbia River and Grays Harbor, ΣDDT concentrations were <10 ng/g ww. Concentrations of ΣDDTs in stomach contents of coho salmon (Fig. 11, Table 2) were low (3 ng/g ww) in fish from all sites. At sites where both species were collected, ΣDDT concentrations were higher in chinook salmon than in coho salmon (9 ng/g ww vs. 1.5 ng/g ww). In chinook salmon from the Elk River Hatchery (Fig. 11, Table 2), concentrations of DDTs were also relatively low, 4.5 ng/g ww.

In stomach contents, as in tissues, *p,p′*-DDE was the predominant isomer detected, accounting for about

Table 4 Mean concentrations (± SE) in ng/g, wet wt of selected organochlorine pesticides in bodies of juvenile chinook and coho salmon collected from Pacific Northwest estuaries and hatcheries. Σchlordanes = summed concentrations of heptachlor, heptachlor epoxide, γ-chlordane, α-chlordane, *cis*-nonachlor, *trans*-nonachlor and nonachlor III. DL = detection limit. Pesticides were measured by GC/ECD in samples collected from 1996–1998 and by GC/MS in samples collected from 1999–2001. Values with different letter superscripts are significantly different (ANOVA, $p < 0.05$). Lindane was also measured, but was below DL (generally < 0.5 ng/g ww) in all samples

60–100% of ΣDDTs in stomach contents of both coho and chinook salmon from all sites (Fig. 12; Table 5). Additionally, *p,p′*-DDD and *p,p′*-DDT were found in both chinook and coho salmon stomach contents from several sites, with highest concentrations in juvenile chinook from the Columbia River (5.9 and 2.5 ng/g ww for *p,p′*-DDD and *p,p′*-DDT, respectively). These isomers accounted for 5–25% of total DDTs. In comparison with salmon whole bodies, *p,p′*-DDT was found at higher concentrations in stomach contents. The *o,p*’-DDTs were found only in stomach contents of chinook salmon from the Columbia River, which had measurable concentrations (0.6–1.1 ng/g ww) of both *o,p′*-DDT and *o,p′*-DDD. In stomach contents of juvenile chinook from the Elk River Hatchery, the only DDT isomer found was *p,p′*-DDE, which was present at a concentration of 4.5 ng/g ww.

In addition to PCBs, DDTs, and PAHs, chlordanes HCBs, HCHs, dieldrin, and mirex were detected in stomach contents of estuarine chinook or coho from one or more sampling sites (Table 6). In stomach contents of chinook from the Elk River Hatchery, chlordanes, HCB, and mirex were detected, all at relatively low levels (0.7–1.4 ng/g ww). Aldrin was below the limits of detection in all samples.

3.5 Relationship between contaminants in stomach contents and in salmon bodies

In chinook salmon, concentrations of PCBs and DDTs in stomach contents were significantly and positively

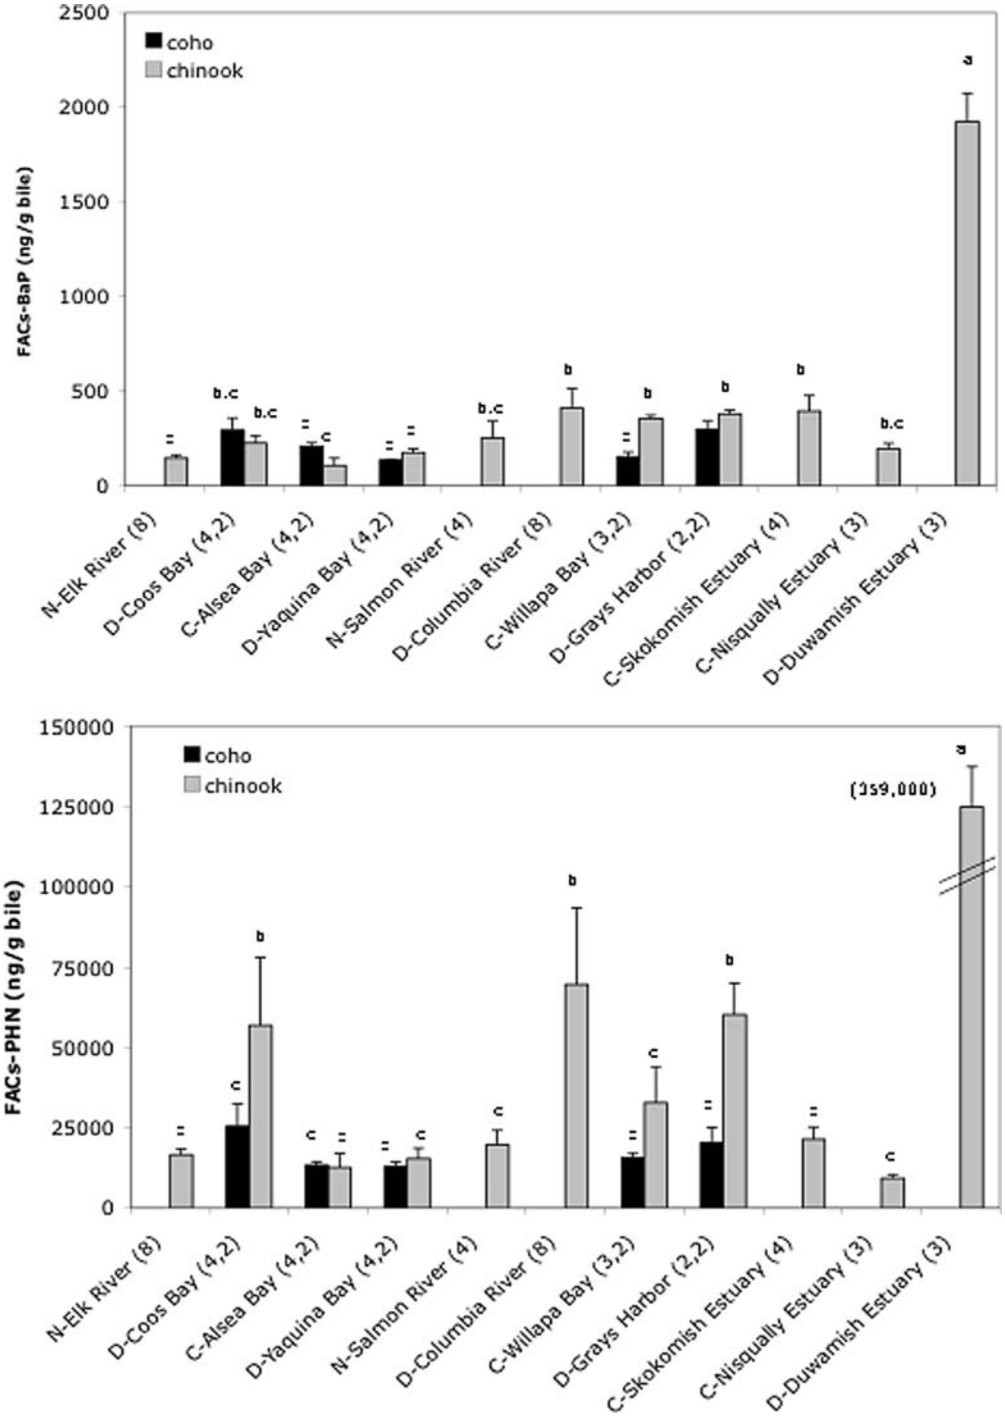

Fig. 8 Mean concentrations of fluorescent aromatic compounds (± SE) measured at phenanthrene wavelengths (FACs-PHN) and benzo[a]pyrene wavelengths (BaP-FACs) in bile of juvenile chinook and coho almon from Pacific Northwest estuaries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Bile metabolites measured at PHN and BaP wavelengths are representative of metabolites of low and high molecular weight PAHs, respectively. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

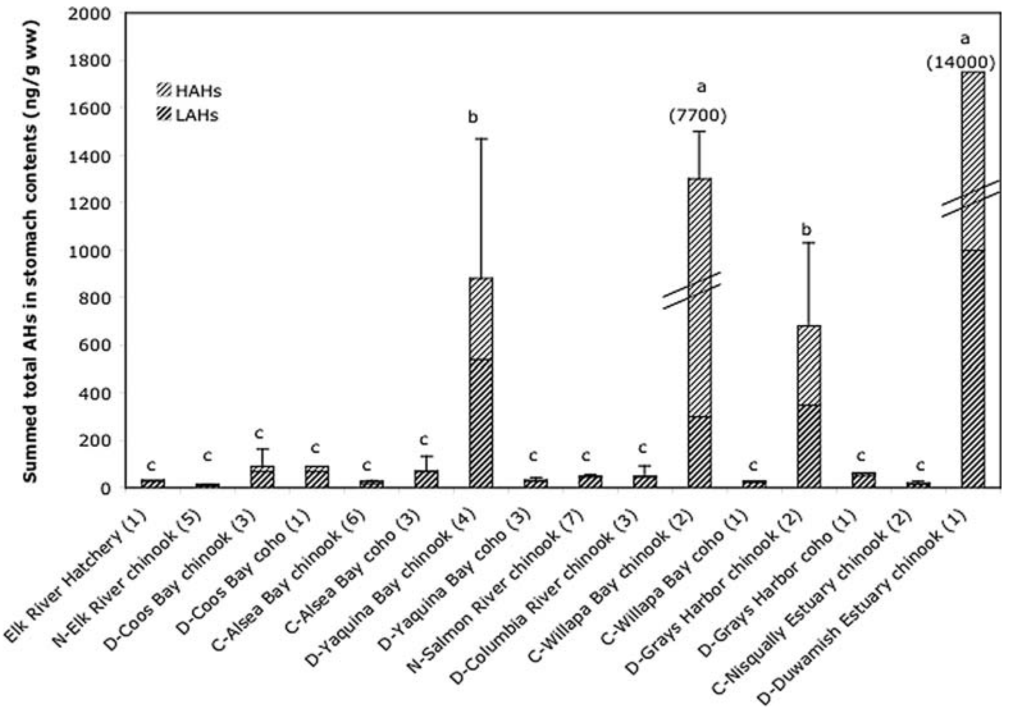

Fig. 9 Mean concentrations of total aromatic hydrocarbons (ΣAHs) (ng/g wet wt, ± SE) in stomach contents of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from Elk River hatchery. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Contributions of low molecular weight and high molecular weight AHs (LAHs and HAHs) to totals are indicated. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

correlated with body burdens of the same contaminants. For PCBs ($n = 46$), $r^2 = 0.32$, $p = 0.0001$; while for DDTs ($n = 40$), $r^2 = 0.38, p = 0.0001$. In coho salmon, concentrations of contaminant in bodies and stomach contents were also positively correlated, but relationships were marginally significant ($0.06 \leq p \leq 0.08$), in part because of smaller sample size. For body DDTs vs. stomach DDTs ($n = 9$), $r^2 = 0.34, p = 0.06$. For body PCBs vs. stomach PCBs ($n = 9$), $r^2 = 0.29$, $p = 0.08$.

In estuarine chinook salmon, concentrations of PCBs and DDTs (ng/g ww) in whole bodies were 3–4 times as high as in stomach contents on average, while in coho salmon, concentrations of PCBs and DDTs in whole bodies and stomach contents were about the same or only slightly higher (1–1.3 times). For chinook salmon from the Elk River Hatchery (the only hatchery where stomach contents data were available), concentrations of PCBs (ng/g ww) were 4.7 times as high in bodies as in stomach contents, while concentrations of DDTs (ng/g ww) were 25 times as high in bodies as in stomach contents.

In chinook salmon, concentrations of PAH metabolites in bile and PAHs in stomach contents were significantly, positively correlated. For ΣLAHs vs. FACs-PHN, $n = 35$, $p = 0.0001$, $r^2 = 0.56$, and for ΣHAHs vs. FACs-BaP, $n = 35$, $p = 0.0006$, $r^2 = 0.28$. In coho salmon, on the other hand, there was no significant correlation between concentrations of either ΣHAHs or ΣLAHs in stomach contents and concentrations of PAH metabolites in bile. For ΣHAHs, $n = 5, r^2 = 0.07$, $p = 0.33$. For ΣLAHs, $n = 5$, $r^2 = 0.18$, $p = 0.26$.

4 Discussion

Estuarine and nearshore ecosystems provide a vital role as juvenile rearing habitat for salmonid species (Levy and Northcote, 1982; Gray *et al.*, 2002; Rice *et al.*, 2005), and can be particularly important in the recovery of species at risk (Feist *et al.*, 2003; Fresh *et al.*, 2005). Unfortunately, estuarine and coastal ecosystems are also among the environments that are most heavily

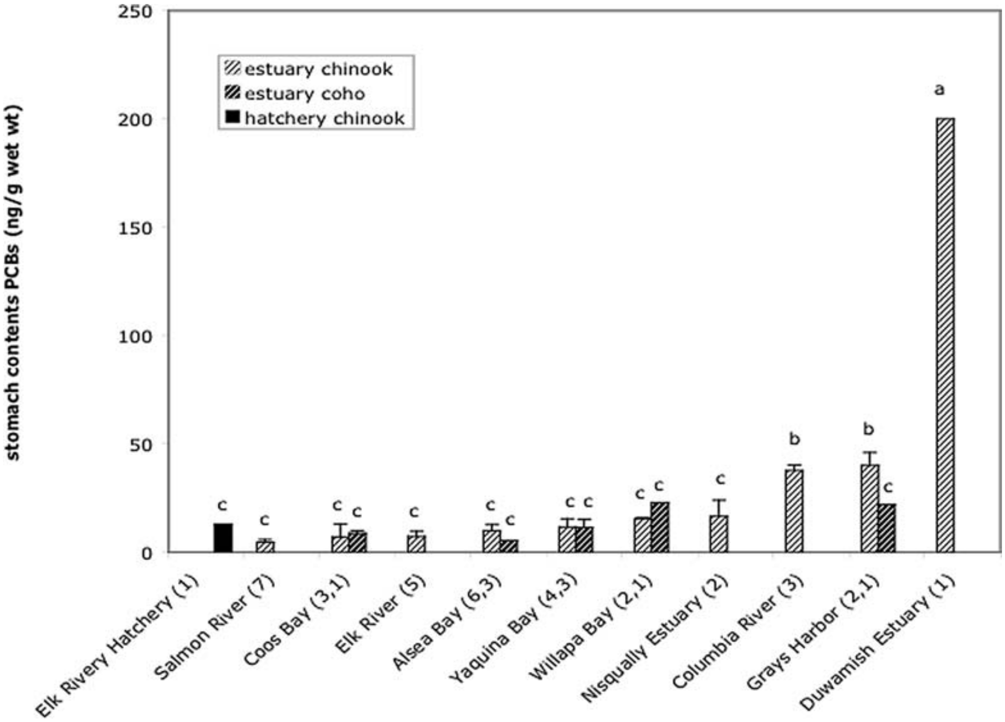

Fig. 10 Mean concentrations of ΣPCBs (ng/g wet wt. ± SE) in stomach contents of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from Elk River hatchery. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

impacted by anthropogenic activities (Shreffler *et al*., 1990; Beck *et al*., 2001; Rice *et al*., 2005). Analyses of risks to salmon populations in estuarine environments have focused largely on alterations to or loss of physical habitat attributes (Bottom *et al*., 2005; Gray *et al*., 2002; Fresh *et al*., 2005), but it is increasingly recognized that habitat degradation associated with chemical contaminants may also pose a significant risk to salmon populations (Spromberg and Meador, 2005; Fresh *et al*., 2005; Loge *et al*., 2005).

The importance of estuarine contamination in terms of the health of salmonid species depends in part on the life history strategy of the species in question. In general, ocean-type stocks, such as fall chinook, which spend an extended period during their first year of life in the estuary, are more vulnerable to the impacts of contaminants in this environment than stream-type stocks, such as coho salmon, which pass through the estuary relatively quickly (Fresh *et al*., 2005). The same may be true of chum salmon, which have a long estuarine residence time (Dorcey *et al*., 1978; Healey, 1982). Juvenile chum have shown relatively high contaminant body burdens at urban sites in previous surveys in Puget Sound, WA (Stehr *et al*., 2000).

The results of the current study confirm that chemical contaminants are present in the prey and tissues of outmigrant juvenile salmon from a number of estuaries in the Pacific Northwest. The most widespread contaminants were PCBs, DDTs, and PAHs, which were observed in both tissues and stomach contents of chinook and coho salmon from all estuarine sampling sites, as well as in chinook salmon from local hatcheries. Although additional organochlorine pesticides (chlordanes, lindane, hexachlorobenzene, dieldrin, aldrin and mirex) were also detected in salmon tissues or stomach contents, the measured concentrations were relatively low. Like earlier studies in Puget Sound, the present study highlights the importance of the estuary as a source of exposure to chemical contaminants, especially for juvenile chinook salmon. The observation of elevated contaminant concentrations in stomach contents of salmon from sites in several estuaries indicates that fish are being exposed to these contaminants during estuarine residence through their

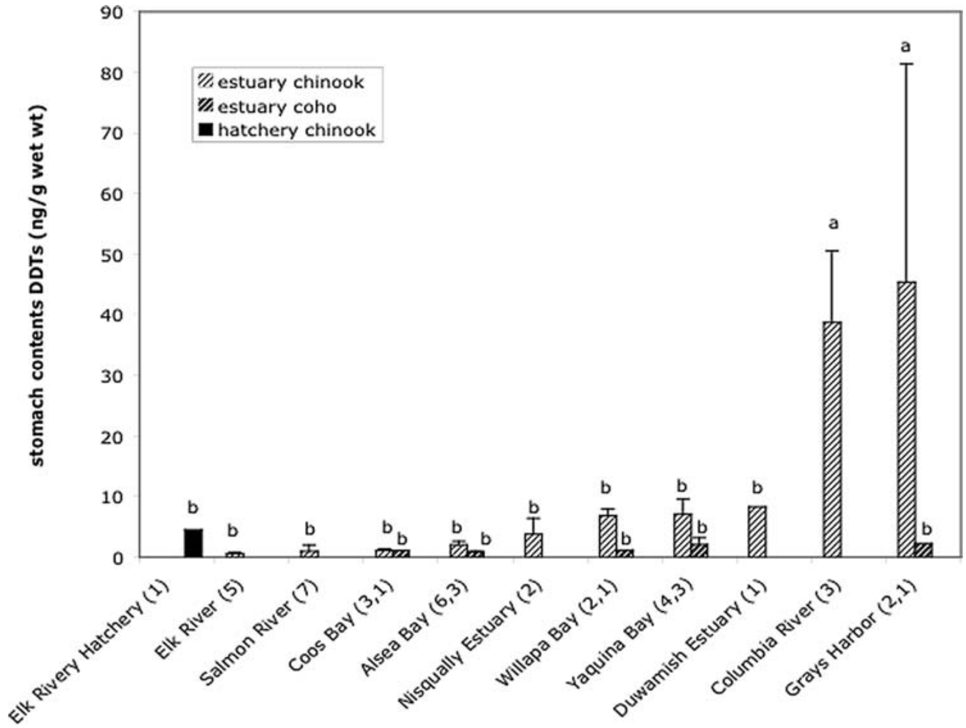

Fig. 11 Mean concentrations of ΣDDTs (ng/g ww, ± SE) in stomach contents of juvenile chinook and coho salmon from Pacific Northwest estuaries and juvenile chinook salmon from Elk River hatchery. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group. Measurements with different letters are significantly different (ANOVA, $p < 0.05$)

prey. The hypothesis that this could be an important source of uptake is further supported by the significant correlations between concentrations of PCBs and DDTs in stomach contents and whole bodies of juvenile chinook salmon, and between PAHs in stomach contents and PAH metabolites in bile. Contaminants in the water column, and in suspended particulate material, are also potential sources of exposure, although they were not measured in this study. Depending on their origin, chinook and coho salmon from some populations could also be taking up certain contaminants through the water column or the diet in freshwater before entering the estuary. This is especially true if they are passing through urbanized watersheds. However, the potential contribution of contaminants in freshwater habitats to juvenile salmon body burdens cannot be evaluated based on the samples collected in the present study.

4.1 Species differences in contaminant uptake

Of the two species we examined, chinook salmon exhibited the highest degree of uptake and accumulation of contaminants. On both a lipid weight and a wet weight basis, contaminant concentrations in whole bodies of chinook salmon were significantly higher than in coho salmon sampled from the same sites, with levels typically 2–5 times as great in chinook than in coho salmon collected at the same sites. Concentrations of contaminants in chinook salmon stomach contents tended to be higher as well, although the difference was less marked. Additionally, correlations between contaminant body burdens and contaminant concentrations in stomach contents were stronger in chinook than in coho salmon.

These findings are consistent with results of other studies on chinook and coho salmon in the Great Lakes (Manchester-Neesvig *et al.*, 2001; Jackson *et al.*, 2001; Rohrer *et al.*, 1982), and are likely related to differences in life history and habitat use, as well as diet and metabolism. Assuming that the estuary is an important source of contaminants for outmigrant salmonids, these differences are consistent with the more prolonged period of estuarine residence in chinook salmon. Of the five species of Pacific salmon, chinook salmon

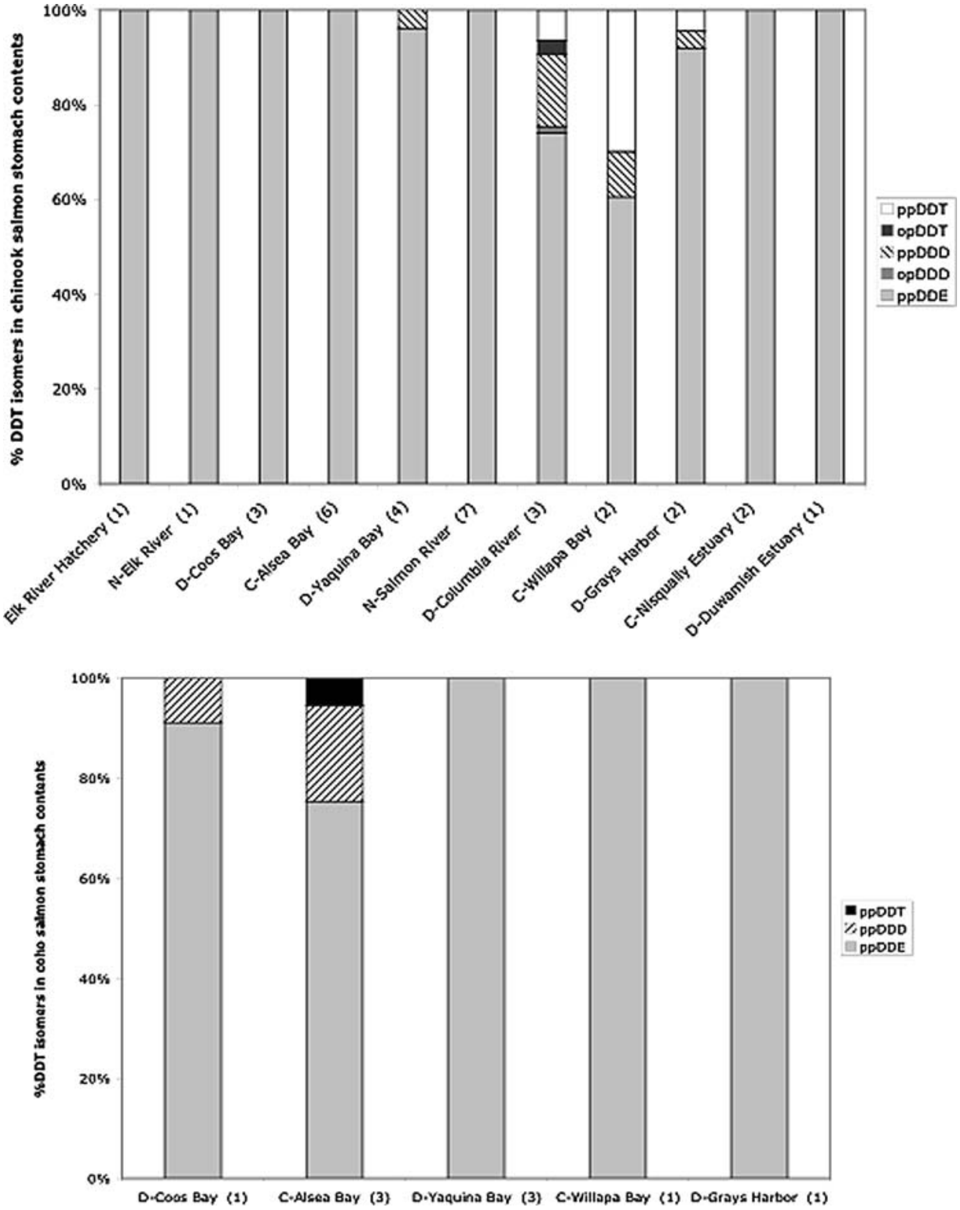

Fig. 12 Proportions of different DDTs in composite stomach contents samples of juvenile chinook and coho salmon collected from Pacific Northwest Estuaries. N = natural estuary; C = conservation estuary; S = shallow draft estuary; D = deep draft estuary. Numbers in parentheses indicate number of composite samples (10–15 fish each) analyzed per site or group

are most dependent upon estuaries during the early stages of their life cycle (Healey, 1982; 1991; Healey and Prince, 1995), typically residing in estuaries for one to two months (Simenstead *et al*., 1982), but in some cases for up to 6 months (Healey, 1982; Reimers, 1973; Levy and Northcote, 1982; Simenstad *et al*., 1982). Outmigrant juvenile coho, on the other hand, are much less estuarine-dependent, typically passing through the estuary within a few days (Moser *et al*., 1991; McMahon and Holtby, 1992; Magnusson, 2003; Duffy *et al*., 2005). Increased bioaccumulation in chinook salmon may also indicate that they are feeding at a higher trophic level than coho salmon, which would be supported by the generally higher concentrations of PCBs and DDTs in stomach contents of chinook salmon in comparison with levels in stomach contents of coho salmon collected from the same sites. This is consistent with dietary studies showing that,

while there is considerable overlap in the diet of juvenile coho and chinook salmon, coho tend to consume a lower proportion of juvenile and larval fish and a higher proportion of invertebrates than chinook (Schabetsberger *et al*., 2003; Brodeur and Pearcy, 1990).

4.2 Site-related differences in contaminant body burdens

Although contaminant concentrations in coho salmon showed no strong spatial trends, in chinook salmon there were marked intersite differences in contaminant concentrations in tissues and stomach contents, with highest exposure levels in the industrial and urbanized estuaries. Concentrations of PCBs were highest in samples from the Duwamish Estuary, and were similar to or somewhat lower than concentrations reported in earlier Puget Sound studies at this location (Stein *et al*., 1995; Varanasi *et al*., 1993; Meador *et al*., 2002). Total PCB concentrations 2 to 3 times higher than those reported in this study have been measured in juvenile chinook collected from heavily contaminated Duwamish Estuary sites (Varanasi *et al*., 1993; Meador *et al*., 2002). The somewhat lower concentrations of PCBs observed in juvenile salmon sampled in the present study may be due to differences in sampling location, or because sampling occurred early in the season, when juvenile salmon may have only recently entered the estuary (Bottom *et al*., 2005). The lower concentrations may also be reflective of a low proportion of hatchery fish in this sample. Such differences in contaminant concentrations between wild and hatchery-released fish have been noted in other studies (Meador *et al*., 2002). In addition to Duwamish chinook, concentrations of PCBs were also relatively high in chinook salmon from the Columbia River and Yaquina Bay.

Interestingly, PCB concentrations in the juvenile chinook salmon we sampled were quite similar to concentrations reported in returning adult chinook salmon from Washington State (Missildine *et al*., 2005). Mean concentrations of PCBs in adult chinook ranged from 48–50 ng/g ww in salmon returning to Puget Sound hatcheries (Deschutes and Issaquah), and from 15–29 ng/g ww in salmon returning to coastal hatcheries (Makah and Quinault). Although it is unlikely that exposures occurring in the juvenile stage make a major contribution to adult contaminant body burdens (O'Neill *et al*., 1998), these data do suggest consistent exposure at multiple life stages for salmon from urban estuaries.

Concentrations of DDTs were especially high in juvenile chinook salmon from the Lower Columbia River and in the Nisqually Estuary in Puget Sound. The high DDT concentrations in Columbia River chinook are consistent with elevated DDT concentrations observed in other resident marine and freshwater fish from the Columbia River in earlier studies by EPA, NOAA, and USGS, and the States of Washington and Oregon (USEPA, 2000; Tetra-Tech Inc., 1993, 1994, 1996; LCREP, 1999; Brown *et al*., 1998; Foster *et al*., 2001a,b). As in most environmental samples, DDT breakdown products, especially p,p'-DDE, predominated in coho and chinook salmon body and stomach contents samples. However, p,p'-DDT and o,p'-DDT were also detected in samples from some sites, particularly chinook salmon from the Columbia River and Yaquina Bay, and coho salmon from Willapa Bay. The presence of these parent compounds suggests that there may be fresher sources of DDT in these areas, although the half-lives of p,p'- and o,p'-DDT in soils can be quite variable (ATSDR, 2002).

Concentrations of PAHs were especially high in stomach contents of fish from the Duwamish Estuary, Willapa Bay, Grays Harbor and Yaquina Bay, although very high concentrations of PAH metabolites in bile (i.e., >1000 ng/g bile for FACs-BaP and $>200{,}000$ ng/g bile for FACs-PHN) were observed only in fish from the Duwamish Estuary. In fish from more pristine estuaries such as Alsea Bay, Salmon River, Elk River, and Tillamook, PAH concentrations were lower than any of those previously reported in Puget Sound (Stein *et al*., 1995; Varanasi *et al*., 1993; McCain *et al*., 1990). High molecular weight AHs, which originate primarily from combustion products (Varanasi *et al*., 1992; MacDonald and Crecelius, 1994), accounted for a higher proportion of total AHs in stomach contents of fish from the Duwamish Estuary, Willapa Bay, Grays Harbor and Yaquina Bay, than in fish from other estuaries. This suggests that atmospheric emissions from incineration and automobile emissions may be major contamination sources in these areas, as well as releases from industries that generate high molecular weight PAHs (e.g., aluminum smelters, oil refineries, creosote plants; Varanasi *et al*., 1992; MacDonald and Crecelius, 1994). The predominance of LAHs, which are primarily associated with petroleum products (Varanasi *et al*., 1992; MacDonald and Crecelius, 1994), in stomach contents of salmon from Alsea Bay, Coos Bay, Nisqually, Salmon River, the Columbia River, and Elk River, suggests that PAHs in these areas come mainly from releases of fuel oil, crude oil, and related materials into the environment.

Ratios of ΣDDT/ΣPCB varied from site to site, indicating differences in contaminant profiles among different groups of fish. For example, the ΣDDT/ΣPCB ratio in bodies of salmon from the Columbia Estuary site (∼1.1) was higher than in juvenile chinook salmon the other estuarine sites, suggesting particularly high uptake of DDTs from the environment at this site. Fish from the Duwamish Estuary, the other hand, had one of the lowest DDT/PCB ratios, reflecting the very high concentrations of PCBs in fish from this site.

4.3 Contaminants in hatchery salmon

Measurable concentrations of PCBs and DDTs were also present in bodies of juvenile chinook salmon sampled directly from Pacific Northwest hatcheries. On a wet weight basis, concentrations of both PCBs and DDTs in hatchery chinook were relatively high, comparable to those in juvenile chinook from the more contaminated estuarine sites. However, as the lipid content of hatchery fish was also quite high (8% as compared to 1–3% in estuarine fish), when PCB and DDT body burdens were calculated on a lipid weight basis, concentrations in hatchery chinook were relatively low in comparison to levels in chinook from urban and industrialized estuaries. In stomach contents of juvenile hatchery chinook, levels of PAHs, PCBs, DDTs, were also relatively low, similar to concentrations in rural estuaries such as Elk River and Alsea Bay. This suggests that elevated contaminant concentrations in the hatchery fish we sampled are due not so much to high concentrations of contaminants in feed, but to the high body fat levels in hatchery reared juveniles that facilitate the uptake of lipid soluble contaminants. It is uncertain, though, whether the Elk River Hatchery sample is representative of feed from other sampled hatcheries, or of feeds in current use.

Chemical contaminants, especially PCBs, have been detected in hatchery fish and feed and in farmed fish in several other studies (Easton *et al.*, 2002; Parkins, 2003; Karl *et al.*, 2003; Hites *et al.*, 2004). Available data suggest that the problem is widespread, and also that contaminant concentrations in different lots of feed and in fish from different hatcheries are highly variable. Concentrations of PCBs in juvenile salmon from the Pacific Northwest hatcheries sampled in this study were similar to mean levels (∼50 ng/g ww) reported by Easton *et al.* (2002) and Hites *et al.* (2004) in farmed salmon. However, PCB concentrations in commercial feed analyzed by Easton *et al.* (2002) and Hites *et al.* (2004) were generally higher than PCB concentrations in stomach contents of Elk River Hatchery salmon, with a number of samples in the 30–90 ng/g ww range.

In the hatchery chinook we analyzed, the DDT isomers *p,p′*-DDT and *o,p′*-DDT made up a substantial proportion of DDTs present. This appears to be common in farmed and hatchery fish, and may indicate use of oils or fish meals from sources where there was relatively recent usage of DDTs (Jacobs *et al.*, 2002).

The observation of chemical contaminants in prerelease hatchery fish is likely to be a concern for the management of these animals. If contaminant body burdens are already moderate to high when fish leave the hatchery, they have an increased risk of reaching exposure concentrations during estuarine residence that could significantly reduce their likelihood of survival. Moreover, contaminated salmon may be a significant source of toxicants in the environment and in the food chain (Kreummel *et al.*, 2003). This represents a hazard for birds and other piscivorous wildlife. More comprehensive sampling of fish and feed from hatcheries is needed to determine the extent of this problem in the Pacific Northwest.

4.4 Potential health effects of contaminants on salmon

For some contaminants, exposure levels in juvenile salmon from selected sites are approaching concentrations that could affect their health and survival. Indeed, adverse health effects have been observed in juvenile salmon from the Duwamish Estuary, which is contaminated with PAHs and PCBs. Fish from this area showed immunosuppression, reduced disease resistance and decreased growth rates (Arkoosh *et al.*, 1991, 1994, 1998, 2001; Varanasi *et al.*, 1993; Casillas *et al.*, 1995, 1998), as well as biochemical alterations such as DNA damage (i.e., PAH-DNA adducts in liver) and induction of cytochrome P4501A (CYP1A), an enzyme that metabolizes selected contaminants including PAHs, dioxins and furans, and dioxin-like PCB congeners (Stein *et al.*, 1995; McCain *et al.*, 1990; Varanasi *et al.*, 1993; Collier *et al.*, 1998; Stehr *et al.*, 2000). These biochemical alterations are not necessarily indicative of adverse health effects in themselves, but are associated with disease conditions including reproductive and developmental abnormalities and liver disease (Williams *et al.*, 1998; Whyte *et al.*, 2000; Myers *et al.*, 2003). Fish from several sites sampled in the present study (Grays Harbor, Yaquina Bay, the Columbia River) had concentrations of PCBs, PAHs or both in tissues or stomach contents that were comparable to those found in Duwamish Estuary fish, suggesting that they may also be at risk for the types of adverse health effects documented in fish from that Puget Sound site. The possibility of increased disease-induced mortality is increased by recent finding of widespread occurrence of potentially lethal parasites and pathogens in juvenile chinook and coho salmon from the estuaries sampled in this study (Arkoosh *et al.*, 2004).

The potential for health risks in Pacific Northwest salmon can also be evaluated by comparing measured tissue contaminant concentrations against established effects thresholds. For PCBs, Meador *et al.* (2002) estimated a critical body residue of 2400 ng/g lipid for protection against 95% of effects ranging from enzyme induction to mortality, based on a range of sublethal effects observed in salmonids in peer-reviewed studies conducted by NMFS and other researchers. Mean PCB body burdens in juvenile salmon analyzed in this study were near or above 2400 ng/g lw in fish from three sampling sites, the Columbia River, the Duwamish Estuary, and Willapa Bay. These findings suggest that a significant portion of outmigrant juvenile chinook salmon from these sites may be at risk of some type of health impairment due to PCB exposure.

A threshold concentration for the impact of DDTs on listed salmon has not been systematically determined, unlike the PCBs (Meador *et al.*, 2002). Most reported effects in salmonids are associated with whole body tissue total DDT concentrations at or above 500 ng/g ww (Allison *et al.*, 1963; Burdick *et al.*, 1964; Buhler *et al.*, 1969; Johnson and Pecor, 1969; Peterson, 1976; Poels *et al.*, 1980), or about 5000 ng/g lipid, assuming that the test fish had a lipid content of around 10%, which is typical of laboratory-reared salmonids (Meador *et al.*, 2002). A number of recent studies suggest that certain DDT isomers, such as *o,p′*-DDT and *o,p′*-DDE, have estrogenic activity, and may have endocrine-disrupting or immunotoxic effects (Donohoe and Curtis, 1996; Arukwe *et al.*, 1998; Celius and Walther, 1998; Khan and Thomas, 1998; Christiansen *et al.*, 2000; Zaroogian *et al.*, 2001; Milston *et al.*, 2003; Papoulias *et al.*, 2003). However, measured or estimated body burdens associated with these effects are typically in the 10–20 ng/g ww or 100–200 ng/g lipid range or above. Lipid-adjusted concentrations of total DDTs and *o,p′*-isomers of DDTs approached these concentrations in some fish from the Columbia River, but DDT body burdens typically found in estuarine chinook and coho salmon were substantially lower. This suggests that, by themselves, body burdens of DDTs would be unlikely to cause adverse health effects in most Pacific Northwest juvenile salmon. However, DDTs do not occur in isolation in Pacific Northwest estuaries, but are present with a variety of other contaminants. Estrogenic DDT metabolites, for example, even at low concentrations, could act in concert with other estrogenic contaminants (e.g., plasticizers, pharmaceuticals, and surfactants) to alter reproductive processes or other physiological functions. In fact, some field studies have reported effect thresholds for DDTs lower than those observed in laboratory exposure studies [e.g., maternal muscle concentrations of 25–30 ng/g ww for increased yolk sac fry mortality in Baltic salmon; Vuorinen *et al.* (1997)], possibly because of the presence of other contaminants, as well as lower lipid concentrations in wild fish. More work is needed to understand the potential cumulative effects of DDTs and other contaminants present in salmon habitats.

Exposure to PAHs may also contribute to health risks in juvenile chinook salmon from some of the sampling sites. In juvenile chinook salmon from Puget Sound sites where immunosuppression and other health effects have been observed (Arkoosh *et al.*, 1991, 1994, 1998, 2001; Varanasi *et al.*, 1993; Stein *et al.*, 1995; Casillas *et al.*, 1995, 1998; Stehr *et al.*, 2000), concentrations of total PAHs in stomach contents of these fish were in the 1,200 to 8,000 ng/g ww range for ΣLAHs and in the 2,000 to 6,000 ng/g ww range for ΣHAHs, or 4,000 to 15,000 ng/g ww for total PAHs (Stein *et al.*, 1995; Varanasi *et al.*, 1993; Stehr *et al.*, 2000). In the present study, PAH concentrations in this range were detected once again in chinook salmon from the Duwamish Estuary, suggesting a potential for health risks to fish from this site. Concentrations of ΣHAHs were also surprisingly high in stomach contents of chinook salmon from Willapa Bay, but this was not reflected in bile metabolite levels of fish from this site. Additional sampling may be needed to determine if there is consistent exposure to PAHs in Willapa Bay salmon.

In laboratory feeding studies where fish were exposed to PAHs alone, reported effect concentrations are somewhat higher than levels of PAHs measured in stomach contents of salmon from sites in where biological effects have been reported in the field, or PAH levels measured in the present study. Meador *et al.* (2005) found physiological changes in juvenile chinook exposed to 120 ppm total PAHs dry wt, or about 25,000 ng/g ww, while Bravo *et al.* (2005) observed immunosuppression, CYP1A induction and DNA damage in rainbow trout exposed to concentrations of 40,000 ng/g ww PAH in diet. Reported no effect doses for immunosuppressive and other physiological effects are in the 8,000–16,000 ng/g ww range (Palm *et al.*, 2004; Meador *et al.*, 2005). Total PAH concentrations in stomach contents of juvenile chinook collected from the Duwamish Estuary and Willapa Bay as part of this study are similar, and thus might be considered as being close to a threshold effect level. Moreover, PAHs may contribute to immunosuppressive or growth-altering impacts of other contaminants in environmental mixtures, even if they are below toxicity thresholds when considered alone (e.g., see Loge *et al.* (2005).

4.5 Trophic transfer and health effects on wildlife

Even if levels of bioaccumulative compounds such as DDTs and PCBs are not sufficient to cause direct effects on juvenile salmonids, they may represent a hazard to fish-eating predators through bioaccumulation and bioconcentration. The U.S. Fish and Wildlife Service (2004) estimated a no-observable adverse effects level (NOAEL) for impacts of fish prey on bald eagles of 60 ng/g ww for PCBs and 40 ng/g ww for DDTs, while Nendza *et al.* (1997) estimated a ΣDDTs NOAEL of 22–50 ng/g ww in fish tissue for impacts of related to bioaccumulation and bioconcentration of DDTs in estuarine systems. Juvenile chinook salmon sampled in this study from the Columbia River, the Duwamish Estuary, and the Nisqually Estuary had whole body DDT concentrations in the 20–50 ng/g ww range, and chinook salmon from the Duwamish Estuary had PCB concentrations above 60 ng/g ww, suggesting these fish may pose a hazard to fish-eating wildlife. Indeed, there is considerable evidence of bioconcentration of DDTs in birds and other wildlife that use the Columbia River, resulting in body burdens high enough to cause reproductive problems (Anthony *et al.*, 1993; USFWS, 1999, 2004; Thomas and Anthony, 2003; Henny *et al.*, 2003; Buck *et al.*, 2005).

4.6 Summary

Overall, the results of this study indicate significant exposure to PCBs, DDTs, and PAHs in outmigrant juvenile chinook salmon from several Pacific Northwest estuaries. Contaminant concentrations were generally highest in stomach contents and tissues of salmon from the deep draft estuaries, with the highest levels of urban and industrial development (i.e., the Duwamish Estuary, the Columbia River, Yaquina Bay, Coos Bay and Grays Harbor), and lowest in the natural estuaries (Elk River and Salmon River), which are largely undeveloped. However, relatively high concentrations of contaminants were detected in juvenile chinook from some of the conservation estuaries (Nisqually Estuary, Skokomish Estuary, Willapa Bay, and Alsea Bay), where land use is primarily agricultural. For example, concentrations of DDTs in salmon from the Nisqually Estuary were among the highest observed in this survey. For juvenile chinook salmon from the Duwamish Estuary, the Columbia River, and Yaquina Bay, whole body PCBs were within the range where they could potentially affect fish health and survival. In juvenile coho salmon, on the other hand, contaminant concentrations were relatively low, below estimated biological effects thresholds, and showed minimal variation from site to site. Juvenile chinook salmon are likely absorbing some contamination during estuarine residence through their prey, as PCBs, PAHs, and DDTs were consistently present in stomach contents, and PCBs and DDTs were significantly correlated with contaminant body burdens in fish from the same sites. Hatchery chinook also showed evidence of contaminant uptake. Although contaminant concentrations were not especially high in stomach contents of fish from the hatchery we tested, body burdens were elevated, in part because of the high lipid content of the fish. More research is needed to document exposure and associated effects of chemical contaminants on endangered Pacific Northwest salmon, but the available data show clearly that tissue burdens of some classes of contaminants are within the range where they could potentially affect survival and productivity of listed stocks or have adverse effects on the ecosystem of which salmon are a part.

Acknowledgements We would like to thank Kari Kopenan, Susan Hinton, O. Paul Olson, Dan Lomax, Sean Sol, Maryjean L. Willis, Paul Bentley, George McCabe, Larry Hufnagle, Gladys Yanagida, Dan Kamikawa, Robert Snider, Natalie Keirstead, Todd Sandell, Todd Bridgeman, Tonya Ramsey, Mark Myers, Ethan Clemons, and Joy Evered for assistance with fish collection and necropsy; Daryle Boyd, Donald Brown, Catherine Sloan, Karen Tilbury, Richard Boyer, Doug Burrows, Ron Pearce, and Margaret Krahn for advice and assistance with chemical analyses, and James Meador and Carla Stehr for helpful comments on earlier versions of this manuscript. Mr. John Knapp and family and Mr. Robert McKenzie and family provided access to the Elk River through their private properties.

Circular A-4

September 17, 2003

TO THE HEADS OF EXECUTIVE AGENCIES AND ESTABLISHMENTS

Subject: Regulatory Analysis

This Circular provides the Office of Management and Budget's (OMB's) guidance to Federal agencies on the development of regulatory analysis as required under Section 6(a)(3)(c) of Executive Order12866, "Regulatory Planning and Review," the Regulatory Right-to-Know Act, and a variety of related authorities. The Circular also provides guidance to agencies on the regulatory accounting statements that are required under the Regulatory Right-to-Know Act.

This Circular refines OMB's "best practices" document of 1996 (http://www.whitehouse.gov/omb/inforeg/riaguide.html), which was issued as a guidance in 2000 (http://www.whitehouse.gov/omb/memoranda/m00-08.pdf), and reaffirmed in 2001 (http://www.whitehouse.gov/omb/memoranda/m01-23.html). It replaces both the 1996 "best practices" and the 2000 guidance.

In developing this Circular, OMB first developed a draft that was subject to public comment, interagency review, and peer review. Peer reviewers included Cass Sunstein, University of Chicago; Lester Lave, Carnegie Mellon University; Milton C. Weinstein and James K. Hammitt of the Harvard School of Public Health; Kerry Smith, North Carolina State University; Jonathan Weiner, Duke University Law School; Douglas K. Owens, Stanford University; and W. Kip Viscusi, Harvard Law School. Although these individuals submitted comments, OMB is solely responsible for the final content of this Circular.

A. Introduction

This Circular is designed to assist analysts in the regulatory agencies by defining good regulatory analysis – called either "regulatory analysis" or "analysis" for brevity – and standardizing the way benefits and costs of Federal regulatory actions are measured and reported. Executive Order 12866 requires agencies to conduct a regulatory analysis for economically significant regulatory actions as defined by Section 3(f)(1). This requirement applies to rulemakings that rescind or modify existing rules as well as to rulemakings that establish new requirements.

The Need for Analysis of Proposed Regulatory Actions[1]

Regulatory analysis is a tool regulatory agencies use to anticipate and evaluate the likely consequences of rules. It provides a formal way of organizing the evidence on the key effects –

---

[1] We use the term "proposed" to refer to any regulatory actions under consideration regardless of the stage of the regulatory process.

good and bad – of the various alternatives that should be considered in developing regulations. The motivation is to (1) learn if the benefits of an action are likely to justify the costs or (2) discover which of various possible alternatives would be the most cost-effective.

A good regulatory analysis is designed to inform the public and other parts of the Government (as well as the agency conducting the analysis) of the effects of alternative actions. Regulatory analysis sometimes will show that a proposed action is misguided, but it can also demonstrate that well-conceived actions are reasonable and justified.

Benefit-cost analysis is a primary tool used for regulatory analysis.[2] Where all benefits and costs can be quantified and expressed in monetary units, benefit-cost analysis provides decision makers with a clear indication of the most efficient alternative, that is, the alternative that generates the largest net benefits to society (ignoring distributional effects). This is useful information for decision makers and the public to receive, even when economic efficiency is not the only or the overriding public policy objective.

It will not always be possible to express in monetary units all of the important benefits and costs. When it is not, the most efficient alternative will not necessarily be the one with the largest quantified and monetized net-benefit estimate. In such cases, you should exercise professional judgment in determining how important the non-quantified benefits or costs may be in the context of the overall analysis. If the non-quantified benefits and costs are likely to be important, you should carry out a "threshold" analysis to evaluate their significance. Threshold or "break-even" analysis answers the question, "How small could the value of the non-quantified benefits be (or how large would the value of the non-quantified costs need to be) before the rule would yield zero net benefits?" In addition to threshold analysis you should indicate, where possible, which non-quantified effects are most important and why.

Key Elements of a Regulatory Analysis

A good regulatory analysis should include the following three basic elements: (1) a statement of the need for the proposed action, (2) an examination of alternative approaches, and (3) an evaluation of the benefits and costs—quantitative and qualitative—of the proposed action and the main alternatives identified by the analysis.

To evaluate properly the benefits and costs of regulations and their alternatives, you will need to do the following:

- Explain how the actions required by the rule are linked to the expected benefits. For example, indicate how additional safety equipment will reduce safety risks. A similar analysis should be done for each of the alternatives.
- Identify a baseline. Benefits and costs are defined in comparison with a clearly stated alternative. This normally will be a "no action" baseline: what the world will be like if the proposed rule is not adopted. Comparisons to a "next best" alternative are also especially useful.

---

[2] See Mishan EJ (1994), *Cost-Benefit Analysis*, fourth edition, Routledge, New York.

- Identify the expected undesirable side-effects and ancillary benefits of the proposed regulatory action and the alternatives. These should be added to the direct benefits and costs as appropriate.

With this information, you should be able to assess quantitatively the benefits and costs of the proposed rule and its alternatives. A complete regulatory analysis includes a discussion of non-quantified as well as quantified benefits and costs. A non-quantified outcome is a benefit or cost that has not been quantified or monetized in the analysis. When there are important non-monetary values at stake, you should also identify them in your analysis so policymakers can compare them with the monetary benefits and costs. When your analysis is complete, you should present a summary of the benefit and cost estimates for each alternative, including the qualitative and non-monetized factors affected by the rule, so that readers can evaluate them.

As you design, execute, and write your regulatory analysis, you should seek out the opinions of those who will be affected by the regulation as well as the views of those individuals and organizations who may not be affected but have special knowledge or insight into the regulatory issues. Consultation can be useful in ensuring that your analysis addresses all of the relevant issues and that you have access to all pertinent data. Early consultation can be especially helpful. You should not limit consultation to the final stages of your analytical efforts.

You will find that you cannot conduct a good regulatory analysis according to a formula. Conducting high-quality analysis requires competent professional judgment. Different regulations may call for different emphases in the analysis, depending on the nature and complexity of the regulatory issues and the sensitivity of the benefit and cost estimates to the key assumptions.

A good analysis is transparent. It should be possible for a qualified third party reading the report to see clearly how you arrived at your estimates and conclusions. For transparency's sake, you should state in your report what assumptions were used, such as the time horizon for the analysis and the discount rates applied to future benefits and costs. It is usually necessary to provide a sensitivity analysis to reveal whether, and to what extent, the results of the analysis are sensitive to plausible changes in the main assumptions and numeric inputs.

A good analysis provides specific references to all sources of data, appendices with documentation of models (where necessary), and the results of formal sensitivity and other uncertainty analyses. Your analysis should also have an executive summary, including a standardized accounting statement.

B. The Need for Federal Regulatory Action

Before recommending Federal regulatory action, an agency must demonstrate that the proposed action is necessary. If the regulatory intervention results from a statutory or judicial directive, you should describe the specific authority for your action, the extent of discretion available to you, and the regulatory instruments you might use. Executive Order 12866 states that "Federal agencies should promulgate only such regulations as are required by law, are necessary to interpret the law, or are made necessary by compelling need, such as material failures of private markets to protect or improve the health and safety of the public, the environment, or the well being of the American people ... ."

Executive Order 12866 also states that "Each agency shall identify the problem that it intends to address (including, where applicable, the failures of private markets or public institutions that warrant new agency action) as well as assess the significance of that problem." Thus, you should try to explain whether the action is intended to address a significant market failure or to meet some other compelling public need such as improving governmental processes or promoting intangible values such as distributional fairness or privacy. If the regulation is designed to correct a significant market failure, you should describe the failure both qualitatively and (where feasible) quantitatively. You should show that a government intervention is likely to do more good than harm. For other interventions, you should also provide a demonstration of compelling social purpose and the likelihood of effective action. Although intangible rationales do not need to be quantified, the analysis should present and evaluate the strengths and limitations of the relevant arguments for these intangible values.

Market Failure or Other Social Purpose

The major types of market failure include: externality, market power, and inadequate or asymmetric information. Correcting market failures is a reason for regulation, but it is not the only reason. Other possible justifications include improving the functioning of government, removing distributional unfairness, or promoting privacy and personal freedom.

1. Externality, common property resource and public good

An externality occurs when one party's actions impose uncompensated benefits or costs on another party. Environmental problems are a classic case of externality. For example, the smoke from a factory may adversely affect the health of local residents while soiling the property in nearby neighborhoods. If bargaining were costless and all property rights were well defined, people would eliminate externalities through bargaining without the need for government regulation.[3] From this perspective, externalities arise from high transactions costs and/or poorly defined property rights that prevent people from reaching efficient outcomes through market transactions.

Resources that may become congested or overused, such as fisheries or the broadcast spectrum, represent common property resources. "Public goods," such as defense or basic scientific research, are goods where provision of the good to some individuals cannot occur without providing the same level of benefits free of charge to other individuals.

2. Market Power

Firms exercise market power when they reduce output below what would be offered in a competitive industry in order to obtain higher prices. They may exercise market power collectively or unilaterally. Government action can be a source of market power, such as when regulatory actions exclude low-cost imports. Generally, regulations that increase market power

---

[3] See Coase RH (1960), *Journal of Law and Economics*, 3, 1-44.

for selected entities should be avoided. However, there are some circumstances in which government may choose to validate a monopoly. If a market can be served at lowest cost only when production is limited to a single producer – local gas and electricity distribution services, for example – a natural monopoly is said to exist. In such cases, the government may choose to approve the monopoly and to regulate its prices and/or production decisions. Nevertheless, you should keep in mind that technological advances often affect economies of scale. This can, in turn, transform what was once considered a natural monopoly into a market where competition can flourish.

3. Inadequate or Asymmetric Information

Market failures may also result from inadequate or asymmetric information. Because information, like other goods, is costly to produce and disseminate, your evaluation will need to do more than demonstrate the possible existence of incomplete or asymmetric information. Even though the market may supply less than the full amount of information, the amount it does supply may be reasonably adequate and therefore not require government regulation. Sellers have an incentive to provide information through advertising that can increase sales by highlighting distinctive characteristics of their products. Buyers may also obtain reasonably adequate information about product characteristics through other channels, such as a seller offering a warranty or a third party providing information.

Even when adequate information is available, people can make mistakes by processing it poorly. Poor information-processing often occurs in cases of low probability, high-consequence events, but it is not limited to such situations. For instance, people sometimes rely on mental rules-of-thumb that produce errors. If they have a clear mental image of an incident which makes it cognitively "available," they might overstate the probability that it will occur. Individuals sometimes process information in a biased manner, by being too optimistic or pessimistic, without taking sufficient account of the fact that the outcome is exceedingly unlikely to occur. When mistakes in information processing occur, markets may overreact. When it is time-consuming or costly for consumers to evaluate complex information about products or services (e.g., medical therapies), they may expect government to ensure that minimum quality standards are met. However, the mere possibility of poor information processing is not enough to justify regulation. If you think there is a problem of information processing that needs to be addressed, it should be carefully documented.

4. Other Social Purposes

There are justifications for regulations in addition to correcting market failures. A regulation may be appropriate when you have a clearly identified measure that can make government operate more efficiently. In addition, Congress establishes some regulatory programs to redistribute resources to select groups. Such regulations should be examined to ensure that they are both effective and cost-effective. Congress also authorizes some regulations to prohibit discrimination that conflicts with generally accepted norms within our society. Rulemaking may also be appropriate to protect privacy, permit more personal freedom or promote other democratic aspirations.

Showing That Regulation at the Federal Level Is the Best Way to Solve the Problem

Even where a market failure clearly exists, you should consider other means of dealing with the failure before turning to Federal regulation. Alternatives to Federal regulation include antitrust enforcement, consumer-initiated litigation in the product liability system, or administrative compensation systems.

In assessing whether Federal regulation is the best solution, you should also consider the possibility of regulation at the State or local level. In some cases, the nature of the market failure may itself suggest the most appropriate governmental level of regulation. For example, problems that spill across State lines (such as acid rain whose precursors are transported widely in the atmosphere) are probably best addressed by Federal regulation. More localized problems, including those that are common to many areas, may be more efficiently addressed locally.

The advantages of leaving regulatory issues to State and local authorities can be substantial. If public values and preferences differ by region, those differences can be reflected in varying State and local regulatory policies. Moreover, States and localities can serve as a testing ground for experimentation with alternative regulatory policies. One State can learn from another's experience while local jurisdictions may compete with each other to establish the best regulatory policies. You should examine the proper extent of State and local discretion in your rulemaking context.

A diversity of rules may generate gains for the public as governmental units compete with each other to serve the public, but duplicative regulations can also be costly. Where Federal regulation is clearly appropriate to address interstate commerce issues, you should try to examine whether it would be more efficient to retain or reduce State and local regulation. The local benefits of State regulation may not justify the national costs of a fragmented regulatory system. For example, the increased compliance costs for firms to meet different State and local regulations may exceed any advantages associated with the diversity of State and local regulation. Your analysis should consider the possibility of reducing as well as expanding State and local rulemaking.

The role of Federal regulation in facilitating U.S. participation in global markets should also be considered. Harmonization of U.S. and international rules may require a strong Federal regulatory role. Concerns that new U.S. rules could act as non-tariff barriers to imported goods should be evaluated carefully.

The Presumption Against Economic Regulation

Government actions can be unintentionally harmful, and even useful regulations can impede market efficiency. For this reason, there is a presumption against certain types of regulatory action. In light of both economic theory and actual experience, a particularly demanding burden of proof is required to demonstrate the need for any of the following types of regulations:

- price controls in competitive markets;

- production or sales quotas in competitive markets;
- mandatory uniform quality standards for goods or services if the potential problem can be adequately dealt with through voluntary standards or by disclosing information of the hazard to buyers or users; or
- controls on entry into employment or production, except (a) where indispensable to protect health and safety (e.g., FAA tests for commercial pilots) or (b) to manage the use of common property resources (e.g., fisheries, airwaves, Federal lands, and offshore areas).

C. Alternative Regulatory Approaches

Once you have determined that Federal regulatory action is appropriate, you will need to consider alternative regulatory approaches. Ordinarily, you will be able to eliminate some alternatives through a preliminary analysis, leaving a manageable number of alternatives to be evaluated according to the formal principles of the Executive Order. The number and choice of alternatives selected for detailed analysis is a matter of judgment. There must be some balance between thoroughness and the practical limits on your analytical capacity. With this qualification in mind, you should nevertheless explore modifications of some or all of a regulation's attributes or provisions to identify appropriate alternatives. The following is a list of alternative regulatory actions that you should consider.

Different Choices Defined by Statute

When a statute establishes a specific regulatory requirement and the agency is considering a more stringent standard, you should examine the benefits and costs of reasonable alternatives that reflect the range of the agency's statutory discretion, including the specific statutory requirement.

Different Compliance Dates

The timing of a regulation may also have an important effect on its net benefits. Benefits may vary significantly with different compliance dates where a delay in implementation may result in a substantial loss in future benefits (e.g., a delay in implementation could result in a significant reduction in spawning stock and jeopardize a fishery). Similarly, the cost of a regulation may vary substantially with different compliance dates for an industry that requires a year or more to plan its production runs. In this instance, a regulation that provides sufficient lead time is likely to achieve its goals at a much lower overall cost than a regulation that is effective immediately.

Different Enforcement Methods

Compliance alternatives for Federal, State, or local enforcement include on-site inspections, periodic reporting, and noncompliance penalties structured to provide the most appropriate incentives. When alternative monitoring and reporting methods vary in their benefits and costs, you should identify the most appropriate enforcement framework. For example, in some circumstances random monitoring or parametric monitoring will be less expensive and nearly as effective as continuous monitoring.

Different Degrees of Stringency

In general, both the benefits and costs associated with a regulation will increase with the level of stringency (although marginal costs generally increase with stringency, whereas marginal benefits may decrease). You should study alternative levels of stringency to understand more fully the relationship between stringency and the size and distribution of benefits and costs among different groups.

Different Requirements for Different Sized Firms

You should consider setting different requirements for large and small firms, basing the requirements on estimated differences in the expected costs of compliance or in the expected benefits. The balance of benefits and costs can shift depending on the size of the firms being regulated. Small firms may find it more costly to comply with regulation, especially if there are large fixed costs required for regulatory compliance. On the other hand, it is not efficient to place a heavier burden on one segment of a regulated industry solely because it can better afford the higher cost. This has the potential to load costs on the most productive firms, costs that are disproportionate to the damages they create. You should also remember that a rule with a significant impact on a substantial number of small entities will trigger the requirements set forth in the Regulatory Flexibility Act. (5 U.S.C. 603(c), 604).

Different Requirements for Different Geographic Regions

Rarely do all regions of the country benefit uniformly from government regulation. It is also unlikely that costs will be uniformly distributed across the country. Where there are significant regional variations in benefits and/or costs, you should consider the possibility of setting different requirements for the different regions.

Performance Standards Rather than Design Standards

Performance standards express requirements in terms of outcomes rather than specifying the means to those ends. They are generally superior to engineering or design standards because performance standards give the regulated parties the flexibility to achieve regulatory objectives in the most cost-effective way. In general, you should take into account both the cost savings to the regulated parties of the greater flexibility and the costs of assuring compliance through monitoring or some other means.

Market-Oriented Approaches Rather than Direct Controls

Market-oriented approaches that use economic incentives should be explored. These alternatives include fees, penalties, subsidies, marketable permits or offsets, changes in liability or property rights (including policies that alter the incentives of insurers and insured parties), and required bonds, insurance or warranties. One example of a market-oriented approach is a program that allows for averaging, banking, and/or trading (ABT) of credits for achieving additional emission reductions beyond the required air emission standards. ABT programs can be extremely valuable in reducing costs or achieving earlier or greater benefits, particularly when the costs of achieving compliance vary across production lines, facilities, or firms. ABT can be allowed on a plant-wide, firm-wide, or region-wide basis rather than vent by vent, provided this does not produce unacceptable local air quality outcomes (such as "hot spots" from local pollution concentration).

Informational Measures Rather than Regulation

If intervention is contemplated to address a market failure that arises from inadequate or asymmetric information, informational remedies will often be preferred. Measures to improve the availability of information include government establishment of a standardized testing and rating system (the use of which could be mandatory or voluntary), mandatory disclosure requirements (e.g., by advertising, labeling, or enclosures), and government provision of information (e.g., by government publications, telephone hotlines, or public interest broadcast announcements). A regulatory measure to improve the availability of information, particularly about the concealed characteristics of products, provides consumers a greater choice than a mandatory product standard or ban.

Specific informational measures should be evaluated in terms of their benefits and costs. Some effects of informational measures are easily overlooked. The costs of a mandatory disclosure requirement for a consumer product will include not only the cost of gathering and communicating the required information, but also the loss of net benefits of any information displaced by the mandated information. The other costs also may include the effect of providing information that is ignored or misinterpreted, and inefficiencies arising from the incentive that mandatory disclosure may give to overinvest in a particular characteristic of a product or service.

Where information on the benefits and costs of alternative informational measures is insufficient to provide a clear choice between them, you should consider the least intrusive informational alternative sufficient to accomplish the regulatory objective. To correct an informational market failure it may be sufficient for government to establish a standardized testing and rating system without mandating its use, because competing firms that score well according to the system should thereby have an incentive to publicize the fact.

D. Analytical Approaches

Both benefit-cost analysis (BCA) and cost-effectiveness analysis (CEA) provide a systematic framework for identifying and evaluating the likely outcomes of alternative regulatory choices. A major rulemaking should be supported by both types of analysis wherever possible. Specifically, you should prepare a CEA for all major rulemakings for which the primary benefits are improved public health and safety to the extent that a valid effectiveness measure can be developed to represent expected health and safety outcomes. You should also perform a BCA for major health and safety rulemakings to the extent that valid monetary values can be assigned to the primary expected health and safety outcomes. In undertaking these analyses, it is important to keep in mind the larger objective of analytical consistency in estimating benefits and costs across regulations and agencies, subject to statutory limitations. Failure to maintain such consistency may prevent achievement of the most risk reduction for a given level of resource expenditure. For all other major rulemakings, you should carry out a BCA. If some of the primary benefit categories cannot be expressed in monetary units, you should also conduct a CEA. In unusual cases where no quantified information on benefits, costs and effectiveness can be produced, the regulatory analysis should present a qualitative discussion of the issues and evidence.

Benefit-Cost Analysis

A distinctive feature of BCA is that both benefits and costs are expressed in monetary units, which allows you to evaluate different regulatory options with a variety of attributes using a common measure.[4] By measuring incremental benefits and costs of successively more stringent regulatory alternatives, you can identify the alternative that maximizes net benefits.

The size of net benefits, the absolute difference between the projected benefits and costs, indicates whether one policy is more efficient than another. The ratio of benefits to costs is not a meaningful indicator of net benefits and should not be used for that purpose. It is well known that considering such ratios alone can yield misleading results.

Even when a benefit or cost cannot be expressed in monetary units, you should still try to measure it in terms of its physical units. If it is not possible to measure the physical units, you should still describe the benefit or cost qualitatively. For more information on describing qualitative information, see the section "*Developing Benefit and Cost Estimates.*"

When important benefits and costs cannot be expressed in monetary units, BCA is less useful, and it can even be misleading, because the calculation of net benefits in such cases does not provide a full evaluation of all relevant benefits and costs.

You should exercise professional judgment in identifying the importance of non-quantified factors and assess as best you can how they might change the ranking of alternatives based on estimated net benefits. If the non-quantified benefits and costs are likely to be important, you should recommend which of the non-quantified factors are of sufficient importance to justify consideration in the regulatory decision. This discussion should also include a clear explanation that support designating these non-quantified factors as important. In this case, you should also consider conducting a threshold analysis to help decision makers and other users of the analysis to understand the potential significance of these factors to the overall analysis.

Cost-Effectiveness Analysis[5]

---

[4] Mishan EJ (1994), *Cost-Benefit Analysis*, fourth edition, Routledge, New York.

[5] For a full discussion of CEA, see Gold, ML, Siegel, JE, Russell, LB, and Weinstein, MC (1996), *Cost Effectiveness in Health and Medicine: The Report of the Panel on Cost-Effectiveness in Health and Medicine*, Oxford University Press, New York.

Cost-effectiveness analysis can provide a rigorous way to identify options that achieve the most effective use of the resources available without requiring monetization of all of relevant benefits or costs. Generally, cost-effectiveness analysis is designed to compare a set of regulatory actions with the same primary outcome (e.g., an increase in the acres of wetlands protected) or multiple outcomes that can be integrated into a single numerical index (e.g., units of health improvement).

Cost-effectiveness results based on averages need to be treated with great care. They suffer from the same drawbacks as benefit-cost ratios. The alternative that exhibits the smallest cost-effectiveness ratio may not be the best option, just as the alternative with the highest benefit-cost ratio is not always the one that maximizes net benefits. Incremental cost-effectiveness analysis (discussed below) can help to avoid mistakes that can occur when policy choices are based on average cost-effectiveness.

CEA can also be misleading when the "effectiveness" measure does not appropriately weight the consequences of the alternatives. For example, when effectiveness is measured in tons of reduced pollutant emissions, cost-effectiveness estimates will be misleading unless the reduced emissions of diverse pollutants result in the same health and environmental benefits.

When you have identified a range of alternatives (e.g., different levels of stringency), you should determine the cost-effectiveness of each option compared with the baseline as well as its incremental cost-effectiveness compared with successively more stringent requirements. Ideally, your CEA would present an array of cost-effectiveness estimates that would allow comparison across different alternatives. However, analyzing all possible combinations is not practical when there are many options (including possible interaction effects). In these cases, you should use your judgment to choose reasonable alternatives for careful consideration.

When constructing and comparing incremental cost-effectiveness ratios, you should be careful to determine whether the various alternatives are mutually exclusive or whether they can be combined. If they can be combined, you should consider which might be favored under different regulatory budget constraints (implicit or explicit). You should also make sure that inferior alternatives identified by the principles of strong and weak dominance are eliminated from consideration.[6]

The value of CEA is enhanced when there is consistency in the analysis across a diverse set of possible regulatory actions. To achieve consistency, you need to carefully construct the two key components of any CEA: the cost and the "effectiveness" or performance measures for the alternative policy options.

With regard to measuring costs, you should be sure to include all the relevant costs to society – whether public or private. Rulemakings may also yield cost savings (e.g., energy savings associated with new technologies). The numerator in the cost-effectiveness ratio should reflect net costs, defined as the gross cost incurred to comply with the requirements (sometimes

---

[6] Gold ML, Siegel JE, Russell LB, and Weinstein MC (1996), *Cost Effectiveness in Health and Medicine: The Report of the Panel on Cost-Effectiveness in Health and Medicine*, Oxford University Press, New York, pp. 284-285.

called “total” costs) minus any cost savings. You should be careful to avoid double-counting effects in both the numerator and the denominator of the cost-effectiveness ratios. For example, it would be incorrect to reduce gross costs by an estimated monetary value on life extension if life-years are already used as the effectiveness measure in the denominator.

In constructing measures of “effectiveness”, final outcomes, such as lives saved or life-years saved, are preferred to measures of intermediate outputs, such as tons of pollution reduced, crashes avoided, or cases of disease avoided. Where the quality of the measured unit varies (e.g., acres of wetlands vary substantially in terms of their ecological benefits), it is important that the measure capture the variability in the value of the selected “outcome” measure. You should provide an explanation of your choice of effectiveness measure.

Where regulation may yield several different beneficial outcomes, a cost-effectiveness comparison becomes more difficult to interpret because there is more than one measure of effectiveness to incorporate in the analysis. To arrive at a single measure you will need to weight the value of disparate benefit categories, but this computation raises some of the same difficulties you will encounter in BCA. If you can assign a reasonable monetary value to all of the regulation’s different benefits, then you should do so. But in this case, you will be doing BCA, not CEA.

When you can estimate the monetary value of *some* but not all of the ancillary benefits of a regulation, but cannot assign a monetary value to the primary measure of effectiveness, you should subtract the monetary estimate of the ancillary benefits from the gross cost estimate to yield an estimated net cost. (This net cost estimate for the rule may turn out to be negative – that is, the monetized benefits exceed the cost of the rule.) If you are unable to estimate the value of some of the ancillary benefits, the cost-effectiveness ratio will be overstated, and this should be acknowledged in your analysis. CEA does not yield an unambiguous choice when there are benefits or costs that have not been incorporated in the net-cost estimates. You also may use CEA to compare regulatory alternatives in cases where the statute specifies the level of benefits to be achieved.

The Effectiveness Metric for Public Health and Safety Rulemakings

When CEA is applied to public health and safety rulemakings, one or more measures of effectiveness must be selected that permits comparison of regulatory alternatives. Agencies currently use a variety of effectiveness measures.

There are relatively simple measures such as the number of lives saved, cases of cancer reduced, and cases of paraplegia prevented. Sometimes these measures account only for mortality information, such as the number of lives saved and the number of years of life saved. There are also more comprehensive, integrated measures of effectiveness such as the number of "equivalent lives" (ELs) saved and the number of "quality-adjusted life years" (QALYs) saved.

The main advantage of the integrated measures of effectiveness is that they account for a rule's impact on morbidity (nonfatal illness, injury, impairment and quality of life) as well as premature death. The inclusion of morbidity effects is important because (a) some illnesses (e.g., asthma) cause more instances of pain and suffering than they do premature death, (b) some population groups are known to experience elevated rates of morbidity (e.g, the elderly and the poor) and thus have a strong interest in morbidity measurement[7], and (c) some regulatory alternatives may be more effective at preventing morbidity than premature death (e.g., some advanced airbag designs may diminish the nonfatal injuries caused by airbag inflation without changing the frequency of fatal injury prevented by airbags).

However, the main drawback of these integrated measures is that they must meet some restrictive assumptions to represent a valid measure of individual preferences.[8] For example, a QALY measure implicitly assumes that the fraction of remaining lifespan an individual would give up for an improvement in health-related quality of life does not depend on the remaining lifespan. Thus, if an individual is willing to give up 10 years of life among 50 remaining years for a given health improvement, he or she would also be willing to give up 1 year of life among 5 remaining years. To the extent that individual preferences deviate from these assumptions, analytic results from CEA using QALYs could differ from analytic results based on willingness-to-pay-measures.[9] Though willingness to pay is generally the preferred economic method for evaluating preferences, the CEA method, as applied in medicine and health, does not evaluate health changes using individual willingness to pay. When performing CEA, you should consider using at least one integrated measure of effectiveness when a rule creates a significant impact on both mortality and morbidity.

When CEA is performed in specific rulemaking contexts, you should be prepared to make appropriate adjustments to ensure fair treatment of all segments of the population. Fairness is important in the choice and execution of effectiveness measures. For example, if QALYs are used to evaluate a lifesaving rule aimed at a population that happens to experience a high rate of disability (i.e., where the rule is not designed to affect the disability), the number of life years saved should not necessarily be diminished simply because the rule saves the lives of people with life-shortening disabilities. Both analytic simplicity and fairness suggest that the estimated number of life years saved for the disabled population should be based on average life expectancy information for the relevant age cohorts. More generally, when numeric adjustments are made for life expectancy or quality of life, analysts should prefer use of population averages rather than information derived from subgroups dominated by a particular demographic or income group.

OMB does not require agencies to use any specific measure of effectiveness. In fact, OMB encourages agencies to report results with multiple measures of effectiveness that offer different insights and perspectives. The regulatory analysis should explain which measures were selected and why, and how they were implemented.

The analytic discretion provided in choice of effectiveness measure will create some inconsistency in how agencies evaluate the same injuries and diseases, and it will be difficult for

OMB and the public to draw meaningful comparisons between rulemakings that employ different effectiveness measures. As a result, agencies should use their web site to provide OMB and the public with the underlying data, including mortality and morbidity data, the age distribution of the affected populations, and the severity and duration of disease conditions and trauma, so that OMB and the public can construct apples-to-apples comparisons between rulemakings that employ different measures.

There are sensitive technical and ethical issues associated with choosing one or more of these integrated measures for use throughout the Federal government. The Institute of Medicine (IOM) may assemble a panel of specialists in cost-effectiveness analysis and bioethics to evaluate the advantages and disadvantages of these different measures and other measures that have been suggested in the academic literature. OMB believes that the IOM guidance will provide Federal agencies and OMB useful insight into how to improve the measurement of effectiveness of public health and safety regulations.

Distributional Effects

Those who bear the costs of a regulation and those who enjoy its benefits often are not the same people. The term “distributional effect” refers to the impact of a regulatory action across the population and economy, divided up in various ways (e.g., income groups, race, sex, industrial sector, geography). Benefits and costs of a regulation may also be distributed unevenly over time, perhaps spanning several generations. Distributional effects may arise through ”transfer payments” that stem from a regulatory action as well. For example, the revenue collected through a fee, surcharge in excess of the cost of services provided, or tax is a transfer payment.

Your regulatory analysis should provide a separate description of distributional effects (i.e., how both benefits and costs are distributed among sub-populations of particular concern) so that decision makers can properly consider them along with the effects on economic efficiency. Executive Order 12866 authorizes this approach. Where distributive effects are thought to be important, the effects of various regulatory alternatives should be described quantitatively to the extent possible, including the magnitude, likelihood, and severity of impacts on particular groups. You should be alert for situations in which regulatory alternatives result in significant changes in treatment or outcomes for different groups. Effects on the distribution of income that are transmitted through changes in market prices can be important, albeit sometimes difficult to assess. Your analysis should also present information on the streams of benefits and costs over time in order to provide a basis for assessing intertemporal distributional consequences, particularly where intergenerational effects are concerned.

E. Identifying and Measuring Benefits and Costs

This Section provides guidelines for your preparation of the benefit and cost estimates required by Executive Order 12866 and the “Regulatory Right-to-Know Act.” The discussions in previous sections will help you identify a workable number of alternatives for consideration in your analysis and an appropriate analytical approach to use.

General Issues

1. Scope of Analysis

Your analysis should focus on benefits and costs that accrue to citizens and residents of the United States. Where you choose to evaluate a regulation that is likely to have effects beyond the borders of the United States, these effects should be reported separately. The time frame for your analysis should cover a period long enough to encompass all the important benefits and costs likely to result from the rule.

2. Developing a Baseline

You need to measure the benefits and costs of a rule against a baseline. This baseline should be the best assessment of the way the world would look absent the proposed action. The choice of an appropriate baseline may require consideration of a wide range of potential factors, including:

- evolution of the market,
- changes in external factors affecting expected benefits and costs,
- changes in regulations promulgated by the agency or other government entities, and
- the degree of compliance by regulated entities with other regulations.

It may be reasonable to forecast that the world absent the regulation will resemble the present. If this is the case, however, your baseline should reflect the future effect of current government programs and policies. For review of an existing regulation, a baseline assuming "no change" in the regulatory program generally provides an appropriate basis for evaluating regulatory alternatives. When more than one baseline is reasonable and the choice of baseline will significantly affect estimated benefits and costs, you should consider measuring benefits and costs against alternative baselines. In doing so you can analyze the effects on benefits and costs of making different assumptions about other agencies' regulations, or the degree of compliance with your own existing rules. In all cases, you must evaluate benefits and costs against the same baseline. You should also discuss the reasonableness of the baselines used in the sensitivity analyses. For each baseline you use, you should identify the key uncertainties in your forecast.

EPA's 1998 final PCB disposal rule provides a good example of using different baselines. EPA used several alternative baselines, each reflecting a different interpretation of existing regulatory requirements. In particular, one baseline reflected a literal interpretation of EPA's 1979 rule and another the actual implementation of that rule in the year immediately preceding the 1998 revision. The use of multiple baselines illustrated the substantial effect changes in EPA's implementation policy could have on the cost of a regulatory program. In the years after EPA adopted the 1979 PCB disposal rule, changes in EPA policy -- especially allowing the disposal of automobile "shredder fluff" in municipal landfills -- reduced the cost of the program by more than $500 million per year.

In some cases, substantial portions of a rule may simply restate statutory requirements that would be self-implementing, even in the absence of the regulatory action. In these cases, you should use a pre-statute baseline. If you are able to separate out those areas where the agency has discretion, you may also use a post-statute baseline to evaluate the discretionary elements of the action.

3. Evaluation of Alternatives

You should describe the alternatives available to you and the reasons for choosing one alternative over another. As noted previously, alternatives that rely on incentives and offer increased flexibility are often more cost-effective than more prescriptive approaches. For instance, user fees and information dissemination may be good alternatives to direct command-and-control regulation. Within a command-and-control regulatory program, performance-based standards generally offer advantages over standards specifying design, behavior, or manner of compliance.

You should carefully consider all appropriate alternatives for the key attributes or provisions of the rule. The previous discussion outlines examples of appropriate alternatives. Where there is a "continuum" of alternatives for a standard (such as the level of stringency), you generally should analyze at least three options: the preferred option; a more stringent option that achieves additional benefits (and presumably costs more) beyond those realized by the preferred option; and a less stringent option that costs less (and presumably generates fewer benefits) than the preferred option.

You should choose reasonable alternatives deserving careful consideration. In some cases, a regulatory program will focus on an option that is near or at the limit of technical feasibility. In this case, the analysis would not need to examine a more stringent option. For each of the options analyzed, you should compare the anticipated benefits to the corresponding costs.

It is not adequate simply to report a comparison of the agency's preferred option to the chosen baseline. Whenever you report the benefits and costs of alternative options, you should present both total and incremental benefits and costs. You should present incremental benefits and costs as differences from the corresponding estimates associated with the next less-stringent alternative.[10] It is important to emphasize that incremental effects are simply differences between successively more stringent alternatives. Results involving a comparison to a "next best" alternative may be especially useful.

In some cases, you may decide to analyze a wide array of options. In 1998, DOE analyzed a large number of options in setting new energy efficiency standards for refrigerators and freezers and produced a rich amount of information on their relative effects. This analysis -- examining more than 20 alternative performance standards for one class of refrigerators with top-mounted freezers -- enabled DOE to select an option that produced $200 more in estimated net benefits per refrigerator than the least attractive option.

---

[10] For the least stringent alternative, you should estimate the incremental benefits and costs relative to the baseline. Thus, for this alternative, the incremental effects would be the same as the corresponding totals. For each alternative that is more stringent than the least stringent alternative, you should estimate the incremental benefits and costs relative to the closest less-stringent alternative.

You should analyze the benefits and costs of different regulatory provisions separately when a rule includes a number of distinct provisions. If the existence of one provision affects the benefits or costs arising from another provision, the analysis becomes more complicated, but the need to examine provisions separately remains. In this case, you should evaluate each specific provision by determining the net benefits of the proposed regulation with and without it.

Analyzing all possible combinations of provisions is impractical if the number is large and interaction effects are widespread. You need to use judgment to select the most significant or relevant provisions for such analysis. You are expected to document all of the alternatives that were considered in a list or table and which were selected for emphasis in the main analysis.

You should also discuss the statutory requirements that affect the selection of regulatory approaches. If legal constraints prevent the selection of a regulatory action that best satisfies the philosophy and principles of Executive Order 12866, you should identify these constraints and estimate their opportunity cost. Such information may be useful to Congress under the Regulatory Right-to-Know Act.

4. Transparency and Reproducibility of Results

Because of its influential nature and its special role in the rulemaking process, it is appropriate to set minimum quality standards for regulatory analysis. You should provide documentation that the analysis is based on the best reasonably obtainable scientific, technical, and economic information available. To achieve this, you should rely on peer-reviewed literature, where available, and provide the source for all original information.

A good analysis should be transparent and your results must be reproducible. You should clearly set out the basic assumptions, methods, and data underlying the analysis and discuss the uncertainties associated with the estimates. A qualified third party reading the analysis should be able to understand the basic elements of your analysis and the way in which you developed your estimates.

To provide greater access to your analysis, you should generally post it, with all the supporting documents, on the internet so the public can review the findings. You should also disclose the use of outside consultants, their qualifications, and history of contracts and employment with the agency (e.g., in a preface to the RIA). Where other compelling interests (such as privacy, intellectual property, trade secrets, etc.) prevent the public release of data or key elements of the analysis, you should apply especially rigorous robustness checks to analytic results and document the analytical checks used.

Finally, you should assure compliance with the Information Quality Guidelines for your agency and OMB's "Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by Federal Agencies" ("data quality guidelines") http://www.whitehouse.gov/omb/fedreg/reproducible.html.

Developing Benefit and Cost Estimates

1. Some General Considerations

The analysis document should discuss the expected benefits and costs of the selected regulatory option and any reasonable alternatives. How is the proposed action expected to provide the anticipated benefits and costs? What are the monetized values of the potential real incremental benefits and costs to society? To present your results, you should:

- include separate schedules of the monetized benefits and costs that show the type and timing of benefits and costs, and express the estimates in this table in constant, undiscounted dollars (for more on discounting see "*Discount Rates*" below);
- list the benefits and costs you can quantify, but cannot monetize, including their timing;
- describe benefits and costs you cannot quantify; and
- identify or cross-reference the data or studies on which you base the benefit and cost estimates.

When benefit and cost estimates are uncertain (for more on this see "*Treatment of Uncertainty*" below), you should report benefit and cost estimates (including benefits of risk reductions) that reflect the full probability distribution of potential consequences. Where possible, present probability distributions of benefits and costs and include the upper and lower bound estimates as complements to central tendency and other estimates.

If fundamental scientific disagreement or lack of knowledge prevents construction of a scientifically defensible probability distribution, you should describe benefits or costs under plausible scenarios and characterize the evidence and assumptions underlying each alternative scenario.

2. The Key Concepts Needed to Estimate Benefits and Costs

"Opportunity cost" is the appropriate concept for valuing both benefits and costs. The principle of "willingness-to-pay" (WTP) captures the notion of opportunity cost by measuring what individuals are willing to forgo to enjoy a particular benefit. In general, economists tend to view WTP as the most appropriate measure of opportunity cost, but an individual's "willingness-to-accept" (WTA) compensation for not receiving the improvement can also provide a valid measure of opportunity cost.

WTP and WTA are comparable measures under special circumstances. WTP and WTA measures may be comparable in the following situations: if a regulation affects a price change rather than a quantity change; the change being evaluated is small; there are reasonably close substitutes available; and the income effect is small.[11] However, empirical evidence from experimental economics and psychology shows that even when income/wealth effects are "small", the measured differences between WTP and WTA can be large.[12] WTP is generally

---

[11] See Hanemann WM (1991), *American Economic Review*, 81(3), 635-647.

[12] See Kahneman D, Knetsch JL, and Thaler RH (1991), "Anomalies: The Endowment Effect, Loss Aversion, and Status Quo Bias," *Journal of Economic Perspectives* 3(1), 192-206.

considered to be more readily measurable. Adoption of WTP as the measure of value implies that individual preferences of the affected population should be a guiding factor in the regulatory analysis.

Market prices provide rich data for estimating benefits and costs based on willingness-to-pay if the goods and services affected by the regulation are traded in well-functioning competitive markets. The opportunity cost of an alternative includes the value of the benefits forgone as a result of choosing that alternative. The opportunity cost of banning a product -- a drug, food additive, or hazardous chemical -- is the forgone net benefit (i.e., lost consumer and producer surplus[13]) of that product, taking into account the mitigating effects of potential substitutes.

The use of any resource has an opportunity cost regardless of whether the resource is already owned or has to be purchased. That opportunity cost is equal to the net benefit the resource would have provided in the absence of the requirement. For example, if regulation of an industrial plant affects the use of additional land or buildings within the existing plant boundary, the cost analysis should include the opportunity cost of using the additional land or facilities.

To the extent possible, you should monetize any such forgone benefits and add them to the other costs of that alternative. You should also try to monetize any cost savings as a result of an alternative and either add it to the benefits or subtract it from the costs of that alternative. However, you should not assume that the "avoided" costs of not doing another regulatory alternative represent the benefits of a regulatory action where there is no direct, necessary relationship between the two. You should also be careful when the costs avoided are attributable to an existing regulation. Even when there is a direct relationship between the two regulatory actions, the use of avoided costs is problematic because the existing regulation may not maximize net benefits and thus may itself be questionable policy. (See the section, "Direct Use of Market Data," for more detail.)

Estimating benefits and costs when market prices are hard to measure or markets do not exist is more difficult. In these cases, you need to develop appropriate proxies that simulate market exchange. Estimates of willingness-to-pay based on revealed preference methods can be quite useful. As one example, analysts sometimes use "hedonic price equations" based on multiple regression analysis of market behavior to simulate market prices for the commodity of interest. The hedonic technique allows analysts to develop an estimate of the price for specific attributes associated with a product. For instance, a house is a product characterized by a variety of attributes including the number of rooms, total floor area, and type of heating and cooling. If there are enough data on transactions in the housing market, it is possible to develop an estimate of the implicit price for specific attributes, such as the implicit price of an additional bathroom or for central air conditioning. This technique can be extended, as well, to develop an estimate for

---

[13] Consumer surplus is the difference between what a consumer pays for a unit of a good and the maximum amount the consumer would be willing to pay for that unit. It is measured by the area between the price and the demand curve for that unit. Producer surplus is the difference between the amount a producer is paid for a unit of a good and the minimum amount the producer would accept to supply that unit. It is measured by the area between the price and the supply curve for that unit.

the implicit price of public goods that are not directly traded in markets. An analyst can develop implicit price estimates for public goods like air quality and access to public parks by assessing the effects of these goods on the housing market. Going through the analytical process of deriving benefit estimates by simulating markets may also suggest alternative regulatory strategies that create such markets.

You need to guard against double-counting, since some attributes are embedded in other broader measures. To illustrate, when a regulation improves the quality of the environment in a community, the value of real estate in the community generally rises to reflect the greater attractiveness of living in a better environment. Simply adding the increase in property values to the estimated value of improved public health would be double counting if the increase in property values reflects the improvement in public health. To avoid this problem you should separate the embedded effects on the value of property arising from improved public health. At the same time, an analysis that fails to incorporate the consequence of land use changes when accounting for costs will not capture the full effects of regulation.

3. Revealed Preference Methods

Revealed preference methods develop estimates of the value of goods and services -- or attributes of those goods and services -- based on actual market decisions by consumers, workers and other market participants. If the market participant is well informed and confronted with a real choice, it may be feasible to determine accurately and precisely the monetary value needed for a rulemaking. There is a large and well-developed literature on revealed preference in the peer-reviewed, applied economics literature.

Although these methods are well grounded in economic theory, they are sometimes difficult to implement given the complexity of market transactions and the paucity of relevant data. When designing or evaluating a revealed preference study, the following principles should be considered:

- the market should be competitive. If the market isn’t competitive (e.g., monopoly, oligopoly), then you should consider making adjustments such that the price reflects the true value to society (often called the “shadow price”);
- the market should not exhibit a significant information gap or asymmetric information problem. If the market suffers from information problems, then you should discuss the divergence of the price from the underlying shadow price and consider possible adjustments to reflect the underlying shadow price;
- the market should not exhibit an externality. In this case, you should discuss the divergence of the price from the underlying shadow price and consider possible adjustments to reflect the underlying shadow price;
- the specific market participants being studied should be representative of the target populations to be affected by the rulemaking under consideration;
- a valid research design and framework for analysis should be adopted. Examples include using data and/or model specifications that include the markets for substitute and complementary goods and services and using reasonably unrestricted functional forms. When specifying substitute and complementary goods, the analysis should preferably be

based on data about the range of alternatives perceived by market participants. If such data are not available, you should adopt plausible assumptions and describe the limitations of the analysis.

- the statistical and econometric models employed should be appropriate for the application and the resulting estimates should be robust in response to plausible changes in model specification and estimation technique; and
- the results should be consistent with economic theory.

You should also determine whether there are multiple revealed-preference studies of the same good or service and whether anything can be learned by comparing the methods, data and findings from different studies. Professional judgment is required to determine whether a particular study is of sufficient quality to justify use in regulatory analysis. When studies are used in regulatory analysis despite their technical weaknesses (e.g., due to the absence of other evidence), the regulatory analysis should discuss any biases or uncertainties that are likely to arise due to those weaknesses. If a study has major weaknesses, the study should not be used in regulatory analysis.

a. Direct Uses of Market Data

Economists ordinarily consider market prices as the most accurate measure of the marginal value of goods and services to society. In some instances, however, market prices may not reflect the true value of goods and services due to market imperfections or government intervention. If a regulation involves changes to goods or services where the market price is not a good measure of the value to society, you should use an estimate that reflects the shadow price. Suppose a particular air pollutant damages crops. One of the benefits of controlling that pollutant is the value of the crop yield increase as a result of the controls. That value is typically measured by the price of the crop. However, if the price is held above the market price by a government program that affects supply, a value estimate based on this price may not reflect the true benefits of controlling the pollutant. In this case, you should calculate the value to society of the increase in crop yields by estimating the shadow price, which reflects the value to society of the marginal use of the crop. If the marginal use is for exports, you should use the world price. If the marginal use is to add to very large surplus stockpiles, you should use the value of the last units released from storage minus storage cost. If stockpiles are large and growing, the shadow price may be low or even negative.

Other goods whose market prices may not reflect their true value include those whose production or consumption results in substantial (1) positive or negative external effects or (2) transfer payments. For example, the observed market price of gasoline may not reflect marginal social value due to the inclusion of taxes, other government interventions, and negative externalities (e.g., pollution). This shadow price may also be needed for goods whose market price is substantially affected by existing regulations that do not maximize net benefits.

b. Indirect Uses of Market Data

Many goods or attributes of goods that are affected by regulation--such as preserving environmental or cultural amenities--are not traded directly in markets. The value for these goods or attributes arise both from use and non-use. Estimation of these values is difficult because of the absence of an organized market. However, overlooking or ignoring these values in your regulatory analysis may significantly understate the benefits and/or costs of regulatory action.

"Use values" arise where an individual derives satisfaction from using the resource, either now or in the future. Use values are associated with activities such as swimming, hunting, and hiking where the individual makes use of the natural environment.

"Non-use values" arise where an individual places value on a resource, good or service even though the individual will not use the resource, now or in the future. Non-use value includes bequest and existence values.

General altruism for the health and welfare of others is a closely related concept but may not be strictly considered a "non-use" value.[14] A general concern for the welfare of others should supplement benefits and costs equally; hence, it is not necessary to measure the size of general altruism in regulatory analysis. If there is evidence of selective altruism, it needs to be considered specifically in both benefits and costs.

Some goods and services are indirectly traded in markets, which means that their value is reflected in the prices of related goods and services that are directly traded in markets. Their use values are typically estimated through revealed preference methods. Examples include estimates of the values of environmental amenities derived from travel-cost studies, and hedonic price models that measure differences or changes in the value of real estate. It is important that you utilize revealed preference models that adhere to economic criteria that are consistent with utility maximizing behavior. Also, you should take particular care in designing protocols for reliably estimating the values of these attributes.

4. Stated Preference Methods

Stated Preference Methods (SPM) have been developed and used in the peer-reviewed literature to estimate both "use" and "non-use" values of goods and services. They have also been widely used in regulatory analyses by Federal agencies, in part, because these methods can be creatively employed to address a wide variety of goods and services that are not easy to study through revealed preference methods.

The distinguishing feature of these methods is that hypothetical questions about use or non-use values are posed to survey respondents in order to obtain willingness-to-pay estimates relevant to benefit or cost estimation. Some examples of SPM include contingent valuation, conjoint analysis and risk-tradeoff analysis. The surveys used to obtain the health-utility values used in CEA are similar to stated-preference surveys but do not entail monetary measurement of value. Nevertheless, the principles governing quality stated-preference research, with some obvious exceptions involving monetization, are also relevant in designing quality health-utility research.

---

[14] See McConnell KE (1997), *Journal of Environmental Economics and Management*, *32*, 22-37.

When you are designing or evaluating a stated-preference study, the following principles should be considered:

- the good or service being evaluated should be explained to the respondent in a clear, complete and objective fashion, and the survey instrument should be pre-tested;
- willingness-to-pay questions should be designed to focus the respondent on the reality of budgetary limitations and alerted to the availability of substitute goods and alternative expenditure options;
- the survey instrument should be designed to probe beyond general attitudes (e.g., a "warm glow" effect for a particular use or non-use value) and focus on the magnitude of the respondent's economic valuation;
- the analytic results should be consistent with economic theory using both "internal" (within respondent) and "external" (between respondent) scope tests such as the willingness to pay is larger (smaller) when more (less) of a good is provided;
- the subjects being interviewed should be selected/sampled in a statistically appropriate manner. The sample frame should adequately cover the target population. The sample should be drawn using probability methods in order to generalize the results to the target population;
- response rates should be as high as reasonably possible. Best survey practices should be followed to achieve high response rates. Low response rates increase the potential for bias and raise concerns about the generalizability of the results. If response rates are not adequate, you should conduct an analysis of non-response bias or further study. Caution should be used in assessing the representativeness of the sample based solely on demographic profiles. Statistical adjustments to reduce non-response bias should be undertaken whenever feasible and appropriate;
- the mode of administration of surveys (in-person, phone, mail, computer, internet or multiple modes) should be appropriate in light of the nature of the questions being posed to respondents and the length and complexity of the instrument;
- documentation should be provided about the target population, the sampling frame used and its coverage of the target population, the design of the sample including any stratification or clustering, the cumulative response rate (including response rate at each stage of selection if applicable); the item non-response rate for critical questions; the exact wording and sequence of questions and other information provided to respondents; and the training of interviewers and techniques they employed (as appropriate);
- the statistical and econometric methods used to analyze the collected data should be transparent, well suited for the analysis, and applied with rigor and care.

Professional judgment is necessary to apply these criteria to one or more studies, and thus there is no mechanical formula that can be used to determine whether a particular study is of sufficient quality to justify use in regulatory analysis. When studies are used despite having weaknesses on one or more of these criteria, those weaknesses should be acknowledged in the regulatory analysis, including any resulting biases or uncertainties that are likely to result. If a study has too many weaknesses with unknown consequences for the quality of the data, the study should not be used.

The challenge in designing quality stated-preference studies is arguably greater for non-use values and unfamiliar use values than for familiar goods or services that are traded (directly or indirectly) in market transactions. The good being valued may have little meaning to respondents, and respondents may be forming their valuations for the first time in response to the questions posed. Since these values are effectively constructed by the respondent during the elicitation, the instrument and mode of administration should be rigorously pre-tested to make sure that responses are not simply an artifact of specific features of instrument design and/or mode of administration.

Since SPM generate data from respondents in a hypothetical setting, often on complex and unfamiliar goods, special care is demanded in the design and execution of surveys, analysis of the results, and characterization of the uncertainties. A stated-preference study may be the only way to obtain quantitative information about non-use values, though a number based on a poor quality study is not necessarily superior to no number at all. Non-use values that are not quantified should be presented as an "intangible" benefit or cost.

If both revealed-preference and stated-preference studies that are directly applicable to regulatory analysis are available, you should consider both kinds of evidence and compare the findings. If the results diverge significantly, you should compare the overall size and quality of the two bodies of evidence. Other things equal, you should prefer revealed preference data over stated preference data because revealed preference data are based on actual decisions, where market participants enjoy or suffer the consequences of their decisions. This is not generally the case for respondents in stated preference surveys, where respondents may not have sufficient incentives to offer thoughtful responses that are more consistent with their preferences or may be inclined to bias their responses for one reason or another.

5. Benefit-Transfer Methods

It is often preferable to collect original data on revealed preference or stated preference to support regulatory analysis. Yet conducting an original study may not be feasible due to the time and expense involved. One alternative to conducting an original study is the use of "benefit transfer" methods. (The transfer may involve cost determination as well). The practice of "benefit transfer" began with transferring existing estimates obtained from indirect market and stated preference studies to new contexts (i.e., the context posed by the rulemaking). The principles that guide transferring estimates from indirect market and stated preference studies should apply to direct market studies as well.

Although benefit-transfer can provide a quick, low-cost approach for obtaining desired monetary values, the methods are often associated with uncertainties and potential biases of unknown magnitude. It should therefore be treated as a last-resort option and not used without explicit justification.

In conducting benefit transfer, the first step is to specify the value to be estimated for the rulemaking. You should identify the relevant measure of the policy change at this initial stage. For instance, you can derive the relevant willingness-to-pay measure by specifying an indirect utility function. This identification allows you to "zero in" on key aspects of the benefit transfer.

The next step is to identify appropriate studies to conduct benefit transfer. In selecting transfer studies for either point transfers or function transfers, you should base your choices on the following criteria:

- The selected studies should be based on adequate data, sound and defensible empirical methods and techniques.
- The selected studies should document parameter estimates of the valuation function.
- The study context and policy context should have similar populations (e.g., demographic characteristics). The market size (e.g., target population) between the study site and the policy site should be similar. For example, a study valuing water quality improvement in Rhode Island should not be used to value policy that will affect water quality throughout the United States.
- The good, and the magnitude of change in that good, should be similar in the study and policy contexts.
- The relevant characteristics of the study and the policy contexts should be similar. For example, the effects examined in the original study should be "reversible" or "irreversible" to a degree that is similar to the regulatory actions under consideration.
- The distribution of property rights should be similar so that the analysis uses the same welfare measure. If the property rights in the study context support the use of WTA measures while the rights in the rulemaking context support the use of WTP measures, benefit transfer is not appropriate.
- The availability of substitutes across study and policy contexts should be similar.

If you can choose between transferring a function or a point estimate, you should transfer the entire demand function (referred to as benefit function transfer) rather than adopting a single point estimate (referred to as benefit point transfer).[15]

Finally, you should not use benefit transfer in estimating benefits if:

- resources are unique or have unique attributes. For example, if a policy change affects snowmobile use in Yellowstone National Park, then a study valuing snowmobile use in the state of Michigan should not be used to value changes in snowmobile use in the Yellowstone National Park.
- If the study examines a resource that is unique or has unique attributes, you should not transfer benefit estimates or benefit functions to value a different resource and vice versa. For example, if a study values visibility improvements at the Grand Canyon, these results should not be used to value visibility improvements in urban areas.
- There are significant problems with applying an *"ex ante"* valuation estimate to an *"ex post"* policy context. If a policy yields a significant change in the attributes of the good, you should not use the study estimates to value the change using a benefit transfer approach.
- You also should not use a value developed from a study involving, small marginal

changes in a policy context involving large changes in the quantity of the good.

Clearly, all of these criteria are difficult to meet. However, you should attempt to satisfy as many as possible when choosing studies from the existing economic literature. Professional judgment is required in determining whether a particular transfer is too speculative to use in regulatory analysis.

6. Ancillary Benefits and Countervailing Risks

Your analysis should look beyond the direct benefits and direct costs of your rulemaking and consider any important ancillary benefits and countervailing risks. An ancillary benefit is a favorable impact of the rule that is typically unrelated or secondary to the statutory purpose of the rulemaking (e.g., reduced refinery emissions due to more stringent fuel economy standards for light trucks) while a countervailing risk is an adverse economic, health, safety, or environmental consequence that occurs due to a rule and is not already accounted for in the direct cost of the rule (e.g., adverse safety impacts from more stringent fuel-economy standards for light trucks).

You should begin by considering and perhaps listing the possible ancillary benefits and countervailing risks. However, highly speculative or minor consequences may not be worth further formal analysis. Analytic priority should be given to those ancillary benefits and countervailing risks that are important enough to potentially change the rank ordering of the main alternatives in the analysis. In some cases the mere consideration of these secondary effects may help in the generation of a superior regulatory alternative with strong ancillary benefits and fewer countervailing risks. For instance, a recent study suggested that weight-based, fuel-economy standards could achieve energy savings with fewer safety risks and employment losses than would occur under the current regulatory structure.

Like other benefits and costs, an effort should be made to quantify and monetize ancillary benefits and countervailing risks. If monetization is not feasible, quantification should be attempted through use of informative physical units. If both monetization and quantification are not feasible, then these issues should be presented as non-quantified benefits and costs. The same standards of information and analysis quality that apply to direct benefits and costs should be applied to ancillary benefits and countervailing risks.

One way to combine ancillary benefits and countervailing risks is to evaluate these effects separately and then put both of these effects on the benefits side, not on the cost side. Although it is theoretically appropriate to include disbenefits on the cost side, legal and programmatic considerations generally support subtracting the disbenefits from direct benefits.

7. Methods for Treating Non-Monetized Benefits and Costs

Sound quantitative estimates of benefits and costs, where feasible, are preferable to qualitative descriptions of benefits and costs because they help decision makers understand the magnitudes of the effects of alternative actions. However, some important benefits and costs (e.g., privacy protection) may be inherently too difficult to quantify or monetize given current data and methods. You should carry out a careful evaluation of non-quantified benefits and costs. Some authorities[16] refer to these non-monetized and non-quantified effects as "intangible".

a. Benefits and Costs that are Difficult to Monetize

You should monetize quantitative estimates whenever possible. Use sound and defensible values or procedures to monetize benefits and costs, and ensure that key analytical assumptions are defensible. If monetization is impossible, explain why and present all available quantitative information. For example, if you can quantify but cannot monetize increases in water quality and fish populations resulting from water quality regulation, you can describe benefits in terms of stream miles of improved water quality for boaters and increases in game fish populations for anglers. You should describe the timing and likelihood of such effects and avoid double-counting of benefits when estimates of monetized and physical effects are mixed in the same analysis.

b. Benefits and Costs that are Difficult to Quantify

If you are not able to quantify the effects, you should present any relevant quantitative information along with a description of the unquantified effects, such as ecological gains, improvements in quality of life, and aesthetic beauty. You should provide a discussion of the strengths and limitations of the qualitative information. This should include information on the key reason(s) why they cannot be quantified. In one instance, you may know with certainty the magnitude of a risk to which a substantial, but unknown, number of individuals are exposed. In another instance, the existence of a risk may be based on highly speculative assumptions, and the magnitude of the risk may be unknown.

For cases in which the unquantified benefits or costs affect a policy choice, you should provide a clear explanation of the rationale behind the choice. Such an explanation could include detailed information on the nature, timing, likelihood, location, and distribution of the unquantified benefits and costs. Also, please include a summary table that lists all the unquantified benefits and costs, and use your professional judgment to highlight (e.g., with categories or rank ordering) those that you believe are most important (e.g., by considering factors such as the degree of certainty, expected magnitude, and reversibility of effects).

While the focus is often placed on difficult to quantify benefits of regulatory action, some costs are difficult to quantify as well. Certain permitting requirements (e.g., EPA's New Source Review program) restrict the decisions of production facilities to shift to new products and adopt innovative methods of production. While these programs may impose substantial costs on the economy, it is very difficult to quantify and monetize these effects. Similarly, regulations that establish emission standards for recreational vehicles, like motor bikes, may adversely affect the performance of the vehicles in terms of driveability and 0 to 60 miles per hour acceleration. Again, the cost associated with the loss of these attributes may be difficult to quantify and monetize. They need to be analyzed qualitatively.

8. Monetizing Health and Safety Benefits and Costs

We expect you to provide a benefit-cost analysis of major health and safety rulemakings in addition to a CEA. The BCA provides additional insight because (a) it provides some indication of what the public is willing to pay for improvements in health and safety and (b) it offers additional information on preferences for health using a different research design than is used in CEA. Since the health-preference methods used to support CEA and BCA have some different strengths and drawbacks, it is important that you provide decision makers with both perspectives.

In monetizing health benefits, a WTP measure is the conceptually appropriate measure as compared to other alternatives (e.g., cost of illness or lifetime earnings), in part because it attempts to capture pain and suffering and other quality-of-life effects. Using the WTP measure for health and safety allows you to directly compare your results to the other benefits and costs in your analysis, which will typically be based on WTP.

If well-conducted revealed-preference studies of relevant health and safety risks are available, you should consider using them in developing your monetary estimates. If appropriate revealed-preference data are not available, you should use valid and relevant data from stated-preference studies. You will need to use your professional judgment when you are faced with limited information on revealed preference studies and substantial information based on stated preference studies.

A key advantage of stated-preference and health-utility methods compared to revealed preference methods is that they can be tailored to address the ranges of probabilities, types of health risks and specific populations affected by your rule. In many rulemakings there will be no relevant information from revealed-preference studies. In this situation you should consider commissioning a stated-preference study or using values from published stated-preference studies. For the reasons discussed previously, you should be cautious about using values from stated-preference studies and describe in the analysis the drawbacks of this approach.

a. Nonfatal Health and Safety Risks

With regard to nonfatal health and safety risks, there is enormous diversity in the nature and severity of impaired health states. A traumatic injury that can be treated effectively in the emergency room without hospitalization or long-term care is different from a traumatic injury resulting in paraplegia. Severity differences are also important in evaluation of chronic diseases. A severe bout of bronchitis, though perhaps less frequent, is far more painful and debilitating than the more frequent bouts of mild bronchitis. The duration of an impaired health state, which can range from a day or two to several years or even a lifetime (e.g., birth defects inducing mental retardation), need to be considered carefully. Information on both the severity and duration of an impaired health state is necessary before the task of monetization can be performed.

When monetizing nonfatal health effects, it is important to consider two components: (1) the private demand for prevention of the nonfatal health effect, to be represented by the preferences of the target population at risk, and (2) the net financial externalities associated with poor health such as net changes in public medical costs and any net changes in economic production that are not experienced by the target population. Revealed-preference or stated-preference studies are necessary to estimate the private demand; health economics data from published sources can typically be used to estimate the financial externalities caused by changes in health status. If you use literature values to monetize nonfatal health and safety risks, it is important to make sure that the values you have selected are appropriate for the severity and duration of health effects to be addressed by your rule.

If data are not available to support monetization, you might consider an alternative approach that makes use of health-utility studies. Although the economics literature on the monetary valuation of impaired health states is growing, there is a much larger clinical literature on how patients, providers and community residents value diverse health states. This literature typically measures health utilities based on the standard gamble, the time tradeoff or the rating scale methods. This health utility information may be combined with known monetary values for well-defined health states to estimate monetary values for a wide range of health states of different severity and duration. If you use this approach, you should be careful to acknowledge your assumptions and the limitations of your estimates.

b. Fatality Risks

Since agencies often design health and safety regulation to reduce risks to life, evaluation of these benefits can be the key part of the analysis. A good analysis must present these benefits clearly and show their importance. Agencies may choose to monetize these benefits. The willingness-to-pay approach is the best methodology to use if reductions in fatality risk are monetized.

Some describe the monetized value of small changes in fatality risk as the "value of statistical life" (VSL) or, less precisely, the "value of a life." The latter phrase can be misleading because it suggests erroneously that the monetization exercise tries to place a “value” on individual lives. You should make clear that these terms refer to the measurement of willingness to pay for reductions in only small risks of premature death. They have no application to an identifiable individual or to very large reductions in individual risks. They do not suggest that any individual’s life can be expressed in monetary terms. Their sole purpose is to help describe better the likely benefits of a regulatory action.

Confusion about the term "statistical life" is also widespread. This term refers to the sum of risk reductions expected in a population. For example, if the annual risk of death is reduced by one in a million for each of two million people, that is said to represent two "statistical lives" extended per year (2 million people x 1/1,000,000 = 2). If the annual risk of death is reduced by one in 10 million for each of 20 million people, that also represents two statistical lives extended.

The adoption of a value for the projected reduction in the risk of premature mortality is the subject of continuing discussion within the economic and public policy analysis community. A considerable body of academic literature is available on this subject. This literature involves either explicit or implicit valuation of fatality risks, and generally involves the use of estimates of

VSL from studies on wage compensation for occupational hazards (which generally are in the range of 10^{-4} annually), on consumer product purchase and use decisions, or from an emerging literature using stated preference approaches. A substantial majority of the resulting estimates of VSL vary from roughly $1 million to $10 million per statistical life.[17]

There is a continuing debate within the economic and public policy analysis community on the merits of using a single VSL for all situations versus adjusting the VSL estimates to reflect the specific rule context. A variety of factors have been identified, including whether the mortality risk involves sudden death, the fear of cancer, and the extent to which the risk is voluntarily incurred.[18] The consensus of EPA's recent Science Advisory Board (SAB) review of this issue was that the available literature does not support adjustments of VSL for most of these factors. The panel did conclude that it was appropriate to adjust VSL to reflect changes in income and any time lag in the occurrence of adverse health effects.

The age of the affected population has also been identified as an important factor in the theoretical literature. However, the empirical evidence on age and VSL is mixed. In light of the continuing questions over the effect of age on VSL estimates, you should not use an age-adjustment factor in an analysis using VSL estimates.[19]

Another way that has been used to express reductions in fatality risks is to use the life expectancy method, the "value of statistical life-years (VSLY) extended." If a regulation protects individuals whose average remaining life expectancy is 40 years, a risk reduction of one fatality is expressed as "40 life-years extended." Those who favor this alternative approach emphasize that the value of a statistical life is not a single number relevant for all situations. In particular, when there are significant differences between the effect on life expectancy for the population affected by a particular health risk and the populations studied in the labor market studies, they prefer to adopt a VSLY approach to reflect those differences. You should consider providing estimates of both VSL and VSLY, while recognizing the developing state of knowledge in this area.

Longevity may be only one of a number of relevant considerations pertaining to the rule. You should keep in mind that regulations with greater numbers of life-years extended are not necessarily better than regulations with fewer numbers of life-years extended. In any event, when you present estimates based on the VSLY method, you should adopt a larger VSLY estimate for senior citizens because senior citizens face larger overall health risks from all causes and they may have accumulated savings to spend on their health and safety.[20]

The valuation of fatality risk reduction is an evolving area in both results and methodology. Hence, you should utilize valuation methods that you consider appropriate for the

[18] Distinctions between "voluntary" and "involuntary" should be treated with care. Risks are best considered to fall within a continuum from "voluntary" to "involuntary" with very few risks at either end of this range. These terms are also related to differences in the cost of avoiding risks.

regulatory circumstances. Since the literature-based VSL estimates may not be entirely appropriate for the risk being evaluated (e.g., the use of occupational risk premia to value reductions in risks from environmental hazards), you should explain your selection of estimates and any adjustments of the estimates to reflect the nature of the risk being evaluated. You should present estimates based on alternative approaches, and if you monetize mortality risk reduction, you should do so on a consistent basis to the extent feasible. You should clearly indicate the methodology used and document your choice of a particular methodology. You should explain any significant deviations from the prevailing state of knowledge. If you use different methodologies in different rules, you should clearly disclose the fact and explain your choices.

c. Valuation of Reductions in Health and Safety Risks to Children

The valuation of health outcomes for children and infants poses special challenges. It is rarely feasible to measure a child's willingness to pay for health improvement and an adult's concern for his or her own health is not necessarily relevant to valuation of child health. For example, the wage premiums demanded by workers to accept hazardous jobs are not readily transferred to rules that accomplish health gains for children.

There are a few studies that examine parental willingness to pay to invest in health and safety for their children. Some of these studies suggest that parents may value children's health more strongly than their own health. Although this parental perspective is a promising research strategy, it may need to be expanded to include a societal interest in child health and safety.

Where the primary objective of a rule is to reduce the risk of injury, disease or mortality among children, you should conduct a cost-effectiveness analysis of the rule. You may also develop a benefit-cost analysis to the extent that valid monetary values can be assigned to the primary expected health outcomes. For rules where health gains are expected among both children and adults and you decide to perform a benefit-cost analysis, the monetary values for children should be at least as large as the values for adults (for the same probabilities and outcomes) unless there is specific and compelling evidence to suggest otherwise.[21]

Discount Rates

Benefits and costs do not always take place in the same time period. When they do not, it is incorrect simply to add all of the expected net benefits or costs without taking account of when the actually occur. If benefits or costs are delayed or otherwise separated in time from each other, the difference in timing should be reflected in your analysis.

As a first step, you should present the annual time stream of benefits and costs expected to result from the rule, clearly identifying when the benefits and costs are expected to occur. The beginning point for your stream of estimates should be the year in which the final rule will begin to have effects, even if that is expected to be some time in the future. The ending point should be far enough in the future to encompass all the significant benefits and costs likely to result from the rule.

---

[21] For more information, see Dockins C., Jenkins RR, Owens N, Simon NB, and Wiggins LB (2002), *Risk Analysis*, 22(2), 335-346.

In presenting the stream of benefits and costs, it is important to measure them in constant dollars to avoid the misleading effects of inflation in your estimates. If the benefits and costs are initially measured in prices reflecting expected future inflation, you can convert them to constant dollars by dividing through by an appropriate inflation index, one that corresponds to the inflation rate underlying the initial estimates of benefits or costs.

1. The Rationale for Discounting

Once these preliminaries are out of the way, you can begin to adjust your estimates for differences in timing. (This is a separate calculation from the adjustment needed to remove the effects of future inflation.) Benefits or costs that occur sooner are generally more valuable. The main rationales for the discounting of future impacts are:

(a) Resources that are invested will normally earn a positive return, so current consumption is more expensive than future consumption, since you are giving up that expected return on investment when you consume today.
(b) Postponed benefits also have a cost because people generally prefer present to future consumption. They are said to have positive time preference.
(c) Also, if consumption continues to increase over time, as it has for most of U.S. history, an increment of consumption will be less valuable in the future than it would be today, because the principle of diminishing marginal utility implies that as total consumption increases, the value of a marginal unit of consumption tends to decline.

There is wide agreement with point (a). Capital investment is productive, but that point is not sufficient by itself to explain positive interest rates and observed saving behavior. To understand these phenomena, points (b) and (c) are also necessary. If people are really indifferent between consumption now and later, then they should be willing to forgo current consumption in order to consume an equal or slightly greater amount in the future. That would cause saving rates and investment to rise until interest rates were driven to zero and capital was no longer productive. As long as we observe positive interest rates and saving rates below 100 percent, people must be placing a higher value on current consumption than on future consumption.

To reflect this preference, a discount factor should be used to adjust the estimated benefits and costs for differences in timing. The further in the future the benefits and costs are expected to occur, the more they should be discounted. The discount factor can be calculated given a discount rate. The formula is 1/ (1+ the discount rate)^t where "t" measures the number of years in the future that the benefits or costs are expected to occur. Benefits or costs that have been adjusted in this way are called "discounted present values" or simply "present values". When, and only when, the estimated benefits and costs have been discounted, they can be added to determine the overall value of net benefits.

2. Real Discount Rates of 3 Percent and 7 Percent

OMB's basic guidance on the discount rate is provided in OMB Circular A-94 (http://www.whitehouse.gov/omb/circulars/index.html). This Circular points out that the analytically preferred method of handling temporal differences between benefits and costs is to adjust all the benefits and costs to reflect their value in equivalent units of consumption and to discount them at the rate consumers and savers would normally use in discounting future consumption benefits. This is sometimes called the "shadow price" approach to discounting because doing such calculations requires you to value benefits and costs using shadow prices, especially for capital goods, to correct for market distortions. These shadow prices are not well established for the United States. Furthermore, the distribution of impacts from regulations on capital and consumption are not always well known. Consequently, any agency that wishes to tackle this challenging analytical task should check with OMB before proceeding.

As a default position, OMB Circular A-94 states that a real discount rate of 7 percent should be used as a base-case for regulatory analysis. The 7 percent rate is an estimate of the average before-tax rate of return to private capital in the U.S. economy. It is a broad measure that reflects the returns to real estate and small business capital as well as corporate capital. It approximates the opportunity cost of capital, and it is the appropriate discount rate whenever the main effect of a regulation is to displace or alter the use of capital in the private sector. OMB revised Circular A-94 in 1992 after extensive internal review and public comment. In a recent analysis, OMB found that the average rate of return to capital remains near the 7 percent rate estimated in 1992. Circular A-94 also recommends using other discount rates to show the sensitivity of the estimates to the discount rate assumption.

Economic distortions, including taxes on capital, create a divergence between the rate of return that savers earn and the private rate of return to capital. This divergence persists despite the tendency for capital to flow to where it can earn the highest rate of return. Although market forces will push after-tax rates of return in different sectors of the economy toward equality, that process will not equate pre-tax rates of return when there are differences in the tax treatment of investment. Corporate capital, in particular, pays an additional layer of taxation, the corporate income tax, which requires it to earn a higher pre-tax rate of return in order to provide investors with similar after-tax rates of return compared with non-corporate investments. The pre-tax rates of return better measure society's gains from investment. Since the rates of return on capital are higher in some sectors of the economy than others, the government needs to be sensitive to possible impacts of regulatory policy on capital allocation.

The effects of regulation do not always fall exclusively or primarily on the allocation of capital. When regulation primarily and directly affects private consumption (e.g., through higher consumer prices for goods and services), a lower discount rate is appropriate. The alternative most often used is sometimes called the "social rate of time preference." This simply means the rate at which "society" discounts future consumption flows to their present value. If we take the rate that the average saver uses to discount future consumption as our measure of the social rate of time preference, then the real rate of return on long-term government debt may provide a fair approximation. Over the last thirty years, this rate has averaged around 3 percent in real terms on a pre-tax basis. For example, the yield on 10-year Treasury notes has averaged 8.1 percent since

1973 while the average annual rate of change in the CPI over this period has been 5.0 percent, implying a real 10-year rate of 3.1 percent.

For regulatory analysis, you should provide estimates of net benefits using both 3 percent and 7 percent. An example of this approach is EPA's analysis of its 1998 rule setting both effluent limits for wastewater discharges and air toxic emission limits for pulp and paper mills. In this analysis, EPA developed its present-value estimates using real discount rates of 3 and 7 percent applied to benefit and cost streams that extended forward for 30 years. You should present a similar analysis in your own work.

In some instances, if there is reason to expect that the regulation will cause resources to be reallocated away from private investment in the corporate sector, then the opportunity cost may lie outside the range of 3 to 7 percent. For example, the average real rate of return on corporate capital in the United States was approximately 10 percent in the 1990s, returning to the same level observed in the 1950s and 1960s. If you are uncertain about the nature of the opportunity cost, then you should present benefit and cost estimates using a higher discount rate as a further sensitivity analysis as well as using the 3 and 7 percent rates.

3. Time Preference for Health-Related Benefits and Costs

When future benefits or costs are health-related, some have questioned whether discounting is appropriate, since the rationale for discounting money may not appear to apply to health. It is true that lives saved today cannot be invested in a bank to save more lives in the future. But the resources that would have been used to save those lives can be invested to earn a higher payoff in future lives saved. People have been observed to prefer health gains that occur immediately to identical health gains that occur in the future. Also, if future health gains are not discounted while future costs are, then the following perverse result occurs: an attractive investment today in future health improvement can always be made more attractive by delaying the investment. For such reasons, there is a professional consensus that future health effects, including both benefits and costs, should be discounted at the same rate. This consensus applies to both BCA and CEA.

A common challenge in health-related analysis is to quantify the time lag between when a rule takes effect and when the resulting physical improvements in health status will be observed in the target population. In such situations, you must carefully consider the timing of health benefits before performing present-value calculations. It is not reasonable to assume that all of the benefits of reducing chronic diseases such as cancer and cardiovascular disease will occur immediately when the rule takes effect. For rules addressing traumatic injury, this lag period may be short. For chronic diseases it may take years or even decades for a rule to induce its full beneficial effects in the target population.

When a delay period between exposure to a toxin and increased probability of disease is likely (a so-called latency period), a lag between exposure reduction and reduced probability of disease is also likely. This latter period has sometimes been referred to as a "cessation lag," and it may or may not be of the same duration as the latency period. As a general matter, cessation lags will only apply to populations with at least some high-level exposure (e.g., before the rule takes effect). For populations with no such prior exposure, such as those born after the rule takes effect, only the latency period will be relevant.

Ideally, your exposure-risk model would allow calculation of reduced risk for each year following exposure cessation, accounting for total cumulative exposure and age at the time of exposure reduction. The present-value benefits estimate could then reflect an appropriate discount factor for each year's risk reduction. Recent analyses of the cancer benefits stemming from reduction in public exposure to radon in drinking water have adopted this approach. They were supported by formal risk-assessment models that allowed estimates of the timing of lung cancer incidence and mortality to vary in response to different radon exposure levels.[22]

In many cases, you will not have the benefit of such detailed risk assessment modeling. You will need to use your professional judgment as to the average cessation lag for the chronic diseases affected by your rule. In situations where information exists on latency but not on cessation lags, it may be reasonable to use latency as a proxy for the cessation lag, unless there is reason to believe that the two are different. When the average lag time between exposures and disease is unknown, a range of plausible alternative values for the time lag should be used in your analysis.

4. Intergenerational Discounting

Special ethical considerations arise when comparing benefits and costs across generations. Although most people demonstrate time preference in their own consumption behavior, it may not be appropriate for society to demonstrate a similar preference when deciding between the well-being of current and future generations. Future citizens who are affected by such choices cannot take part in making them, and today's society must act with some consideration of their interest.

One way to do this would be to follow the same discounting techniques described above and supplement the analysis with an explicit discussion of the intergenerational concerns (how future generations will be affected by the regulatory decision). Policymakers would be provided with this additional information without changing the general approach to discounting.

Using the same discount rate across generations has the advantage of preventing time-inconsistency problems. For example, if one uses a lower discount rate for future generations, then the evaluation of a rule that has short-term costs and long-term benefits would become more favorable merely by waiting a year to do the analysis. Further, using the same discount rate across generations is attractive from an ethical standpoint. If one expects future generations to be better off, then giving them the advantage of a lower discount rate would in effect transfer resources from poorer people today to richer people tomorrow.

Some believe, however, that it is ethically impermissible to discount the utility of future generations. That is, government should treat all generations equally. Even under this approach,

---

[22] Committee on Risk Assessment of Exposure to Radon in Drinking Water, Board on Radiation Effects Research, Commission on Life Sciences (1996), *Risk Assessment of Radon in Drinking Water*, National Research Council, National Academy Press, Washington, DC.

it would still be correct to discount future costs and consumption benefits generally (perhaps at a lower rate than for intragenerational analysis), due to the expectation that future generations will be wealthier and thus will value a marginal dollar of benefits or costs by less than those alive today. Therefore, it is appropriate to discount future benefits and costs relative to current benefits and costs, even if the welfare of future generations is not being discounted. Estimates of the appropriate discount rate appropriate in this case, from the 1990s, ranged from 1 to 3 percent per annum.[23]

A second reason for discounting the benefits and costs accruing to future generations at a lower rate is increased uncertainty about the appropriate value of the discount rate, the longer the horizon for the analysis. Private market rates provide a reliable reference for determining how society values time within a generation, but for extremely long time periods no comparable private rates exist. As explained by Martin Weitzman[24], in the limit for the deep future, the properly averaged certainty-equivalent discount factor (i.e., $1/[1+r]^t$) corresponds to the minimum discount rate having any substantial positive probability. From today's perspective, the only relevant limiting scenario is the one with the lowest discount rate – all of the other states at the far-distant time are relatively much less important because their expected present value is so severely reduced by the power of compounding at a higher rate.

If your rule will have important intergenerational benefits or costs you might consider a further sensitivity analysis using a lower but positive discount rate in addition to calculating net benefits using discount rates of 3 and 7 percent.

5. Time Preference for Non-Monetized Benefits and Costs

Differences in timing should be considered even for benefits and costs that are not expressed in monetary units, including health benefits. The timing differences can be handled through discounting. EPA estimated cost-effectiveness in its 1998 rule, "Control of Emissions from Nonroad Diesel Engines," by discounting both the monetary costs and the non-monetized emission reduction benefits over the expected useful life of the engines at the 7 percent real rate recommended in OMB Circular A-94.

Alternatively, it may be possible in some cases to avoid discounting non-monetized benefits. If the expected flow of benefits begins as soon as the cost is incurred and is expected to be constant over time, then annualizing the cost stream is sufficient, and further discounting of benefits is unnecessary. Such an analysis might produce an estimate of the annualized cost per ton of reduced emissions of a pollutant.

6. The Internal Rate of Return

The internal rate of return is the discount rate that sets the net present value of the discounted benefits and costs equal to zero. The internal rate of return does not generally

---

[23] Portney PR and Weyant JP, eds. (1999), *Discounting and Intergenerational Equity*, Resources for the Future, Washington, DC.

[24] Weitzman ML In Portney PR and Weyant JP, eds. (1999), *Discounting and Intergenerational Equity*, Resources for the Future, Washington, DC.

provide an acceptable decision criterion, and regulations with the highest internal rate of return are not necessarily the most beneficial. Nevertheless, it does provide useful information and for many it will offer a meaningful indication of regulation's impact. You should consider including the internal rate of return implied by your regulatory analysis along with other information about discounted net present values.

Other Key Considerations

1. Other Benefit and Cost Considerations

You should include these effects in your analysis and provide estimates of their monetary values when they are significant:

- Private-sector compliance costs and savings;
- Government administrative costs and savings;
- Gains or losses in consumers' or producers' surpluses;
- Discomfort or inconvenience costs and benefits; and
- Gains or losses of time in work, leisure and/or commuting/travel settings.

Estimates of benefits and costs should be based on credible changes in technology over time. For example, retrospective studies may provide evidence that “learning” will likely reduce the cost of regulation in future years. The weight you give to a study of past rates of cost savings resulting from innovation (including “learning curve” effects) should depend on both its timeliness and direct relevance to the processes affected by the regulatory alternative under consideration. In addition, you should take into account cost-saving innovations that result from a shift to regulatory performance standards and incentive-based policies. On the other hand, significant costs may result from a slowing in the rate of innovation or of adoption of new technology due to delays in the regulatory approval process or the setting of more stringent standards for new facilities than existing ones. In some cases agencies are limited under statute to consider only technologies that have been demonstrated to be feasible. In these situations, it may be useful to estimate costs and cost savings assuming a wider range of technical possibilities.

When characterizing technology changes over time, you should assess the likely technology changes that would have occurred in the absence of the regulatory action (technology baseline). Technologies change over time in both reasonably functioning markets and imperfect markets. If you assume that technology will remain unchanged in the absence of regulation when technology changes are likely, then your analysis will over-state both the benefits and costs attributable to the regulation.

Occasionally, cost savings or other forms of benefits accrue to parties affected by a rule who also bear its costs. For example, a requirement that engine manufacturers reduce emissions from engines may lead to technologies that improve fuel economy. These fuel savings will normally accrue to the engine purchasers, who also bear the costs of the technologies. There is no apparent market failure with regard to the market value of fuel saved because one would expect that consumers would be willing to pay for increased fuel economy that exceeded the cost of providing it. When these cost savings are substantial, and particularly when you estimate them to be greater than the cost associated with achieving them, you should examine and discuss why market forces would not accomplish these gains in the absence of regulation. As a general matter, any direct costs that are averted as a result of a regulatory action should be monetized wherever possible and either added to the benefits or subtracted from the costs of that alternative.

2. The Difference between Costs (or Benefits) and Transfer Payments

Distinguishing between real costs and transfer payments is an important, but sometimes difficult, problem in cost estimation. Benefit and cost estimates should reflect real resource use. Transfer payments are monetary payments from one group to another that do not affect total resources available to society. A regulation that restricts the supply of a good, causing its price to rise, produces a transfer from buyers to sellers. The net reduction in the total surplus (consumer plus producer) is a real cost to society, but the transfer from buyers to sellers resulting from a higher price is not a real cost since the net reduction automatically accounts for the transfer from buyers to sellers. However, transfers from the United States to other nations should be included as costs, and transfers from other nations to the United States as benefits, as long as the analysis is conducted from the United States perspective.

You should not include transfers in the estimates of the benefits and costs of a regulation. Instead, address them in a separate discussion of the regulation's distributional effects. Examples of transfer payments include the following:

- Scarcity rents and monopoly profits
- Insurance payments
- Indirect taxes and subsidies

Treatment of Uncertainty

The precise consequences (benefits and costs) of regulatory options are not always known for certain, but the probability of their occurrence can often be developed. The important uncertainties connected with your regulatory decisions need to be analyzed and presented as part of the overall regulatory analysis. You should begin your analysis of uncertainty at the earliest possible stage in developing your analysis. You should consider both the statistical variability of key elements underlying the estimates of benefits and costs (for example, the expected change in the distribution of automobile accidents that might result from a change in automobile safety standards) and the incomplete knowledge about the relevant relationships (for example, the uncertain knowledge of how some economic activities might affect future climate change).[25] By assessing the sources of uncertainty and the way in which benefit and cost estimates may be affected under plausible assumptions, you can shape your analysis to inform decision makers and the public about the effects and the uncertainties of alternative regulatory actions.

---

[25] In some contexts, the word "variability" is used as a synonym for statistical variation that can be described by a theoretically valid distribution function, whereas "uncertainty" refers to a more fundamental lack of knowledge. Throughout this discussion, we use the term "uncertainty" to refer to both concepts.

The treatment of uncertainty must be guided by the same principles of full disclosure and transparency that apply to other elements of your regulatory analysis. Your analysis should be credible, objective, realistic, and scientifically balanced.[26] Any data and models that you use to analyze uncertainty should be fully identified. You should also discuss the quality of the available data used. Inferences and assumptions used in your analysis should be identified, and your analytical choices should be explicitly evaluated and adequately justified. In your presentation, you should delineate the strengths of your analysis along with any uncertainties about its conclusions. Your presentation should also explain how your analytical choices have affected your results.

In some cases, the level of scientific uncertainty may be so large that you can only present discrete alternative scenarios without assessing the relative likelihood of each scenario quantitatively. For instance, in assessing the potential outcomes of an environmental effect, there may be a limited number of scientific studies with strongly divergent results. In such cases, you might present results from a range of plausible scenarios, together with any available information that might help in qualitatively determining which scenario is most likely to occur.

When uncertainty has significant effects on the final conclusion about net benefits, your agency should consider additional research prior to rulemaking. The costs of being wrong may outweigh the benefits of a faster decision. This is true especially for cases with irreversible or large upfront investments. If your agency decides to proceed with rulemaking, you should explain why the costs of developing additional information—including any harm from delay in public protection—exceed the value of that information.

For example, when the uncertainty is due to a lack of data, you might consider deferring the decision, as an explicit regulatory alternative, pending further study to obtain sufficient data.[27] Delaying a decision will also have costs, as will further efforts at data gathering and analysis. You will need to weigh the benefits of delay against these costs in making your decision. Formal tools for assessing the value of additional information are now well developed in the applied decision sciences and can be used to help resolve this type of complex regulatory question.

"Real options" methods have also formalized the valuation of the added flexibility inherent in delaying a decision. As long as taking time will lower uncertainty, either passively or actively through an investment in information gathering, and some costs are irreversible, such as the potential costs of a sunk investment, a benefit can be assigned to the option to delay a decision. That benefit should be considered a cost of taking immediate action versus the alternative of delaying that action pending more information. However, the burdens of delay—including any harm to public health, safety, and the environment—need to be analyzed carefully.

1. Quantitative Analysis of Uncertainty

---

[26] When disseminating information, agencies should follow their own information quality guidelines, issued in conformance with the OMB government-wide guidelines (67 FR 8452, February 22, 2002).

[27] Clemen RT (1996), *Making Hard Decisions: An Introduction to Decision Analysis*, second edition, Duxbury Press, Pacific Grove.

Examples of quantitative analysis, broadly defined, would include formal estimates of the probabilities of environmental damage to soil or water, the possible loss of habitat, or risks to endangered species as well as probabilities of harm to human health and safety. There are also uncertainties associated with estimates of economic benefits and costs, such as the cost savings associated with increased energy efficiency. Thus, your analysis should include two fundamental components: a quantitative analysis characterizing the probabilities of the relevant outcomes and an assignment of economic value to the projected outcomes. It is essential that both parts be conceptually consistent. In particular, the quantitative analysis should be conducted in a way that permits it to be applied within a more general analytical framework, such as benefit-cost analysis. Similarly, the general framework needs to be flexible enough to incorporate the quantitative analysis without oversimplifying the results. For example, you should address explicitly the implications for benefits and costs of any probability distributions developed in your analysis.

As with other elements of regulatory analysis, you will need to balance thoroughness with the practical limits on your analytical capabilities. Your analysis does not have to be exhaustive, nor is it necessary to evaluate each alternative at every step. Attention should be devoted to first resolving or studying the uncertainties that have the largest potential effect on decision making. Many times these will be the largest sources of uncertainties. In the absence of adequate data, you will need to make assumptions. These should be clearly identified and consistent with the relevant science. Your analysis should provide sufficient information for decision makers to grasp the degree of scientific uncertainty and the robustness of estimated probabilities, benefits, and costs to changes in key assumptions.

For major rules involving annual economic effects of $1 billion or more, you should present a formal quantitative analysis of the relevant uncertainties about benefits and costs. In other words, you should try to provide some estimate of the probability distribution of regulatory benefits and costs. In summarizing the probability distributions, you should provide some estimates of the central tendency (e.g., mean and median) along with any other information you think will be useful such as ranges, variances, specified low-end and high-end percentile estimates, and other characteristics of the distribution.

Your estimates cannot be more precise than their most uncertain component. Thus, your analysis should report estimates in a way that reflects the degree of uncertainty and not create a false sense of precision. Worst-case or conservative analyses are not usually adequate because they do not convey the complete probability distribution of outcomes, and they do not permit calculation of an expected value of net benefits. In many health and safety rules, economists conducting benefit-cost analyses must rely on formal risk assessments that address a variety of risk management questions such as the baseline risk for the affected population, the safe level of exposure or, the amount of risk to be reduced by various interventions. Because the answers to some of these questions are directly used in benefits analyses, the risk assessment methodology must allow for the determination of expected benefits in order to be comparable to expected costs. This means that conservative assumptions and defaults (whether motivated by science policy or by precautionary instincts), will be incompatible with benefit analyses as they will result in benefit estimates that exceed the expected value. Whenever it is possible to characterize quantitatively the probability distributions, some estimates of expected value (e.g., mean and median) must be provided in addition to ranges, variances, specified low-end and high-end percentile estimates, and other characteristics of the distribution.

Whenever possible, you should use appropriate statistical techniques to determine a probability distribution of the relevant outcomes. For rules that exceed the $1 billion annual threshold, a formal quantitative analysis of uncertainty is required. For rules with annual benefits and/or costs in the range from 100 million to $1 billion, you should seek to use more rigorous approaches with higher consequence rules. This is especially the case where net benefits are close to zero. More rigorous uncertainty analysis may not be necessary for rules in this category if simpler techniques are sufficient to show robustness. You may consider the following analytical approaches that entail increasing levels of complexity:

- Disclose qualitatively the main uncertainties in each important input to the calculation of benefits and costs. These disclosures should address the uncertainties in the data as well as in the analytical results. However, major rules above the $1 billion annual threshold require a formal treatment.
- Use a numerical sensitivity analysis to examine how the results of your analysis vary with plausible changes in assumptions, choices of input data, and alternative analytical approaches. Sensitivity analysis is especially valuable when the information is lacking to carry out a formal probabilistic simulation. Sensitivity analysis can be used to find "switch points" -- critical parameter values at which estimated net benefits change sign or the low cost alternative switches. Sensitivity analysis usually proceeds by changing one variable or assumption at a time, but it can also be done by varying a combination of variables simultaneously to learn more about the robustness of your results to widespread changes. Again, however, major rules above the $1 billion annual threshold require a formal treatment.
- Apply a formal probabilistic analysis of the relevant uncertainties – possibly using simulation models and/or expert judgment as revealed, for example, through Delphi methods.[28] Such a formal analytical approach is appropriate for complex rules where there are large, multiple uncertainties whose analysis raises technical challenges, or where the effects cascade; it is required for rules that exceed the $1 billion annual threshold. For example, in the analysis of regulations addressing air pollution, there is uncertainty about the effects of the rule on future emissions, uncertainty about how the change in emissions will affect air quality, uncertainty about how changes in air quality will affect health, and finally uncertainty about the economic and social value of the change in health outcomes. In formal probabilistic assessments, expert solicitation is a useful way to fill key gaps in your ability to assess uncertainty.[29] In general, experts can be used to quantify the probability distributions of key parameters and relationships. These solicitations, combined with other sources of data, can be combined in Monte Carlo simulations to derive a probability distribution of benefits and costs. You should

---

[28] The purpose of Delphi methods is to generate suitable information for decision making by eliciting expect judgment. The elicitation is conducted through a survey process which eliminates the interactions between experts. See Morgan MG and Henrion M (1990), *Uncertainty: A Guide to Dealing with Uncertainty in Quantitative Riskand Policy Analysis*, Cambridge University Press.

[29] Cooke RM (1991), *Experts in Uncertainty: Opinion and Subjective Probability in Science*, Oxford University Press.

pay attention to correlated inputs. Often times, the standard defaults in Monte Carlo and other similar simulation packages assume independence across distributions. Failing to correctly account for correlated distributions of inputs can cause the resultant output uncertainty intervals to be too large, although in many cases the overall effect is ambiguous. You should make a special effort to portray the probabilistic results—in graphs and/or tables—clearly and meaningfully.

New methods may become available in the future. This document is not intended to discourage or inhibit their use, but rather to encourage and stimulate their development.

2. Economic Values of Uncertain Outcomes

In developing benefit and cost estimates, you may find that there are probability distributions of values as well for each of the outcomes. Where this is the case, you will need to combine these probability distributions to provide estimated benefits and costs.

Where there is a distribution of outcomes, you will often find it useful to emphasize summary statistics or figures that can be readily understood and compared to achieve the broadest public understanding of your findings. It is a common practice to compare the "best estimates" of both benefits and costs with those of competing alternatives. These "best estimates" are usually the average or the expected value of benefits and costs. Emphasis on these expected values is appropriate as long as society is "risk neutral" with respect to the regulatory alternatives. While this may not always be the case, you should in general assume "risk neutrality" in your analysis. If you adopt a different assumption on risk preference, you should explain your reasons for doing so.

3. Alternative Assumptions

If benefit or cost estimates depend heavily on certain assumptions, you should make those assumptions explicit and carry out sensitivity analyses using plausible alternative assumptions. If the value of net benefits changes from positive to negative (or vice versa) or if the relative ranking of regulatory options changes with alternative plausible assumptions, you should conduct further analysis to determine which of the alternative assumptions is more appropriate. Because different estimation methods may have hidden assumptions, you should analyze estimation methods carefully to make any hidden assumptions explicit.

F. Specialized Analytical Requirements

In preparing analytical support for your rulemaking, you should be aware that there are a number of analytic requirements imposed by law and Executive Order. In addition to the regulatory analysis requirements of Executive Order 12866, you should also consider whether your rule will need specialized analysis of any of the following issues.

Impact on Small Businesses and Other Small Entities

Under the Regulatory Flexibility Act (5 U.S.C. chapter 6), agencies must prepare a proposed and final "regulatory flexibility analysis" (RFA) if the rulemaking could "have a significant impact on a substantial number of small entities." You should consider posting your RFA on the internet so the public can review your findings.

Your agency should have guidelines on how to prepare an RFA and you are encouraged to consult with the Chief Counsel for Advocacy of the Small Business Administration on expectations concerning what is an adequate RFA. Executive Order 13272 (67 FR 53461, August 16, 2002) requires you to notify the Chief Counsel for Advocacy of any draft rules that might have a significant economic impact on a substantial number of small entities. Executive Order 13272 also directs agencies to give every appropriate consideration to any comments provided by the Advocacy Office. Under SBREFA, EPA and OSHA are required to consult with small business prior to developing a proposed rule that would have a significant effect on small businesses. OMB encourages other agencies to do so as well.

Analysis of Unfunded Mandates

Under the Unfunded Mandates Act (2 U.S.C. 1532), you must prepare a written statement about benefits and costs prior to issuing a proposed or final rule (for which your agency published a proposed rule) that may result in aggregate expenditure by State, local, and tribal governments, or by the private sector, of $100,000,000 or more in any one year (adjusted annually for inflation). Your analytical requirements under Executive Order 12866 are similar to the analytical requirements under this Act, and thus the same analysis may permit you to comply with both analytical requirements.

Information Collection, Paperwork, and Recordkeeping Burdens

Under the Paperwork Reduction Act (44 U.S.C. chapter 35), you will need to consider whether your rulemaking (or other actions) will create any additional information collection, paperwork or recordkeeping burdens. These burdens are permissible only if you can justify the practical utility of the information for the implementation of your rule. OMB approval will be required of any new requirements for a collection of information imposed on 10 or more persons and a valid OMB control number must be obtained for any covered paperwork. Your agency's CIO should be able to assist you in complying with the Paperwork Reduction Act.

Information Quality Guidelines

Under the Information Quality Law, agency guidelines, in conformance with the OMB government-wide guidelines (67 FR 8452, February 22, 2002), have established basic quality performance goals for all information disseminated by agencies, including information disseminated in support of proposed and final rules. The data and analysis that you use to support your rule must meet these agency and OMB quality standards. Your agency's CIO should be able to assist you in assessing information quality. The Statistical and Science Policy

Branch of OMB's Office of Information and Regulatory Affairs can provide you assistance. This circular defines OMB's minimum quality standards for regulatory analysis.

Environmental Impact Statements

The National Environmental Policy Act (42 U.S.C. 4321-4347) and related statutes and executive orders require agencies to consider the environmental impacts of agency decisions, including rulemakings. An environmental impact statement must be prepared for "major Federal actions significantly affecting the quality of the human environment." You must complete NEPA documentation before issuing a final rule. The White House Council on Environmental Quality has issued regulations (40 C.F.R. 1500-1508) and associated guidance for implementation of NEPA, available through CEQ's website (http://www.whitehouse/gov/ceq/).

Impacts on Children

Under Executive Order 13045, "Protection of Children from Environmental Health Risks and Safety Risks," each agency must, with respect to its rules, "to the extent permitted by law and appropriate, and consistent with the agency's mission," "address disproportionate risks to children that result from environmental health risks or safety risks." For any substantive rulemaking action that "is likely to result in" an economically significant rule that concerns "an environmental health risk or safety risk that an agency has reason to believe may disproportionately affect children," the agency must provide OMB/OIRA "an evaluation of the environmental health or safety effects of the planned regulation on children," as well as "an explanation of why the planned regulation is preferable to other potentially and reasonably feasible alternatives considered by the agency."

Energy Impacts

Under Executive Order 13211 (66 FR 28355, May 22, 2001), agencies are required to prepare and submit to OMB a Statement of Energy Effects for significant energy actions, to the extent permitted by law. This Statement is to include a detailed statement of "any adverse effects on energy supply, distribution, or use (including a shortfall in supply, price increases, and increased use of foreign supplies)" for the action and reasonable alternatives and their effects. You need to publish the Statement or a summary in the related NPRM and final rule. For further guidance, see OMB Memorandum 01-27 ("Guidance on Implementing Executive Order 13211", July 13, 2001), available on OMB's website.

G. Accounting Statement

You need to provide an accounting statement with tables reporting benefit and cost estimates for each major final rule for your agency. You should use the guidance outlined above to report these estimates. We have included a suggested format for your consideration.

Categories of Benefits and Costs

To the extent feasible, you should quantify all potential incremental benefits and costs. You should report benefit and cost estimates within the following three categories: monetized quantified, but not monetized; and qualitative, but not quantified or monetized.

These categories are mutually exclusive and exhaustive. Throughout the process of listing preliminary estimates of benefits and costs, agencies should avoid double-counting. This problem may arise if more than one way exists to express the same change in social welfare.

Quantifying and Monetizing Benefits and Costs

You should develop quantitative estimates and convert them to dollar amounts if possible. In many cases, quantified estimates are readily convertible, with a little effort, into dollar equivalents.

Qualitative Benefits and Costs

You should categorize or rank the qualitative effects in terms of their importance (e.g., certainty, likely magnitude, and reversibility). You should distinguish the effects that are likely to be significant enough to warrant serious consideration by decision makers from those that are likely to be minor.

Treatment of Benefits and Costs over Time

You should present undiscounted streams of benefit and cost estimates (monetized and net) for each year of the analytic time horizon. You should present annualized benefits and costs using real discount rates of 3 and 7 percent. The stream of annualized estimates should begin in the year in which the final rule will begin to have effects, even if the rule does not take effect immediately. Please report all monetized effects in 2001 dollars. You should convert dollars expressed in different years to 2001 dollars using the GDP deflator.

Treatment of Risk and Uncertainty

You should provide expected-value estimates as well as distributions about the estimates, where such information exists. When you provide only upper and lower bounds (in addition to best estimates), you should, if possible, use the 95 and 5 percent confidence bounds. Although we encourage you to develop estimates that capture the distribution of plausible outcomes for a particular alternative, detailed reporting of such distributions is not required, but should be available upon request.

The principles of full disclosure and transparency apply to the treatment of uncertainty. Where there is significant uncertainty and the resulting inferences and/or assumptions have a critical effect on the benefit and cost estimates, you should describe the benefits and costs under plausible alternative assumptions. You may add footnotes to the table as needed to provide documentation and references, or to express important warnings.

In a previous section, we identified some of the issues associated with developing estimates of the value of reductions in premature mortality risk. Based on this discussion, you should present alternative primary estimates where you use different estimates for valuing reductions in premature mortality risk.

Precision of Estimates

Reported estimates should reflect, to the extent feasible, the precision in the analysis. For example, an estimate of $220 million implies rounding to the nearest $10 million and thus a precision of +/-$5 million; similarly, an estimate of $222 million implies rounding to the nearest $1 million and thus, a precision of +/-$0.5 million.

Separate Reporting of Transfers

You should report transfers separately and avoid the misclassification of transfer payments as benefits or costs. Transfers occur when wealth or income is redistributed without any direct change in aggregate social welfare. To the extent that regulatory outputs reflect transfers rather than net welfare gains to society, you should identify them as transfers rather than benefits or costs. You should also distinguish transfers caused by Federal budget actions -- such as those stemming from a rule affecting Social Security payments -- from those that involve transfers between non-governmental parties -- such as monopoly rents a rule may confer on a private party. You should use as many categories as necessary to describe the major redistributive effects of a regulatory action. If transfers have significant efficiency effects in addition to distributional effects, you should report them.

Effects on State, Local, and Tribal Governments, Small Business, Wages and Economic Growth

You need to identity the portions of benefits, costs, and transfers received by State, local, and tribal governments. To the extent feasible, you also should identify the effects of the rule or program on small businesses, wages, and economic growth.[30] Note that rules with annual costs that are less than one billion dollars are likely to have a minimal effect on economic growth.

H. Effective Date

The effective date of this Circular is January 1, 2004 for regulatory analyses received by OMB in support of proposed rules, and January 1, 2005 for regulatory analyses received by OMB in support of final rules. In other words, this Circular applies to the regulatory analyses for draft proposed rules that are formally submitted to OIRA after December 31, 2003, and for draft final rules that are formally submitted to OIRA after December 31, 2004. (However, if the draft proposed rule is subject to the Circular, then the draft final rule will also be subject to the Circular, even if it is submitted prior to January 1, 2005.) To the extent practicable, agencies should comply earlier than these effective dates. Agencies may, on a case-by-case basis, seek a waiver from OMB if these effective dates are impractical.

Regulatory Impact Analysis: Frequently Asked Questions (FAQs)

February 7, 2011

With this document, the Office of Information and Regulatory Affairs (OIRA) is providing answers to frequently asked questions about the regulatory impact analysis that is required by Executive Order 12866 and OMB Circular A-4.[1] In addition, President Obama signed Executive Order 13563, "Improving Regulation and Regulatory Review," on January 18, 2011; that Executive Order incorporates the requirements of Executive Order 12866 and specifically directs agencies "to use the best available techniques to quantify anticipated present and future benefits and costs as accurately as possible."

The purpose of this document is to offer answers to questions often asked with respect to regulatory impact analysis; nothing said here is meant to alter existing requirements in any way. For more complete guidance, please consult Executive 13563, Executive Order 12866, and Circular A-4.

1. When do I need to provide a regulatory impact analysis, and what is the definition of "economically significant"?

Executive Order 12866 provides that agencies must submit a regulatory impact analysis for those regulatory actions that are "significant" within the meaning of Section 3(f)(1) – or what Circular A-4 describes as "economically significant."[2] A regulatory action is economically significant if it is anticipated (1) to "[h]ave [1] an annual effect on the economy of $100 million or more" or (2) to "adversely affect in a material way the economy, a sector of the economy, productivity, competition, jobs, the environment, public health or safety, or State, local, or tribal governments or communities."

The $100 million threshold applies to the impact of the proposed or final regulation in *any one year,* and it includes *benefits, costs, or transfers*. (The word "or" is important: $100 million in annual benefits, *or* costs, *or* transfers is sufficient; $50 million in benefits and $49 million in costs, for example, is not.)

The second criterion – whether the rule would "adversely affect in a material way the economy, a sector of the economy, productivity, competition, jobs, the environment, public health or safety, or State, local, or tribal governments or communities" – requires careful consideration of the phrase "adversely affect in a material way." There are no hard-and-fast rules here. Suppose, for example, that a regulation (1) would impose $98 million in first-year costs for pollution control equipment, with lower annual costs thereafter, (2) would disproportionately and adversely affect a small sector of the economy, and (3) would threaten to create significant job loss. This rule would be considered economically significant.

The $100 million threshold is identical to the monetary threshold for determining whether a rule is “major” under the Congressional Review Act (CRA). Under that Act, a “major rule” is one that “has resulted in or is likely to result in . . . an annual effect on the economy of $100,000,000 or more.”[3] For both Executive Order 12866 and the CRA, the $100 million threshold is not adjusted for inflation (unlike the expenditure threshold contained in the Unfunded Mandates Reform Act[4]). Under the Congressional Review Act, a rule also qualifies as “major” if it has resulted in or is likely to result in “a major increase in costs or prices for consumers, individual industries, Federal, State, or local government agencies, or geographic regions” or “significant adverse effects on competition, employment, investment, productivity, innovation, or on the ability of United States-based enterprises to compete with foreign-based enterprises in domestic and export markets.”[5]

2. How should my regulatory impact analysis be presented to the public?

To inform the public of the expected consequences of regulations, agencies should present their analysis in plain language. To promote transparency and public participation, they should provide a clear executive summary of their central conclusions.[6] They should clearly and prominently include a standardized accounting statement, and are particularly encouraged to do so in the preamble and executive summary.[7] That statement should include one or more tables summarizing their assessment of costs, benefits, and transfers, at both 3% and 7% discount rates.[8] Consistent with the Executive Order 13563 and Executive Order 12866, OMB recommends that the tables provide a transparent statement of both quantitative and qualitative benefits and costs of the proposed or planned action as well as of reasonable alternatives.[9] In addition to providing a clear table of aggregate costs and benefits, agencies are strongly encouraged to provide one or more separate tables disaggregating and showing the components of those figures.[10]

In comparing benefits to costs, agencies should emphasize net benefits rather than ratios. As Circular A-4 states, “[t]he size of net benefits, the absolute difference between the projected benefits and costs, indicates whether one policy is more efficient than another. The ratio of benefits to costs is not a meaningful indicator of net benefits and should not be used for that purpose. It is well known that considering such ratios alone can yield misleading results.”[11]

3. Can something other than a “market failure” be identified as the “need” for the regulation?

Yes. Executive Order 13563 states, “Where appropriate and permitted by law, each agency may consider (and discuss qualitatively) values that are difficult or impossible to quantify, including equity, human dignity, fairness, and distributive impacts.” Circular A-4 states that “you should try to explain whether the action is intended to address a significant market failure *or* to meet some other compelling public need such as improving governmental processes or promoting intangible values such as distributional fairness or privacy.”[12] The word “or” is once again significant: if a market failure does not exist but there is a compelling public need for regulation, then the agency should clearly identify the problem that it intends to address and explain and assess the significance of that problem.[13]

4. Even if I have identified a market failure or other need for regulation, should I still consider alternatives to Federal regulation?

Yes. In taking into account a range of alternatives, you should begin by asking whether to regulate at all. Even where a market failure clearly exists, there may be alternatives to Federal regulation, including antitrust enforcement, consumer-initiated litigation in the product liability system, and administrative compensation systems.[14]

You should also consider the option of deferring to regulation at the State or local level. To be sure, problems that affect interstate commerce or spill across State lines may best be addressed by Federal regulation. But more localized problems may be more efficiently addressed locally.[15] In such situations, deferring to state and local regulation can encourage regulatory experimentation and innovation while also fostering learning and competition to establish the best regulatory policies.[16]

There are often questions about the proper relationship among Federal, state, and local requirements. Where Federal regulation is warranted, you should avoid imposing conflicting or duplicative requirements wherever possible. Executive Order 13563 states, “Some sectors and industries face a significant number of regulatory requirements, some of which may be redundant, inconsistent, or overlapping. Greater coordination across agencies could reduce these requirements, thus reducing costs and simplifying and harmonizing rules. In developing regulatory actions and identifying appropriate approaches, each agency shall attempt to promote such coordination, simplification, and harmonization.”

While some problems are best handled at the state level, others can be handled through simultaneous regulation from different levels of government. In some cases, however, the increased compliance costs required for firms to meet different State and local regulations may exceed any benefits stemming from the diversity of State and local regulation.[17] With close reference to statutory requirements and governing legal principles, you should consider when and whether it is appropriate to retain State and local regulation.

5. After determining that Federal regulation is the best way to proceed, how do I identify and provide an adequate analysis of “potentially effective and reasonably feasible alternatives” as required by Executive Order 12866 ?

Executive Order 12866 requires an “assessment, including the underlying analysis, of costs and benefits of potentially effective and reasonably feasible alternatives to the planned regulation” and “an explanation why the planned regulatory action is preferable to the identified potential alternatives.”[18] You should ordinarily consider analyzing at least three options: the preferred option; a more stringent option; and a less stringent one.[19]

In some cases, the relevant alternatives might not line up on a continuum of stringency, but might involve different approaches, with distinct advantages and disadvantages. If, for example, an agency is considering banning the sale of a potentially unsafe product, it might consider instead requiring disclosure of health risks to the public. Executive Order 13563 states, "Where relevant, feasible, and consistent with regulatory objectives, and to the extent permitted by law, agencies shall identify and consider regulatory approaches that reduce burdens and maintain flexibility and freedom of choice for the public." Warnings, appropriate default rules, and disclosure requirements are examples.

In considering which alternatives to discuss, you should explore which approaches are feasible and plausible ways of meeting the regulatory objective. When the preferred option includes a number of distinct provisions, the benefits and costs of different regulatory provisions should be analyzed separately in order to facilitate consideration of the full range of potential alternatives.[20]

6. What is the appropriate time horizon for estimating costs and benefits?

Executive Order 13563 directs agencies "to use the best available techniques to quantify anticipated present and future benefits and costs as accurately as possible." When choosing the appropriate time horizon for estimating costs and benefits, agencies should consider how long the regulation being analyzed is likely to have resulting effects. The time horizon begins when the regulatory action is implemented and ends when those effects are expected to cease.[21] Ideally, analysis should include all future costs and benefits. Here as elsewhere, however, a "rule of reason" is appropriate, and the agency should consider for how long it can reasonably predict the future and limit its analysis to this time period. Thus, if a regulation has no predetermined sunset provision, the agency will need to choose the endpoint of its analysis on the basis of a judgment about the foreseeable future. For rules that require large up-front capital investments, the life of the capital is also an option. For most agencies, a standard time period of analysis is 10 to 20 years, and rarely exceeds 50 years.

7. What is a baseline and how do I identify it?

The baseline is the best assessment of how the world would look in the absence of the proposed action during the relevant time horizon. Specifically, the baseline should incorporate the agency's best forecast for how the world will change (if at all) during the identified time horizon, with particular attention to factors such as the evolution of relevant markets; population or economic growth; possible behavioral changes, learning, and adaptation by relevant members of the public; technological changes and advances; and changes in regulations promulgated by the agency or other government entities. Identifying this baseline is necessary to allow assessment of the relative benefits and costs attributable to the proposed action.[22]

For review of an existing regulation or one that simply restates statutory requirements that are self-implementing, a pre-statute baseline, assuming "no change," is appropriate.[23]

Multiple baselines could be appropriate when more than one baseline is reasonable – perhaps because another agency's existing regulation could be implemented in different ways – and the choice would significantly affect estimated benefits and costs.[24]

8. When should I conduct an uncertainty analysis? A sensitivity analysis?

Regulatory analysis requires predictions about the future. What the future holds, both in the baseline and under the regulatory alternative under consideration, is rarely certain. The important uncertainties connected with the regulatory decision should be analyzed and presented as part of the regulatory impact analysis.[25] It is common practice for an agency's uncertainty analysis to present a central "best estimate," which reflects the expected value of the benefits and costs of the rule, as well as a description of the ranges of plausible values for benefits, costs, and net benefits. This description informs the decision-makers and the public of the degree of uncertainty associated with the regulatory decision.[26]

In general, you should also include a "sensitivity analysis" that shows how results of your analysis vary with plausible changes in assumptions, choices of input data, and alternative analytical approaches.[27] The level of detail in the analysis can vary with the expected effects of the rule; you should use more rigorous analytical approaches, and more comprehensive sensitivity analysis, for rules with especially large consequences. For rules that exceed the $1 billion annual threshold, Circular A-4 states that "a formal quantitative analysis of uncertainty is required."

9. What is the difference between a transfer and a cost?

Costs affect the total resources available to society. Transfer payments are monetary payments from one group to another that do not affect total resources.[28] The agency should not include transfer payments in its estimates of the benefits and costs of a regulation. Instead, it should address them in a separate discussion of the distributional effects of the regulation.[29] Distinguishing between real costs and transfer payments is an important, but sometimes difficult, problem in cost estimation.

Examples of costs include:

- Expenditures, including goods and services, required to comply with the regulation
- Reductions in consumer and producer well-being resulting from regulation-induced price or quantity changes
- Increases in premature death, illness, or disability (e.g., in the case where a regulation that would reduce certain safety risks would have the consequence of increasing other safety risks).

Examples of transfers include:

- Fees to government agencies for goods or services already provided by the agency (that is, monetary transfers from feepayers to the government—because the goods and services are already counted as government costs, including them as private costs would entail double counting)
- Increases in sales tax revenue as a result of increases in sales (that is, monetary transfers from consumers to government)
- Payments by the Federal government for goods or services provided by the private sector (that is, monetary transfers by the government to service providers, such as reimbursements by the Medicare program)
- Reductions in sales by one business that are matched by increases in sales by another (that is, transfers in economic activity from one business to another)
- Reductions in resources for some consumers that are matched by increases for others (that is, transfers of resources among consumers)[30]

10. <u>Why must I present the estimates using both 3% and 7% discount rates</u>?

The 7 percent rate is a recent estimate of the average before-tax rate of return to private capital in the U.S. economy. It is a broad measure that reflects the returns to real estate and small business capital in the private sector.[31] The effects of regulation, however, do not always fall exclusively or primarily on the allocation of capital. When regulation primarily and directly affects private consumption (e.g., through higher consumer prices for goods and services), a lower discount rate is appropriate. The alternative most often used is sometimes called the "social rate of time preference," which simply means the rate at which "society" discounts future consumption flows to their present value. If we use the rate that the average saver uses to discount future consumption as our measure, then the real rate of return on long-term government debt provides a fair approximation. Historically, this rate has averaged around 3 percent in real terms on a pre-tax basis.[32]

Special considerations arise when comparing benefits and costs across generations. If the regulatory action will have important intergenerational benefits or costs, the agency should consider a sensitivity analysis, using a lower but positive discount rate, in addition to calculating net benefits using discount rates of 3 percent and 7 percent.[33]

11. <u>How do I value time</u>?

Some regulations require people to spend time on certain activities to comply with their provisions – as, for example, through paperwork or monitoring. The costs of such requirements should be described both in terms of hours and to the extent feasible, in terms of monetary equivalents. In order to value the cost of time, agencies should consider what those people would be doing with their time if they did not need to comply with the regulations.[34] The resulting figures, like all other costs and benefits, should be annualized (see below). As a general rule, workers' hourly wages can be used as a proxy for the value of the time that they could have spent doing other work. If the regulation requires paperwork, it may be appropriate to value the relevant time at the hourly wage for the workers asked to complete the required tasks. If specific expertise is needed to complete those tasks, the average wages of workers with that expertise should be used. If, for example, the regulation will require software changes by computer programmers, it would be appropriate to use the wages of computer programmers.

In some cases, regulations will result in time savings for individuals, and such savings should be described both in terms of hours saved and to the extent feasible, in terms of monetary equivalents. Monetized estimates should include a measure of the value of that time calculated in the same way as costs. If the time saved is not work, it is appropriate to try to estimate people's willingness to pay for the improvement. This estimate attempts to measure what individuals would be willing to pay to enjoy the particular benefit of time saved for the relevant activity.[35]

Sometimes regulations do not save time, but do lead to improvements in the quality of time spent on an activity. An example would be a regulation that requires airlines to provide adequate food and potable water to passengers within two hours of being delayed in an aircraft grounded on the tarmac. The regulation would not shorten people's waiting time, but would improve the quality of that waiting time. In this case, it is appropriate to try to estimate people's willingness to pay for the improvement. Studies or surveys of individuals in similar circumstances may be available to use as a reference point for estimates.

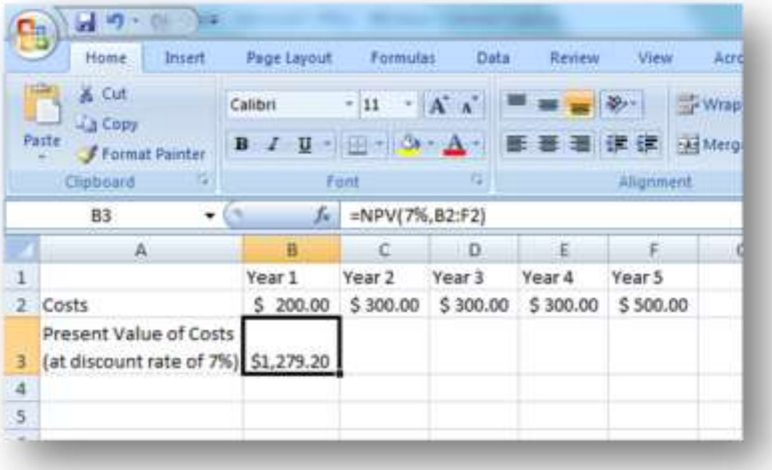
12. <u>How do I annualize?</u>

As part of a regulatory analysis, agencies are asked to provide estimates of the annualized costs and benefits of a regulation.[36] Under this requirement, agencies should take a stream of future benefits and costs of the rule and estimate its approximate yearly costs and benefits. The first step in the annualization of costs is to find the present value of the stream of future costs. To find that value, each year's expected costs should be discounted back to the present using the following formula:

$$Present\ Value\ of\ Year\ T's\ Costs = \frac{C_t}{(1+i)^t}$$

where C_t is the cost t years in the future and i is the discount rate.

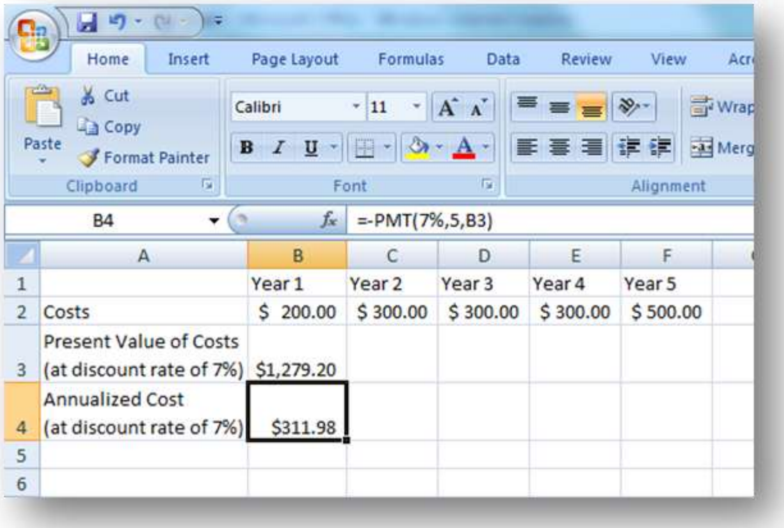
Then, each year's discounted costs should be added together to find the present value of costs. If you are using an Excel spreadsheet, you can use the NPV (Net Present Value) function to calculate the present value of costs from a set of future costs, as follows:



B3 =NPV(7%,B2:F2)

	A	B	C	D	E	F
1		Year 1	Year 2	Year 3	Year 4	Year 5
2	Costs	$ 200.00	$ 300.00	$ 300.00	$ 300.00	$ 500.00
3	Present Value of Costs (at discount rate of 7%)	$1,279.20				
4						
5						

The next step is to compute an annualized cost from this present value. This step is akin to spreading the costs equally over each period, taking account of the discount rate. If you are using Excel, an easy way to compute this amount is to use the PMT function, which calculates the annualized amount needed over a number of years to equal a given present value at a particular discount rate. The formula returns a negative number, so the result should be multiplied by -1 to obtain the annualized cost.



B4 =-PMT(7%,5,B3)

	A	B	C	D	E	F
1		Year 1	Year 2	Year 3	Year 4	Year 5
2	Costs	$ 200.00	$ 300.00	$ 300.00	$ 300.00	$ 500.00
3	Present Value of Costs (at discount rate of 7%)	$1,279.20				
4	Annualized Cost (at discount rate of 7%)	$311.98				
5						
6						

Annualized benefits can be computed from a stream of expected future benefits using the same method.

---

[1] Executive Order 12866 is available at: http://www.whitehouse.gov/sites/default/files/omb/inforeg/eo12866.pdf. Circular A-4 is available at: http://www.whitehouse.gov/sites/default/files/omb/assets/regulatory_matters_pdf/a-4.pdf.

[2] Executive Order 12866 refers to "those matters identified as, or determined by the Administrator of OIRA to be, a significant regulatory action within the scope of section 3(f)(1)." Circular A-4 states that "Executive Order 12866 requires agencies to conduct a regulatory analysis for economically significant regulatory actions as defined by Section 3(f)(1)." (P. 1).

[3] 5 U.S.C. § 804(2).

[4] Under the Unfunded Mandates Reform Act, each agency must prepare a benefit-cost analysis "before promulgating any general notice of proposed rulemaking that is likely to result in promulgation of any rule" that "includes any Federal mandate that may result in the expenditure by State, local, and tribal governments, in the aggregate, or by the private sector, of $100,000,000 or more (adjusted annually for inflation) in any 1 year." 2 U.S.C. §1532. For such rules, with limited exceptions, the "agency shall identify and consider a reasonable number of regulatory alternatives and from those alternatives select the least costly, most cost-effective or least burdensome alternative that achieves the objectives of the rule, for (1) State, local, and tribal governments, in the case of a rule containing a Federal intergovernmental mandate; and (2) the private sector, in the case of a rule containing a Federal private sector mandate." 2 U.S.C. §1535.

[5] *Id.* See also "Guidance for Implementing the Congressional Review Act," M-99-13, available at http://www.whitehouse.gov/sites/default/files/omb/assets/memoranda_2010/m99-13.pdf. Note that these alternative tests for a "major rule" under the CRA are not the same as the second criterion under Executive Order 12866 (to "adversely affect in a material way the economy, a sector of the economy, productivity, competition, jobs, the environment, public health or safety, or State, local, or tribal governments or communities"); by contrast, the CRA's language is drawn from Executive Order 12291, which was revoked in 1993. See Executive Order 12291, §1(b), available at http://www.archives.gov/federal-register/codification/executive-order/12291.html; Executive Order 12866, §11 ("Executive Order Nos. 12291 and 12498; all amendments to those Executive orders; all guidelines issued under those orders; and any exemptions from those orders heretofore granted for any category of rule are revoked.").

[6] Circular A-4 states: "Your analysis should . . . have an executive summary." (P. 3).

[7] Circular A-4 states that "[y]our analysis should . . . have an executive summary, including a standardized accounting statement." (P. 3). It also states that "[y]ou need to provide an accounting statement with tables reporting benefit and cost estimate for each major final rule for your agency." (P. 44). See also OMB's "2010 Report to Congress on the Benefits and Costs of Federal Regulations and Unfunded Mandates on State, Local, and Tribal Entities," available at http://www.whitehouse.gov/sites/default/files/omb/legislative/reports/2010_Benefit_Cost_Report.pdf. This report states that:

> For all economically significant regulatory actions, we recommend that agencies should clearly and prominently present, in the preamble and in the executive summary of the regulatory impact analysis, one or more tables summarizing the assessment of costs and benefits required under Executive Order 12866 Section 6(a)(3)(C)(i)-(iii). The tables should provide a transparent statement of both quantitative and qualitative benefits and costs of the proposed or planned action as well as of reasonable alternatives. The tables should include all relevant information that can be quantified and monetized, along with relevant information that can be described only in qualitative terms . . . . To the extent feasible in light of the nature of the issue and the relevant data, all benefits and costs should be quantified and monetized. To communicate any uncertainties, we recommend that the table should offer a range of values, in addition to best estimates, and it should clearly indicate impacts that cannot be quantified or monetized. If nonquantifiable variables are involved, they should be clearly identified. Agencies should attempt, to the extent feasible, not merely to identify such variables but also to signify their importance.
> (P. 51).

[8] Under the heading of "Accounting Statement," Circular A-4 states that "[y]ou should present undiscounted streams of benefit and cost estimates (monetized and net) for each year of the analytic time horizon. You should present annualized benefits and costs using real discount rates of 3 and 7 percent." (P. 45).

[9] Circular A-4 states: "The analysis document should discuss the expected benefits and costs of the selected regulatory option and any reasonable alternatives . . . . To present your results, you should: include separate schedules of the monetized benefits and costs that show the type and timing of benefits and costs, and express the estimates in this table in constant, undiscounted dollars . . . ; list the benefits and costs you can quantify, but cannot

---

monetize, including their timing; describe benefits and costs you cannot quantify; and identify or cross-reference the data or studies on which you base the benefit and cost estimates." (P. 18).

[10] See OMB's "2010 Report to Congress on the Benefits and Costs of Federal Regulations and Unfunded Mandates on State, Local, and Tribal Entities," available at http://www.whitehouse.gov/sites/default/files/omb/legislative/reports/2010_Benefit_Cost_Report.pdf. It states that "[i]t will often be useful to accompany a simple, clear table of aggregated costs and benefits with a separate table offering disaggregated figures, showing the components of the aggregate figures." (P. 51).

[11] See p. 10 of Circular A-4.

[12] See p. 4 of Circular A-4.

[13] Executive Order 12866 states that "Federal agencies should promulgate only such regulations as are required by law, are necessary to interpret the law, or are made necessary by compelling public need, such as material failures of private markets to protect or improve the health and safety of the public, the environment, or the well-being of the American people." Circular A-4 states that "you should try to explain whether the action is intended to address a significant market failure or to meet some other compelling public need such as improving governmental processes or promoting intangible values such as distributional fairness or privacy." (P. 4).

[14] Circular A-4 states: "Even where a market failure exists, you should consider other means of dealing with the failure before turning to Federal regulation. Alternatives to Federal regulation include antitrust enforcement, consumer-initiated litigation in the product liability system, or administrative compensation systems. In assessing whether Federal regulation is the best solution, you should also consider the possibility of regulation at the State or local level. In some cases, the nature of the market failure may itself suggest the most appropriate level of governmental level of regulation." (P. 5)

[15] Circular A-4 states: "In assessing whether Federal regulation is the best solution, you should also consider the possibility of regulation at the State or local level. In some cases, the nature of the market failure may itself suggest the most appropriate governmental level of regulation. For example, problems that spill across State lines (such as acid rain whose precursors are transported widely in the atmosphere) are probably best addressed by Federal regulation. More localized problems, including those that are common to many areas, may be more efficiently addressed locally." (P. 6).

[16] Circular A-4 states: "The advantages of leaving regulatory issues to State and local authorities can be substantial. If public values and preferences differ by region, those differences can be reflected in varying State and local regulatory policies. Moreover, States and localities can serve as a testing ground for experimentation with alternative regulatory policies. One State can learn from another's experience while local jurisdictions may compete with each other to establish the best regulatory policies. You should examine the proper extent of State and local discretion in your rulemaking context." (P. 6).

[17] Circular A-4 states: "Where Federal regulation is clearly appropriate to address interstate commerce issues, you should try to examine whether it would be more efficient to retain or reduce State and local regulation. The local benefits of State regulation may not justify the national costs of a fragmented regulatory system. For example, the increased compliance costs for firms to meet different State and local regulations may exceed any advantages associated with the diversity of State and local regulation. Your analysis should consider the possibility of reducing as well as expanding State and local rulemaking." (P. 6).

[18] See Section 6(a)(3)(C) of Executive Order 12866.

[19] Circular A-4 states: "In general, both the benefits and costs associated with a regulation will increase with the level of stringency (although marginal costs generally increase with stringency, whereas marginal benefits may decrease). You should study alternative levels of stringency to understand more fully the relationship between stringency and the size and distribution of benefits and costs among different groups." (P. 8).

[20] Circular A-4 states that when "consider[ing] alternative regulatory approaches," there "must be some balance between thoroughness and the practical limits on your analytical capacity. With this qualification in mind, you should nevertheless explore modifications of some or all of a regulation's attributes or provisions to identify appropriate alternatives." (P. 7).

[21] Circular A-4 states: "You should present undiscounted streams of benefit and cost estimates (monetized and net) for each year of the analytic time horizon." (P. 45). A-4 also provides that "you should present the annual time stream of benefits and costs expected to result from the rule, clearly identifying when the benefits and costs are expected to occur. The beginning point for your stream of estimates should be the year in which the final rule will begin to have effects, even if that is expected to be some time in the future. The ending point should be far enough in the future to encompass all the significant benefits and costs likely to result from the rule." (P. 31).

---

[22] Circular A-4 states that "[y]ou need to measure the benefits and costs of a rule against a baseline. This baseline should be the best assessment of the way the world would look absent the proposed action. The choice of an appropriate baseline may require consideration of a wide range of potential factors, including: evolution of the market, changes in external factors affecting expected benefits and costs, changes in regulations promulgated by the agency or other government entities, and the degree of compliance by regulated entities with other regulations." (P. 15).

[23] Circular A-4 states: "It may be reasonable to forecast that the world absent the regulation will resemble the present. If this is the case, however, your baseline should reflect the future effect of current government programs and policies. For review of an existing regulation, a baseline assuming 'no change' in the regulatory program generally provides an appropriate basis for evaluating regulatory alternatives. . . . In some cases, substantial portions of a rule may simply restate statutory requirements that would be self-implementing, even in the absence of the regulatory action. In these cases, you should use a pre-statute baseline." (PP. 15-16).

[24] Circular A-4 states: "When more than one baseline is reasonable and the choice of baseline will significantly affect estimated benefits and costs, you should consider measuring benefits and costs against alternative baselines. In doing so you can analyze the effects on benefits and costs of making different assumptions about other agencies' regulations, or the degree of compliance with your own existing rules. In all cases, you must evaluate benefits and costs against the same baseline." (P. 15).

[25] Circular A-4 states that the "important uncertainties connected with your regulatory decisions need to be analyzed and presented as part of the overall regulatory analysis." (P. 38).

[26] Circular A-4 states: "Where there is a distribution of outcomes, you will often find it useful to emphasize summary statistics or figures that can be readily understood and compared to achieve the broadest public understanding of your findings. It is a common practice to compare the 'best estimate' of both benefits and costs with those of competing alternatives. These 'best estimates' are usually the average or the expected value of benefits and costs." (P. 48).

[27] Circular A-4 states: "Use a numerical sensitivity analysis to examine how the results of your analysis vary with plausible changes in assumptions, choices of input data, and alternative analytical approaches." (P. 41).

[28] This general statement does not take into account the potential inefficiencies that may arise from taxation (other than lump-sum taxation). Transfer payments could affect total resources available to society because of the marginal cost of public funds.

[29] Circular A-4 states: "You should report transfers, separately and avoid and misclassification of transfer payments as benefits or costs. Transfers occur when wealth or income is redistributed without any direct change in aggregate social welfare." (P. 46).

[30] Circular A-4 states: "A regulation that restricts the supply of a good, causing its price to rise, produces a transfer from buyers to sellers. The net reduction in the total surplus (consumer plus producer) is a real cost to society, but the transfer from buyers to sellers resulting from a higher price is not a real cost since the net reduction automatically accounts for the transfer from buyers to sellers." (P. 38).

[31] Circular A-4 states: "The 7 percent rate is an estimate of the average before-tax rate of return to private capital in the U.S. economy. It is a broad measure that reflects the returns to real estate and small business capital as well as corporate capital. It approximates the opportunity cost of capital, and it is the appropriate discount rate whenever the main effect of a regulation is to displace or alter the use of capital in the private sector." (P. 33).

[32] Circular A-4 provides: "The effects of regulation do not always fall exclusively or primarily on the allocation of capital. When regulation primarily and directly affects private consumption (e.g., through higher consumer prices for goods and services), a lower discount rate is appropriate. The alternative most often used is sometimes called the 'social rate of time preference.' This simply means the rate at which 'society' discounts future consumption flows to their present value. If we take the rate that the average saver uses to discount future consumption as our measure of the social rate of time preference, then the real rate of return on long-term government debt may provide a fair approximation. Over the last thirty years, this rate has averaged around 3 percent in real terms on a pre-tax basis." (P. 33).

[33] Circular A-4 offers a brief relevant background on economic and ethical issues and states: "If your rule will have important intergenerational benefits or costs you might consider a further sensitivity analysis using a lower but positive discount rate in addition to calculating net benefits using discount rates of 3 and 7 percent." (P. 36).

[34] Circular A-4 states: "You should include [other benefit and cost considerations] in your analysis and provide estimates of their monetary values when they are significant: [p]rivate-sector compliance costs and savings; [g]overnment administrative costs and savings; [g]ains or losses in consumers' or producers' surpluses; [d]iscomfort

---

or inconvenience costs and benefits; and [g]ains or losses of time in work, leisure and/or commuting/travel settings." (P. 37).

[35] According to Circular A-4, "[o]pportunity cost is the appropriate concept for valuing both benefits and costs. The principle of 'willingness-to-pay' (WTP) captures the notion of opportunity cost by measuring what individuals are willing to forgo to enjoy a particular benefit." (P. 18). Circular A-4 adds: "In general, economists tend to view WTP as the most appropriate measure of opportunity cost, but an individual's 'willingness-to-accept' (WTA) compensation for not receiving the improvement can also provide a valid measure of opportunity cost." Hence it may be valid for agencies to consider use of WTA. See pp. 18-19 of Circular A-4 for a general discussion of the concept of "willingness to pay."

[36] Circular A-4 states: "As a first step, you should present the annual time stream of benefits and costs expected to result from the rule, clearly identifying when the benefits and costs are expected to occur . . . . Benefits and costs that occur sooner are generally more valuable . . . . To reflect this preference, a discount factor should be used to adjust the estimated benefits and costs for differences in timing. The further in the future the benefits and costs are expected to occur, the more they should be discounted. The discount factor can be calculated given a discount rate." (PP. 31-32). It also states that "[y]ou should present annualized benefits and costs . . ." (P. 45).

ABSTRACT

This report summarizes available data on human intake of inorganic arsenic by consumption of fish and shellfish and arsenic in drinking water. It estimates total exposure to inorganic arsenic from these vehicles under a variety of exposure scenarios.

Much of the arsenic in fish and shellfish is present in the form of organic compounds rather than as inorganic arsenic. For this report, EPA utilized published data on the concentrations of total arsenic and inorganic arsenic in a variety of fish and shellfish species. These data along with data from the U.S. Department of Agriculture Food Consumption Survey on fish/shellfish intake of consumers and non consumers were used to generate estimates for the inorganic arsenic intake for several exposure scenarios. The scenario for the group with the highest potential exposure (90 μg/day) was individuals consuming a diet high in fish and shellfish and having a preference for shellfish. An scenario for the average fish consumer estimated an intake of 4 μg/day and the scenario for the general consumer with only occasional fish/shellfish intake estimated an intake of 0.6 μg/inorganic arsenic per day. Scenarios for consumer groups with other fish/shellfish consumption patterns were evaluated as well.

The evaluation of inorganic arsenic exposure from fish and shellfish provides support for utilizing the existing MCL of 50 ppb for arsenic as an ambient water criterion in some areas until EPA updates its risk assessment for arsenic and revises the MCL. The exposure evaluation also illustrates a need for site specific criterion when high consumption of fish and shellfish is coupled with arsenic contamination of drinking water. Toxicity concern related to the arsenic in marine fish and shellfish is mitigated by the fact that it is largely present as arsenobetaine, a metabolically stable compound that is rapidly excreted. Additional studies of the forms of organic arsenic in fresh water species are needed.

1.0 INTRODUCTION

The U.S. Environmental Protection Agency's (EPA) guidance for arsenic under the Safe Drinking Water Act and the Clean Water Act are different. EPA's drinking water standard, or maximum contaminant level (MCL) for arsenic is 50 ppb and was developed by the Public Health Service in the 1940's. The Ambient Water Quality Criterion under the Clean Water Act is 0.018 ppb based on an estimated one in a million cancer risk (EPA, 1980). EPA has recognized that there is considerable uncertainty in the cancer risk value and is presently in the process of developing a new risk analysis in order to propose a new MCL. Under legislative requirements, the EPA will issue a proposal for an arsenic MCL in the year 2000. Until that time the 50 ppb will remain in effect for public potable water sources.

The question has been raised as to whether the 50 ppb MCL for arsenic in drinking water can also serve as an Ambient Water Quality Criterion for arsenic until the risk assessment revision is complete and whether fish/shellfish consumption from the same waters adds significantly to the inorganic arsenic exposure. According to the Clean Water Act Criteria Document for arsenic (EPA, 1980), trivalent and pentavalent, inorganic, arsenic compounds are the most toxic species. This document accepts that premise and updates the Criteria Document in terms of the forms of arsenic in fish and shellfish.

The following report examines the available quantitative data on arsenic in fish and shellfish as well as its speciation (inorganic vs. organic). Estimates are made for human exposures to inorganic arsenic from fish/shellfish and drinking water under several exposure scenarios that apply to the average and high end of the distribution curve for fish/shellfish consumption. An exposure assessment for the average consumer within the general population (which includes nonconsumers) is also presented. The document is a technical summary of the available data on the arsenic in fish and shellfish as well as an exposure evaluation for inorganic arsenic.

2.0 ARSENIC IN FISH

The quantitative data on arsenic concentrations and speciation in fish are limited but are generally consistent with the hypothesis that most and sometimes all of the arsenic in fish is organic rather than inorganic. The available analytical data on arsenic in fish are presented below. The data are grouped by the source of the fish and the type of arsenic. All data are reported in terms of wet mass. The following presents data on total arsenic in marine species and then freshwater species followed by inorganic arsenic for marine species and then freshwater species.

Total Arsenic in Marine and Estuarine Species. Ballin et al. (1994) analyzed samples of 13 species of marine fish for total arsenic. Average concentrations ranged from 0.6 to 37 ppm. Only two of 20 samples had values greater than 10 ppm, one of three plaice samples and a catfish sample. In cases where samples for a given species originated from different source waters, there was considerable variability in total arsenic concentration. Total arsenic concentrations from three different herring samples ranged from 0.7 to 4 ppm; there was also variability among the results for 5 samples from the same fish. The two species with the highest average levels of total arsenic were plaice from Fladenground (32 ppm; standard deviation 14) and catfish from Gr. Fisherbank (37 ppm; standard deviation 28).

In another study, Lawrence et al. (1986) obtained samples of fish muscle from different areas in Canada. Both Atlantic and Pacific fish species were evaluated. The average total arsenic concentrations for replicate samples ranged from 1.1 ppm (herring) to 13.2 ppm (sole) for Atlantic species and 0.31 (salmon) to 7.4 ppm (cod) for Pacific Species. A total of 6 Atlantic species and 5 Pacific species were evaluated. Slight differences were apparent in the Atlantic versus Pacific samples of the same species. For example the sole sample from the Atlantic had **13.2 ppm while that from the Pacific had 5.2 ppm and the cod sample from the Atlantic had 5.2 ppm while that from the Pacific had 7.4 ppm. Based on the sample variability observed by Ballin et al. (1994), these differences are most likely a reflection of variability in samples rather than differences that result because of the arsenic in the source water. Additional support for this conclusion is provided by analysis of a sample of sole purchased locally in Ottawa which had only 0.10 ppm total arsenic, a value far lower than that for either the Atlantic or Pacific samples. The low value for this sample may represent loss during storage and shipping. Le et al. (1994) found that up to 48% of the total arsenic could be released in defrost liquid.**

In order to evaluate microwave assisted distillation with atomic absorption spectrometry as a method for determining inorganic arsenic, Lopes et al. (1994) analyzed commercially purchased canned or frozen samples of anchovies, tuna, sardines, hake and sole for total as well as inorganic arsenic. Total arsenic concentrations ranged from 0.82 ppm (tuna) to 7.76 ppm (sole)

In a report developed for Region 10 of the U.S. EPA, Chew (1996) **summarized data from the published literature on the concentrations of total arsenic and inorganic arsenic in fish and shellfish. The data apply primarily to samples from Japan and all but one sample came from the** Pacific Ocean. Total average arsenic concentrations ranged from values less than 1 to 10 ppm for fish with two outliers: skate (64 ppm) and stingray (17 ppm).

Total Arsenic in Fresh Water Species. Ballin et al. (1994) examined the total arsenic in fresh water fish from rivers in Northern Germany, the River Elbe or from a fish hatchery. Seven species were examined; the average total arsenic concentrations were lower than those for marine fish and ranged from the detection limit to 1.5 ppm. The highest concentration was present in rainbow trout specimens from a fish hatchery and the lowest concentration was found in perch from a river in Northern Germany. The trout sample was the only one with a concentration of greater than 0.1 ppm.

The lower levels of total arsenic in fresh water fish are substantiated by analysis of the muscle tissue of several species collected in Ontario and Alberta, Canada (Lawrence et al., 1986). Concentrations ranged from 0.007 ppm (yellow perch) to 0.24 ppm (striped perch). Nine replicate samples were analyzed. Among the 23 samples of fresh water fish analyzed by Ballin et al (1994) and Lawrence et al. (1986), the total arsenic was less than 0.3 ppm for 22.

Inorganic Arsenic in Marine and Estuarine Species. In the data summarized by Chew (1996), average inorganic arsenic concentrations ranged from the detection limit to 0.2 ppm. The species with the highest average percentage of arsenic as inorganic arsenic were shark (9.5%), sturgeon (6.9%) and sucker (8.5%). In all other cases the percent of inorganic arsenic was less than 4 %. The two species with the highest average concentrations of total arsenic (skate, stingray) had none of their arsenic present as inorganic arsenic and the species with the highest concentrations of inorganic arsenic (shark, sturgeon, sucker) had low average total arsenic concentrations (2.1, 0.6 and 0.2 ppm respectively). In the study by Lopez et al. (1994), the percent inorganic arsenic in the 5 fish samples analyzed was less than 5% in all samples when analyzed by microwave-assisted distillation and atomic absorption spectrometry.

Ballin et al. (1994) did not analyze the fish for either inorganic arsenic or total organic arsenic. They did analyze the tissues for arsenobetaine and phospholipid arsenic, the major organic forms of arsenic in fish. In marine fish, the arsenobetaine accounted for 96% to 100% of the total arsenic and the phospholipid arsenic for 0.17 to 4.12 % of the total. Assuming, no other organic arsenic forms were present in the fish examined, the maximum amount of inorganic arsenic present was 2%.

Lawrence et al. (1986) analyzed 11 replicate samples of fish muscle for arsenobetaine and arsenocholine using purification by high performance liquid chromatography (HPLC) and identification with atomic absorption spectrometry and fast atom bombardment mass spectrometry. In addition to arsenobetaine and arsenocholine, the method was able to identify two unknown organic compounds containing arsenic. In all fish samples except salmon, the only compound identified was arsenobetaine which accounted for 78 to 88% of the total arsenic. In salmon an unidentified form of organic arsenic was present in addition to arsenobetaine. The arsenobetaine was 41% of the total arsenic and the unknown compound was 42 % of the total arsenic.

Caution must be used in evaluating the Lawrence et al. (1986) data because the percent recovery from samples spiked with arsenobetaine was 80 to 84% quite similar to the percent of arsenic reported to be present as arsenobetaine in most samples. Thus, this method could under report the amount of arsenic present as organic arsenic because of recovery problems. The authors point out that when the results are corrected for recovery they indicate that arsenobetaine accounted for "essentially all of the arsenic present in the marine samples analyzed". It must also be remembered that Lawrence et al. (1986) did not analyze the samples for phospholipid containing arsenic which Ballin et al. (1994) demonstrated to be present in marine fish tissues.

Inorganic Arsenic in Fresh Water Species. In analysis of 9 replicate samples of fresh water fish, Lawrence et al. (1986) did not identify either arsenobetaine or arsenocholine. An unknown organoarsenic compound was present in all samples. This compound accounted for 71 to 85% of the total arsenic. Caution must be used in evaluating these data since it was not possible to quantify the recovery for the unidentified compound. The same unknown compound was present in all fresh fish samples whether they were from Manitoba or Alberta. Elution of the unidentified compound from the HPLC column indicated that it was more hydrophilic than arsenobetaine.

3.0 ARSENIC IN SHELLFISH

Total Arsenic. Total arsenic concentrations in shellfish tend to be higher than those for finfish. In the data summarized by Chew (1996), average total arsenic concentrations for shellfish ranged from 0.2 to 126 ppm. The highest concentrations were seen in two mollusk samples. However, mollusk values were highly variable among the 20 samples tested (range: 1-126 ppm; Chew, 1996). In the study by Ballin et al. (1994), the total arsenic in 4 species of shellfish ranged from 2.6 to 21 ppm; the highest concentration was found in lobster. The average value from pooled samples of blue mussels (40 samples) was 2.6 ppm (Ballin et al., 1994). Lawrence et al. (1986) found the total arsenic in replicate lobster, scallop and shrimp samples to be 5.2 ppm, 0.68 ppm and 20.8 ppm respectively. The concentrations of total arsenic in a samples of lobster purchased commercially in Ottawa was 4.7 ppm and in a shrimp sample was 7.2 ppm. Lopez et al. (1994) found values of 4.01 ppm, 0.34 ppm and 2.95 ppm for commercially purchased samples of cockles, prawns, and mussels respectively.

Inorganic Arsenic. The average amount of arsenic present as inorganic arsenic in shellfish was less than 3% in all cases but one among the data summarized by Chew (1996). In the case of *Barnea dilatata*, the one exception, 98% of the arsenic was inorganic but the total arsenic was low (0.2 ppm) making the net exposure to inorganic arsenic low despite the high percentage present. Lopez et al. (1994) found the inorganic arsenic to account for 8% of the total in cockles and 11% in muscles. The amount of inorganic arsenic in the prawns was below the limit of detection (0.023 ppm).

The data by Ballin et al. (1994) are of minimal value for deriving an estimate of the inorganic arsenic in shellfish because samples were not analyzed for inorganic arsenic and the authors felt that two organic forms of arsenic monitored (arsenobetaine and phospholipid arsenic) did not account for all of the organic arsenic.

Ballin et al. (1994) evaluated shrimp, lobster, mussels and oysters for their arsenobetaine and arsenic containing phospholipids. Oysters and blue mussels had the lowest concentrations of arsenobetaine plus phospholipid arsenic (30 and 40%). The authors hypothesized that water soluble arsenocholine, the metabolic precursor to arsenobetaine, accounted for most of the difference between the arsenobetaine and total arsenic concentrations rather than inorganic arsenic. Oysters and muscles had a fair amount of their arsenic present in the fat soluble phospholipid phase (10 to 20%) suggesting that some arsenocholine had been incorporated in the choline-containing phospholipids or sphingolipids.

In shrimp, Ballin et al. (1994) found that 87% of the arsenic was present as arsenobetaine and 4% as phospholipid arsenic while Lawrence et al.(1986) found that 76% was present as arsenobetaine and 15% as arsenocholine. In lobster, 59% of the arsenic was present as arsenobetaine and 2 % as phospholipid arsenic according to Ballin et al. (1994) and Lawrence et al. (1886) found 87% as arsenobetaine and none as arsenocholine. As discussed above, one cannot infer from these data that the remaining arsenic is present in inorganic compounds. Le et al. (1994) found arsenobetaine to be the primary organic arsenic compound in shrimp and prawns.

Table I summarizes the data on total, organic and inorganic concentrations of arsenic in fish and shellfish. The organic arsenic data are extrapolated from either the total arsenic and inorganic arsenic data (Chew, 1996) or the total arsenic plus the arsenobetaine, arsenocholine and/or phospholipid arsenic data (Ballin et al., 1994; Lawrence et al., 1986). In general, the data support the conclusion, that, in fish, less than 10% of the total arsenic is inorganic (Chew, 1996). Indeed, it was 4% or less for all fish species other than shark, sturgeon and sucker evaluated by Chew (1996); a total of 40 species were evaluated.

Table 1
Arsenic in Fish and Shellfish

Genus	Total Arsenic ppm.	Inorganic Arsenic ppm	Organic Arsenic ppm or %.	Reference
Fish	0.6-37	ND	>98%	Ballin et al., 1994

4.0 SPECIATION OF ORGANIC ARSENIC IN FISH AND SHELLFISH

The predominant organic arsenic compounds in marine fish and shellfish are arsenobetaine and arsenocholine (Ballin et al., 1994). Some of the arsenocholine is found in tissue phospholipids. The amount of arsenobetaine exceeds the arsenocholine (Chew, 1996). In both compounds, arsenic has replaced the nitrogen of the natural metabolite (choline; betaine). Arsenic is incorporated into the betaine molecule by microorganisms, phytoplankton, zooplankton and algae (Ballin et al., 1994). The fish obtain arsenobetaine from their food supply. The principle organic form of arsenic in freshwater fish is neither arsenobetaine or arsenocholine according to data collected by Lawrence wt al. (1986). A single compound was isolated from all samples and accounted at least 70 to 85% of all the arsenic present if recovery was complete. The composition of this compound was not identified but it appeared to be more hydrophilic than arsenobetaine.

Betaine is formed metabolically from choline through oxidation and becomes an excretory nitrogen metabolite. Betaine excretions vary between species. In addition, betaine can serve as a methyl donor in biological systems, becoming N,N-dimethyl glycine (Montgomery, 1990). Betaine acts as an osmolyte in marine species (Neufield and Wright, 1996) and as a chemosensory agent (Knutsen, 1992). A study of feeding behavior in North Sea turbot and Dover sole suggest that betaine is one of a number of water-soluble, nitrogen-containing compounds that stimulate feeding behavior in fish larvae and may help to attract the larvae to the plankton layer (Knutsen, 1992). Betaine is probably released to water in plankton-rich areas producing an betaine-enriched microenvironment.

Arsenobetaine is metabolically inert in mammalian systems. Almost all of the radiolabeled arsenic in arsenobetaine administered orally or intravenously to rats, mice or guinea pig was excreted in three days (Vahter et al., 1983; Yamauchi et al. 1986). In rats and mice, more than 99% of the excreted label was found in the urine as arsenobetaine. In comparable studies using arsenocholine, there was greater label retention with 70-80% excreted in three days (Marafante et al., 1984). Extracts from mouse urine showed that more than 90% of the water soluble arsenic excreted was present as arsenobetaine. It can be assumed that some of the retained arsenocholine is incorporated in membranes as phosphatidyl choline compounds or in lipoprotein complexes and, thus, will have little tendency to bioaccumulate as inorganic arsenic.

Small amounts of methylarsonic acid and dimethylarsinic acid have been identified in fish and shellfish (Buchet et al., 1994; Chew 1996). Chew (1996) reported data from a study of fish at the ASARCO Tacoma Smelter Site in Washington state. The amount of methylarsonic acid in striped sea perch was 0.02 ppb and that in rock sole was 0.002 ppb. The dimethylarsinic acid in these two species was 0.02 ppb and $\leq$ 6.6 ppb, respectively. In mussels there was 0.02 ppb for both the methylarsonic and dimethylarsinic acid. The total arsenic concentration was only available for the rock sole and the total arsenic data were not internally consistent with the speciation data. Therefore, it is difficult to evaluate the significance of these results. Buchet et al. (1994) found that the recovery of methylarsonic acid and dimethylarsinic acid varied with the extraction technique and between samples for the same fish.

The data available on the speciation of arsenic in fish and shellfish mitigate some of the concerns generally associated with arsenic exposure. In most cases, more than 95% of the arsenic is present as organic rather than inorganic compounds (Chew, 1996). The most prevalent of the organic species, especially in marine fish, is arsenobetaine (Ballin et al., 1994; Lawrence et al. 1986), a compound with minimal tissue retention in the animals species studied and a compound that is excreted without metabolic alteration. The compound present in the next highest concentration is arsenocholine. The arsenocholine is estimated to be less than 1% of the total arsenic (Edmonds and Francesconi, 1993). Most of the arsenocholine is converted to arsenobetaine and excreted. A small portion may become incorporated in phospholipids and retained; another small amount may be converted to trimethylarsine oxide (Chew, 1996).

Arsenobetaine and arsenocholine and the unidentified organic arsenic compound in freshwater fish are hydrophilic and have little tendency to bioaccumulate in edible fish tissues. They are unlikely to be present in adipose deposits due to their hydrophilic nature although some arsenocholine may be present in membrane phospholipids. Organic arsenicals, especially arsenobetaine, appear to be significantly less toxic than inorganic arsenic species (Edmonds and Francesconi, 1993). Each of these factors diminishes human health concerns related to exposure to organic arsenic compounds in fish and shellfish. Additional support for a conclusion that the organic arsenic compounds from fish and shellfish do not bioconcentrate is provided by data showing that samples of human milk from 88 mothers from the Faroe Islands did not show elevated arsenic in their transition milk despite consumption of diets rich in seafoods (Grandjean et al., 1995).

5.0 ESTIMATED ARSENIC IN FISH AND SHELLFISH FROM WATER CONTAINING 50 PPB ARSENIC

5.1 EPA Bioconcentration Factors for Arsenic

The EPA bioconcentration factor for total arsenic in a fish and shellfish is 44 (EPA, 1980, 1984). It applies to bioconcentration from a mixture of fish and shellfish (roughly 10-15% shellfish). The arsenic concentration by shellfish exceeds that for fish by nearly two orders of magnitude (EPA, 1980). The shellfish value (350) came from a 112 day test of a saltwater oyster species exposed to trivalent arsenic while the bioconcentration factor for bluegill was 4 after a 28 day exposure (EPA, 1980).

The EPA bioconcentration factors were derived from laboratory studies where the water was spiked with trivalent inorganic arsenic. Thus, they may not be representative of what happens in a natural ecosystem where inorganic arsenic is processed through a number of trophic levels before it reaches the fish or shellfish.

The data presented in Sections 2.0 and 3.0 of this report do not include any information on the amount of arsenic in the source waters from which samples were obtained. Thus, it is not possible to evaluate the bioaccumulation that lead to the tissue levels of arsenic measured in the fish or shellfish. In general, the average total arsenic in clean costal and ocean waters is low, about 1 to 3 ug/L. Levels are much higher in estuary systems receiving arsenic discharges (Neff, 1997). The arsenic concentration for most lakes and rivers is less than 5 ug/L (Crecelius, 1997).

A comparison of the amounts of total arsenic in some of the fish and shellfish samples collected from the marine environment with normal background levels of inorganic arsenic in the water, suggests that, for at least the marine environment, arsenic accumulated to a greater extent than suggested by laboratory bioconcentration factor of 4 measured for a freshwater species in a laboratory study. The data on the accumulation of arsenic in fresh water species is conceptually closer to laboratory bioconcentration factors.

5.2 Estimated Total Arsenic

For this report, concentrations of total and inorganic arsenic in edible tissues from fish and shellfish are estimated using the EPA bioconcentration factor for arsenic and the arsenic concentration in ambient water. Deficiencies in the bioconcentration factor are part of the uncertainty for the analysis.

In cases where the fish and shellfish come from water containing 50 ppb arsenic, the estimated total arsenic concentration in edible tissues is 2.2 mg/kg or 2.2 ppm when calculated using the EPA bioconcentration factor.

$$50\ \mu g/L \times 44\ L/kg(BCF) \times 1\ mg/1000\ \mu g = 2.2\ mg/kg \text{ total arsenic}$$

This estimate is within the range observed for fish and shellfish in the most recent USFDA Total Diet Study (0.75 ppm for fish sticks to 2.8 for cod/haddock; MacIntosh, 1997; personal communications). In the data for fish collected by Chew (1996), 70% of the samples had total arsenic concentrations below 2.2 ppm. In the studies by Ballin et al. (1994 and Lawrence et al. (1986) over 60% of the combined marine and fresh water fish data set fell below this value. Because nothing is known concerning the arsenic concentrations in the source water for the field sample data presented by Ballin et al. (1994), Chew (1996) Lawrence et al. (1986) or Lopez et al. (1994), the comparison of the calculated concentration for fish and shellfish with the field data merely supports the calculated value as plausible.

5.3 Estimated Inorganic Arsenic

The maximum inorganic arsenic in fish and shellfish used for this estimate is 4% as discussed in Sections 2.0 and 3.0 above. The median inorganic arsenic value for the fish and shellfish data reported by Chew (1996) is 0.4 %. No inorganic arsenic was detected in 23 of 42 fish samples

and 18 of 50 shellfish samples. Therefore, the median value reflects the higher inorganic arsenic concentrations found in shellfish and is a conservative value.

Using a 4% maximum inorganic arsenic value for a mixed fish and shellfish diet, 2.2 ppm total arsenic in fish/shellfish is equivalent to 0.09 ppm inorganic arsenic.

$$2.2 \text{ mg/kg As}_{\text{total}} \times 4 \text{ g As}_{\text{inorganic}}/100 \text{ g As}_{\text{total}} = 0.09 \text{ mg/kg As}_{\text{inorganic}}$$

Using 0.4% as the median inorganic arsenic concentration for a mixed fish and shellfish diet, 2.2 ppm total arsenic in fish/shellfish is equivalent to 0.01 ppm inorganic arsenic.

$$2.2 \text{ mg/kg As}_{\text{total}} \times 0.4 \text{ g As}_{\text{inorganic}}/100 \text{ g As}_{\text{total}} = 0.01 \text{ mg/kg As}_{\text{inorganic}}$$

6.0 ESTIMATED INORGANIC ARSENIC EXPOSURE FROM FISH/SHELLFISH CONSUMPTION

Inorganic arsenic exposure estimates for high and average fish and shellfish consumers can be derived using the inorganic arsenic concentrations estimates above and information on population fish/shellfish consumption. The following exposure scenarios are presented for this report based on available data.

High fish/high arsenic - The 99.9th percentile fish/shellfish consumer and the estimated maximum inorganic arsenic concentration for a mixed fish/shellfish diet (4%). This group eats the maximum amount of fish and shellfish on a daily basis and consistently chooses species that have the higher percentages of inorganic arsenic.

High fish/average arsenic -The 99.9th percentile fish/shellfish consumer and the median inorganic arsenic concentration (0.4%). This group eats the maximum amount of fish and shellfish on a daily basis and chooses species with a variety of inorganic arsenic concentrations over a range from low to high.

Average fish/high arsenic - The 50th percentile fish/shellfish consumer and the estimated maximum inorganic arsenic concentration for a mixed fish /shellfish diet. This group has a diet that includes fish and/or shellfish frequently but is not totally dependant on fish/shellfish as a dietary protein source. The group preferences tend towards the fish/shellfish species that have the higher concentrations of inorganic arsenic.

Average fish/ average arsenic - The 50th percentile fish/shellfish consumer and the median inorganic arsenic concentration. This group has a diet that includes fish and/or shellfish frequently but is not totally dependant on fish/shellfish as a dietary protein source.
The group preferences include a variety of fish and shellfish species with inorganic arsenic concentrations that range from low to high.

The fish consumption values used for these calculation were derived from the 1989-1991 dietary records from the USDA Continuing Survey of Food Intake (USEPA, 1995). The USDA food consumption survey collects data on three consecutive days of food intake. Data for one day is provided through a 24-hour recall interview and data for two days through food intake records kept by the respondent. Fish-consumers were segregated from all respondents based on their consumption of fish at least once during the three day survey period. The population data used for the exposure estimates described above apply only to the fish-consuming population rather than the entire population Therefore the data may represent a rather skewed distribution. For the purpose of defining a exposure on the high end of the distribution curve the data are appropriate and useful.

The 99.9th percentile value for females (461 g/day) is used to simulate the eating habits of subsistence fishers such as the Eskimos and other native Indian tribes that consume a diet that is very high in fish and shellfish. This is the highest intake value reported. The 99.9th percentile value or maximum reported value is more than 4 times the 95th percentile value (USEPA, 1995). The 50th percentile value from the USDA data for males was used for the exposure estimate rather than that for females because it is a higher value.

Eskimo's and other native Indian tribes in Alaska have the highest consumption of fish and shellfish within the United States (Wolfe, 1996). In one study of 351 Eskimos, Indians and Aleuts, average fish and shellfish consumption was 109 g/day (Nobmann et al., 1992). This intake lies between the 75th and 95th percentiles of fish consumers in the country as a whole (EPA, 1995). Wolfe (1996) found that the average intake of wild foods by the subsistence populations in Alaska was slightly greater than one pound of wild food per day with 61% of this total contributed by fish and shellfish. In some areas the average consumption of wild foods was two pounds per day. In studies of the Tulalip and Squaxin Island tribes of Puget Sound the mean fish/shellfish consumption for a 70 Kg adult was 71 g/day and the 95% percentile value was 226 g/day (Toy et al., 1995). In a study of the Native Tribes of the Columbia River Basin, the mean value for the adult fish consuming population was 63 g/day and the 99th percentile value was 389 g/day (CRITFC, 1994). These data support the fish/shellfish intake values used for the exposure estimates.

Two addition exposure estimates are also included in this report. These groups are identified as follows:

High fish (shellfish preference)/high arsenic -The 99.9% fish/shellfish consumer who is also at the 99% for shellfish consumption (125 g/day). These individuals consume a high percent of their fish/shellfish in the form of shellfish and select species with the high concentrations of inorganic arsenic.

General population/high arsenic - The average person who consumes fish or shellfish only occasionally but selects species with the high concentrations of inorganic arsenic.

The first of the added groups cover subsistence users of fish and shellfish who have a greater than average intake of shellfish. The arsenic exposure for this group includes separate calculations for the arsenic in fish and shellfish using a fish bioconcentration factor of 4 for fish and a factor of 350 for shellfish (USEPA, 1980, 1985). The 99th percentile shellfish consumption from the USDA data (125 g/day) was used for the shellfish portion of the diet and the difference between the 99.9th percentile fish/shellfish value (461 g/day) and the shellfish value was used for fish consumption (336 g/day).

The first five exposure scenarios defined above apply to those individuals who routinely consume fish and/or shellfish as a dietary protein source. However, most of the general population consumes fish and shellfish only occasionally, and some individuals never eat fish or shellfish. Thus, the general population has a lower exposure averaged over time. The EPA uses a daily fish intake of 6.5 g/day to represent these individuals (EPA, 1989). This is a normalized concentration which recognizes that, on the days that fish and/or shellfish are consumed, the intake will be higher than 6.5 grams but there will also be many days in the course of a year that there is no consumption of either fish or shellfish. This group is identified as "General Population " in subsequent tables. As a worst case, the higher inorganic arsenic concentration was used for the general population arsenic exposure calculation. Individuals who consume fish or shellfish only occasionally tend to have a few species they favor (e.g. tuna, shrimp) and the species of preference may be among the higher arsenic species.

Inorganic arsenic exposures from fish and shellfish under the different exposure scenarios listed above are summarized in Table 2. The fish/shellfish consumption values apply to total fish/shellfish consumption and include marine, estuarine and freshwater species. They are calculated using the following equation:

$$2.2 \text{ mg As}_{\text{total}}/\text{ kg fish/shellfish} \times \text{fish/shellfish intake (kg/day)} \times \text{mg As}_{\text{inorganic}}/100 \text{ mg As}_{\text{total}} = \text{mg As}_{\text{inorganic}}/\text{day}$$

Units have been adjusted so that the inorganic arsenic concentrations are expressed in μg/ day in Table 2. The USEPA limitation on arsenic in marine waters is 36 ppb (USEPA, 1992). Therefore, the estimates based on all fish and shellfish being from waters containing 50 ppb is an overestimate in situations where a mixture of marine, estuarine and freshwater species are consumed.

Table 2
Inorganic Arsenic Exposure from Fish and Shellfish Consumption

Consumer Category	Inorganic Arsenic %	Fish/Shellfish Consumption g/day	Inorganic Arsenic Exposure μg/day
High Fish - High Arsenic	4	461*	41
High Fish - Average Arsenic	0.4	461*	4
Average Fish - High Arsenic	4	42 *	4
Average Fish -Average Arsenic	0.4	42*	0.4
High Fish (shellfish preference)- High Arsenic	4	125 (shellfish) 336 (fish)	87.5 shellfish 2.7 fish 90 total
General Population	4	6.5**	0.6

* 1989-1991 data from the USDA Continuing Survey of Food Intake (USEPA, 1995)

** 1973-1974 data from the National Purchase Dairy Survey (USEPA, 1989)

Other dietary components can have an impact on the net inorganic arsenic exposure for the for all consumer groups. Macintosh et al. (1996) found that other foods in the Total Diet Study such as chicken and rice contributed to the total arsenic exposure. The form of arsenic in food may also contribute to the effect of a given food material on the total body arsenic load.

7.0 INORGANIC ARSENIC EXPOSURE FROM FISH, SHELLFISH AND POTABLE WATER

The data on inorganic arsenic from fish and shellfish from Table 2 can be combined with data on arsenic concentrations in potable water to obtain a profile for net inorganic arsenic exposures in the population groups characterized above. The high estimate for the arsenic concentration in potable water is 20 ppb and the average estimate is 5 ppb. These values were obtained from a study of arsenic in potable water sources conducted by the University of Colorado at Boulder and Malcolm Pirnie, Inc. (1997). Water consumption is estimated as 2 liters/day.

In the University of Colorado at Boulder/ Malcolm Pirnie Study (1997), 88 % or more of the ground water samples analyzed in the Western United States in three separate surveys had concentrations of 20 ppb or less. Concentrations were 5 ppb or less in more than 50% of the ground water systems evaluated. The highest arsenic concentration from ground water sources were in the Western region. None of the surface water systems surveyed in the Western United States contained greater than 5 ppb arsenic. In one survey, there were a few surface water systems in the North Central region of the country that exceeded 20 ppb arsenic (12%). Most arsenic in potable water is inorganic and ground water sources contain higher arsenic concentrations than surface water sources. The highest arsenic concentrations in the country are concentrated on the west coast.

Table 3 presents the estimates for net exposure to inorganic arsenic when the estimates from fish and shellfish consumption are combined with the data on the average and high concentrations of arsenic in Public Water supplies across the country. The value used as the high arsenic concentrations is 20 ppb based on survey data rather than the Arsenic MCL and is exceeded by only about 10% of Public Water Systems. Each of the exposure estimates for inorganic arsenic intakes from fish, shellfish and water is less than the exposure that results from ingesting 2 L of water containing the 50 ppb arsenic except for the High fish/shellfish preference scenarios.

Table 3
Total Inorganic Arsenic Exposures Fish/Shellfish and Water
for High and Average Fish Consuming Populations

Consumer Category	Fish/shellfish* μg/day	Water** μg/day	Total μg/day
High Fish - High Arsenic	41	40	81
	41	10	51
High Fish - Average Arsenic	4	40	44
	4	10	14
Average Fish - High Arsenic	4	40	44
	4	10	14
Average Fish - Average Arsenic	0.40	40	40
	0.40	10	10
High Fish (Shellfish Preference)- High Arsenic	90	40	130
	90	10	100
General Population	0.6	40	41
	0.6	10	11

* Based on a maximum 4% of the total arsenic being inorganic arsenic in an mixed fish/shellfish diet

** Water consumption is estimated as 2 liters/ day.

There are some regions in the western part of the country where arsenic levels in potable water from public systems are equal to the MCL and other private systems where the arsenic may exceed the MCL. For Public Water Systems where the potable water concentration is equal to the MCL, fish and shellfish consumption by the general populations does not increase the risk from arsenic exposure since it represents a less than a 1 μg (1%) increase in the net arsenic exposure. However, for regions where high levels of arsenic in the potable water are accompanied by high levels of fish and shellfish consumption the net increase in inorganic arsenic exposure would be greater and site-specific criteria can be developed for surface waters and for fish consumption.

In developing site-specific criteria the state should characterize the size and location of the population of concern and determine their fish/shellfish and water intake rate. The fish and shellfish consumption should consider the species and dietary intake per species. Actual total arsenic and inorganic arsenic values for the species consumed and actual concentrations in drinking water should be used in the exposure calculations wherever possible. Other sources of arsenic exposure should also be considered and quantified.

8.0 UNCERTAINTY

There are a number of uncertainties in the preceding exposure assessment for inorganic arsenic from fish and shellfish originating from water containing 50 ppb arsenic. The exposure estimates assume a mixed fish and shellfish diet in which average inorganic arsenic concentration is no greater than 4% of the total arsenic. This would not apply to any diet with high consumption of shark, sturgeon and sucker. However, these species are not used by the Eskimo and other northern Indian tribes that serve as an example of a 99.9 percentile fish/shellfish-consuming population. Species that constitute the fish component of the diet for Eskimo's and other northern Indians are salmon, halibut, herring, whitefish, sheefish, blackfish and cod (Wolfe, 1996).

The exposure assessments for all but the High Fish (Shellfish Preference) group are also based on a bioconcentration factor that applies to a mixed fish/shellfish diet. It does not apply to a diet that is heavily weighted towards shellfish, particularly mollusks. In the Eskimo and other northern Indian tribes, shellfish is a maximum of 9% of the diet (Wolfe, 1996) a value that is representative of the fish/shellfish biconcentration factor used for the inorganic arsenic exposure calculations. However, shellfish consumption for the Tulalip tribe of Washington State is about 60% of the fish/shellfish intake (Toy et al., 1996). Thus, the inorganic arsenic exposure estimates presented above would not apply to this group.

There is also some uncertainty in the bioconcentration factor since it results from laboratory studies in which the water was spiked with inorganic arsenic. The values obtained may not be representative of natural ecosystems where arsenic can passes through various trophic levels before entry into fish tissues. The data suggest that bioaccumulation through the food chain is more complex in marine species than in fresh water species.

There is some uncertainty in the toxicological assessment for organic arsenic compounds. To the extent that most of the organic arsenic species in the fish are trimethylated species such as arsenobetaine, arsenocholine and trimethylarsine oxide, toxicokinetic data support the conclusion that there is little, if any interaction of the arsenic metabolite with other biomolecules. Thus, the toxicity of these compounds is low. However, in cases where dimethylarsinic acid is found in fish/shellfish species, low toxicity cannot be assumed because there are some data that suggest that dimethylarsinic acid is a tumor promotor (Chew, 1996). If dimethylarsinic acid is a promotor, it could become a risk factor for carcinogenicity. A weight-of -evidence determination for the promoting properties of dimethylarsinic acid has not been established. Lack of data on the nature of the organoarsenic compound or compounds present in freshwater fish contributes additional uncertainty in cases where most fish consumed are freshwater species.

Cc: Croxton, Dave; Nickel, Brian
Subject: PCB response to Don

Mark,
Here's our response (reviewed by Dave C, Brian & me)

Don,
We want to make sure there is common understanding regarding the sources of PCBs in the Spokane River. Based on information in the email you sent us, we think that you may have misunderstood the information that was provided to you by members of the Task Force, and we believe that EPA and the Task Force have the same general understanding of the origins of the PCB contamination:

1) There is a mix of past (legacy) and present sources of PCBs contributing to the current PCB impairments in the Spokane river. Many contaminant pathways, like air deposition, contain a mix of legacy PCBs and new, inadvertently generated PCBs.
2) We believe that the relatively high levels of PCBs seen today in the Spokane River are likely the result of legacy contamination from industrial use of PCBs prior to the ban on PCB manufacturing in 1979. Today, those historic sources continue to contribute PCBs to the river through a variety of pathways including PCB contamination in soils (traveling to the river via stormwater and groundwater), building materials (traveling to the river via air deposition and stormwater) and lake and river sediment.
3) One reason we believe that newer consumer products with inadvertently-generated PCBs are a small fraction of the problem is that the PCB impairments in the Spokane River are unusually high relative to other parts of the State. If consumer products were the primary source of PCB contamination in the Spokane River, we would expect to see high levels of PCB contamination throughout Washington – and we don't.
4) The point source dischargers to the Spokane River (excluding stormwater) contribute between 8 and 33% of the loading in the River (varying with river flow). The remainder of the PCB loading comes from a variety of sources, including groundwater, stormwater, air deposition, tributaries, and unidentified sources in Idaho. Inadvertently-generated PCBs likely contribute loading to some of these pathways, especially air deposition, stormwater, and wastewater.

EPA is concerned about all of these potential sources, past and present, and strongly supports the work of the Task Force to further delineate the sources of PCB loading in the Spokane watershed.

If you have any further questions, please feel free to contact us. EPA's response to the remainder of your questions are included below:

> Question #1
>
> Why, when production of PCBs is banned in this country, does the EPA still allow a certain percentage of PCBs to occur in products sold here?
>
> While EPA's PCB regulations generally ban the manufacture (defined to include import as well) of PCBs, an exception is made for inadvertently generated PCBs that are unintentional impurities of many common commercial chemical or

manufacturing processes. EPA's regulations impose an annual average of 25 ppm and a 50 ppm maximum on the concentration of inadvertently generated PCBs manufactured or imported into the United States (see definition of "excluded manufacturing process, 40 CFR §761.3). Imported products and products produced domestically are regulated in the same manner. EPA has concluded that allowing such inadvertent generation has important economic benefits and does not pose an unreasonable risk to human health or the environment (see 49 FR 28172).

Question #2

Does the EPA have a short or long term plan to modify that policy?

Revising current regulations to reduce inadvertently generated PCBs presents both policy and scientific challenges. EPA currently has no plans to modify its policy regarding regulations of inadvertently generated PCBs.

Currently, EPA is considering restricting and/or eliminating many of the remaining authorized uses of higher-concentration liquid PCBs (see "Polychlorinated Biphenyls: Reassessment of Use Authorizations", April 10, 2010; 75 FR 17645). These remaining uses are the largest reservoir of commercial mixtures (Aroclors) that contain the dioxin-like PCBs. While restricting such uses would not address inadvertently generated non-dioxin-like PCBs, EPA believes this effort would help to reduce potential exposure and risk from remaining dioxin-like PCB uses. EPA is in the process of evaluating options for revising current PCB regulations, it has not made any proposed or final decisions.

In addition to potential rulemakings, another activity that may help to address inadvertently generated PCBs in products is EPA's Green Chemistry Program. EPA has provided funding to Washington State Department of Ecology to establish a Green Chemistry Center and is a member of the Advisory Board for the Center. The Green Chemistry Center plans to host a workshop later this year on PCBs inadvertently produced in inks and pigments, perhaps leading to improvements in the production and use of PCB-free inks and pigments.

Subject: Re: Spokane River

hi Mark- I am writing a two part piece on the PCBs in the Spokane River for crosscut.com. I have interviewed many of the stakeholders there, most of whom have committed a great deal of time to serve

on the Task Force trying to find solutions to the problem of PCBs getting in the tissue of fish in the river. All have told me that they began their work years ago thinking that the issue was legacy polluters who left PCBs in the soil that drains into the river, or who flushed the pollutants into the river directly. But those point sources only account for 8% of the PCBs in the Spokane River. The rest are coming in from common everyday use, that are buried in products used by us all. The EPA allows a certain percentage of PCBs to occur in such products. Why is that when production of PCBs is banned in this country? And does the EPA have a short/long term plan to modify that policy? I would greatly appreciate speaking with someone who can answer my questions.
thanks,
Don Fels

[Letter to leaders of federally-recognized tribes, signed by Kenneth J. Kopocis, August 11, 2015]

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY

WASHINGTON, D.C. 20460

OFFICE OF WATER

Dear Honorable Leader:

The U.S. Environmental Protection Agency is initiating consultation and coordination with federally recognized Indian tribes to consider a potential rulemaking that would establish baseline water quality standards under the Clean Water Act for waters on Indian reservations that currently do not have EPA-approved WQS in place to protect water quality. The EPA's goal is to address the existing gaps in CWA protection of reservation waters where there are no existing EPA-approved WQS. Standards would establish baseline human health and environmental goals as the basis for the CWA protection. This potential rulemaking effort adds to a growing list of initiatives the EPA is undertaking that recognize the importance of tribal waters, tribal sovereignty, and the need to better protect the water resources that tribes rely on.

The potential benefits to tribes and the environment of establishing baseline WQS through a federal rulemaking are significant. WQS define the goals for the quality of reservation waters and serve as the foundation of the water quality-based pollution control program mandated by the CWA to protect human health, recreation, wildlife, aquatic life, and other uses. WQS are the cornerstone to prevent future degradation of waters, and improve water quality in impaired waters, by providing a basis to assess the health of water bodies and impose limits in permits to control pollution discharges, including upstream discharges.

The EPA strongly supports and will continue to encourage eligible tribes to obtain Treatment in a Similar Manner as a State under the CWA in order for tribes to establish their own WQS for approval by the EPA and to administer their own WQS program. The EPA recognizes, however, that not all tribes may seek TAS and some tribes may continue to experience challenges to establishing their own WQS. Out of over 300 tribes with Indian reservations, only 40 have EPA-approved tribal WQS in place. This means those tribal waters without WQS may not have the full suite of protections afforded under the CWA.

Establishing baseline WQS for Indian reservations through a federal rulemaking could ensure a baseline level of protection for tribal waters and a step in supporting tribal interests in protecting their water quality and use of reservation waters. In addition, baseline WQS could provide more protections now than currently exist to address concerns about waters flowing into the reservation from adjacent jurisdictions, until such time that the tribe establishes its own customized WQS and obtains the EPA's approval to make them effective under the CWA.

Working as government-to-government partners with tribes, the EPA seeks to explore this potential effort to establish baseline WQS for Indian reservations, and solicits feedback from tribes on factors to consider to ensure the EPA crafts an effective federal rulemaking that reflects tribes' interests in protecting reservation waters under the CWA. This effort is consistent with the EPA's responsibilities under the CWA and the goals of the EPA's 1984 Indian Policy. Some tribal leaders may recall that between 1999 and 2003, the EPA developed a draft rulemaking of federal WQS for those waters in Indian country that did not have EPA-approved WQS. The EPA is interested in building on elements of that earlier effort to ensure a baseline level of protection exists for reservation waters.

Enclosed is a consultation and coordination plan that includes a description of the action under consultation and the process the EPA intends to follow, including a timeline for the consultation and coordination period, and information on how you can provide input on this action. The EPA's consultation information is also available on EPA's Tribal Portal (http://www.epa.gov/tribal/consultation).

This consultation and coordination process will be conducted in accordance with the *EPA Policy on Consultation and Coordination with Indian Tribes* (http://www.epa.gov/tribal/consultation). The EPA invites you and your designated representative(s) to participate in this process. The EPA's anticipated timeline for the consultation and coordination period is expected to extend from the date of this letter to November 6, 2015.

If you have any questions, please contact Danielle Anderson (anderson.danielle@epa.gov) of my staff. We look forward to hearing from you on this important matter.

Sincerely,

Kenneth J. Kopocis
Deputy Assistant Administrator

Enclosure

Consultation Plan
For Considering a Baseline Water Quality Standards Proposed Rule

August 2015

Background Information

The EPA is exploring a federal rulemaking to establish baseline Water Quality Standards (WQS) for waters on Indian reservations that do not have Clean Water Act (CWA) WQS in place. This adds to a growing list of initiatives that the EPA is undertaking to better protect tribal water quality and uses. For example, the EPA proposed an action to streamline the TAS process for tribes on August 7 (see http://water.epa.gov/scitech/swguidance/standards/wqslibrary/tribal.cfm), and is planning to propose a process later this year for tribes to apply for the section 303(d) program for listing impaired waters and developing total maximum daily loads (TMDLs) (see http://water.epa.gov/lawsregs/lawsguidance/cwa/tmdl/policy.cfm).

This baseline WQS action is focused on establishing baseline federal WQS for Indian reservations that are not currently covered by EPA-approved WQS. Such WQS could be used in water quality permitting decisions that impact reservation waters, including permits directly upstream from reservation waters. At any time, tribes, with assistance from the EPA, could still seek to obtain TAS authority (under CWA section 518) to adopt and administer their own tribal-specific WQS for EPA approval. Tribe-adopted, EPA-approved WQS would supersede any baseline WQS established by this potential rulemaking.

The EPA is considering including a combination of CWA 101(a)(2) designated uses, numeric criteria, narrative “free from” criteria, and general WQS provisions in the baseline WQS. The EPA may also consider providing some very limited regional adjustments for consistency with other federal actions. However, the EPA recognizes that fully customized standards are best achieved by a tribe with TAS that develops its own WQS for approval by the EPA. Tribe-adopted, EPA-approved WQS best reflect tribal-specific circumstances and uses that are not feasible for national baseline WQS. Nonetheless, baseline WQS could be developed to be fully protective of water quality, and may be critical for those tribes that may never seek TAS or adopt their own WQS. This rulemaking could impact the EPA’s direct implementation of the CWA on Indian reservations including facilitating the use of approved WQS in EPA-issued permits, providing water quality certifications, and other protective actions.

Tribal leaders may recall that in 1999-2003, the EPA initiated the process of promulgating federal WQS for Indian reservations that did not have EPA-approved WQS. The EPA is interested in your feedback on how we might build on elements of that earlier effort to better ensure Indian reservations have EPA-approved WQS and the full slate of protections under the CWA.

Potential Benefits for Tribes

The potential benefits of establishing baseline WQS through a federal rulemaking are significant given that WQS define the goals for a waterbody and serve as the foundation of the water quality-based pollution control program mandated by the CWA to protect human health, recreation, wildlife, aquatic life, and other uses.

In this potential rulemaking, the EPA would be providing a set of WQS that the EPA, states, and tribes would use on a consistent basis for water quality management decisions where there are currently no EPA-approved WQS in place. The benefits of having federal WQS in place for reservation waters where no EPA-approved WQS exist include:

- Facilitating tribal participation with states and the federal government to inform water quality management decisions impacting those waters on the reservation;
- Establishing goals for the quality of reservation waters that are recognized under the CWA;
- Providing a basis for enforceable National Pollutant Discharge Elimination System (NPDES) permits to require controls beyond basic technology-based controls. (Water discharges allowed by NPDES permits must meet WQS set under the CWA for those receiving waters);
- Providing a mechanism to control discharges through other federal licenses and permits (CWA section 401 certification); and
- Protecting reservation water quality from upstream discharges flowing into reservation waters from other jurisdictions.

Areas for Consultation and Coordination

Consistent with the EPA's Policy on Consultation and Coordination with Tribes, the EPA seeks to consult and coordinate with federally recognized tribes to solicit feedback on all aspects of this potential rulemaking, including input on how best to structure and develop baseline WQS for Indian reservations which currently do not have EPA-approved WQS. The EPA is particularly interested in hearing from tribes on the following questions:

Questions relating to tribes' interests in protecting water quality:

(1) What would an effective federal rulemaking look like to you and your tribe?

(2) What water quality protection issues (or issues specifically related to WQS) are you and your tribe facing that should be considered in this potential rulemaking?

   a. Concerns for reservation water quality and degradation of water quality?
   b. Concerns for upstream sources of water pollution?
   c. Concerns for neighboring state WQS?
   d. Concerns for water uses relating to equity, safety, drinking water, treaty rights, or economic interests?

(3) Do tribes have examples of situations they are facing regarding water quality that could help inform, or that should be addressed, by this potential rulemaking?

Questions relating to the EPA's CWA implementation responsibilities:

(4) What approaches in a potential rulemaking should the EPA consider to implement CWA WQS on reservations and be most effective for you and your tribe?

(5) Do you have any concerns about this action? Are there any sensitivities or unintended consequences that the EPA should consider before moving forward on this action?

(6) If the EPA provided baseline standards, would this change your tribe's interest in pursuing TAS?

   a. Would your tribe be more likely to pursue TAS? If yes, would your tribe be interested in using baseline standards as a starting point to develop more specific standards for reservation waters?
   b. Would your tribe be more likely **not** to pursue TAS?
   c. No effect?

Tribes may submit written consultation comments by email or mail to:

Danielle Anderson, anderson.danielle@epa.gov
USEPA Headquarters
William Jefferson Clinton Building
1200 Pennsylvania Avenue, N.W.
Mail Code: 4305T
Washington, DC 20460

Tribal Consultation and Coordination Process and Time Frame

Consultation and coordination with tribes on a proposed rulemaking will occur according to the table below. If the EPA decides to move forward with a proposed rulemaking, tribes will have the opportunity to further consult with the EPA once the rule is proposed. In addition, tribes may provide input as part of the public comment period that immediately follows the publication of a proposed rule.

The table on the next page describes the process and timeline for consultation and coordination on this action. Tribes may access this letter through the Tribal Consultation Opportunities Tracking System (TCOTS), located at: http://tcots.epa.gov/oita/TConsultation.nsf/TC?OpenView.

Tribal Consultation and Coordination Process and Timeline	
Date	**Event**
Date of this letter through November 6, 2015.	Consultation and coordination period
August 17-20, 2015	Information presentation and discussion at the Tribal Lands and Environment Forum, Minneapolis, MN EPA's Office of Water will participate in this conference, and is available for consultation discussions during the conference. For more information, see http://www7.nau.edu/itep/main/Conferences/confr_tlef/. Session: USEPA Major Initiatives Discussion with Senior USEPA Staff, Tuesday, August 18, 10:30 a.m. to 12:00 p.m.
September 9-11, 2015	Information presentation and discussion at the Region 10 Region Tribal Operations Committee meeting. EPA's Office of Water will participate in this conference by telephone. Details will be announced via TCOTS and email, "Time-Sensitive U.S. EPA Office of Water Information and Tribal Participation Opportunities"
September 23, 2015 Time: 2:00 – 4:00 p.m. EDT	Tribes-only information, coordination and consultation webinar* Details will be announced via TCOTS and email, "Time-Sensitive U.S. EPA Office of Water Information and Tribal Participation Opportunities"
October 18, 2015 Time: Afternoon	72nd Annual Meeting, National Congress of American Indians, San Diego, CA. Session details to be determined. EPA officials will participate in this conference, and will be available for consultation discussions during the conference. For more information, see http://www.ncai.org/events/2015/10/18/72nd-annual-convention-and-marketplace.
October 26, 2015	Information presentation and discussion at the Region 9 Region Tribal Operations Committee meeting in Reno, NV. EPA's Office of Water will participate in the accompanying Annual Tribal/EPA conference, and is available for consultation discussions during the conference. Details will be announced via TCOTS and email, "Time-Sensitive U.S. EPA Office of Water Information and Tribal Participation Opportunities"

*The webinar will include two segments: The first segment will be used to coordinate and share information, and provide an opportunity for input and questions on the proposal. The second segment will provide an opportunity for consultation comments from tribal consultation officials.

Acquisition of Polychlorinated Biphenyls (PCBs) By Pacific Chinook Salmon: An Exploration of Various Exposure Scenarios

Bruce K Hope†‡
†Oregon Department of Environmental Quality, 811 SW Sixth Avenue, Portland, Oregon 97204-1390, USA

(Submitted 31 October 2011; Returned for Revision 2 December 2011; Accepted 3 January 2012)

ABSTRACT

In 2011, as part of an update to its state water quality standards (WQS) for protection of human health, the State of Oregon adopted a fish consumption rate of 175 g/day for freshwater and estuarine finfish and shellfish, including anadromous species. WQS for the protection of human health whose derivation is based in part on anadromous fish, create the expectation that implementation of these WQS will lead to lower contaminant levels in returning adult fish. Whether this expectation can be met is likely a function of where and when such fish are exposed. Various exposure scenarios have been advanced to explain acquisition of bioaccumulative contaminants by Pacific salmonids. This study examined 16 different scenarios with bioenergetics and toxicokinetic models to identify those where WQS might be effective in reducing polychlorinated biphenyls (PCBs)—a representative bioaccumulative contaminant—in returning adult Fall chinook salmon, a representative salmonid. Model estimates of tissue concentrations and body burdens in juveniles and adults were corroborated with observations reported in the literature. Model results suggest that WQS may effect limited ($<$ approximately 2 $\times$) reductions in PCB levels in adults who were resident in a confined marine water body or who transited a highly contaminated estuary as out-migrating juveniles. In all other scenarios examined, WQS would have little effect on PCB levels in returning adults. Although the results of any modeling study must be interpreted with caution and are not necessarily applicable to all salmonid species, they do suggest that the ability of WQS to meet the expectation of reducing contaminant loadings in anadromous species is limited. Integr Environ Assess Manag 2012;8:553–562. © 2012 SETAC

Keywords: Anadromous fish Pacific salmonids Chinook Water quality standards PCBs

INTRODUCTION

In 2011, as part of the update of its state water quality standards (WQS) for protection of human health (USEPA 2000), the State of Oregon adopted a fish consumption rate (FCR) of 175 g/day for freshwater and estuarine finfish and shellfish. This value is the highest among all US states and 10 times higher than the US Environmental Protection Agency's (USEPA) national default FCR of 17.5 g/day for the general population (Matzke and Wigal 2011; USEPA 2000). Fish consumption surveys among 4 Native American tribes in the Columbia River basin demonstrated that they consume fish, primarily anadromous, at higher rates than the general population. When Oregon's WQS for organic chemicals and trace metals were calculated using the national FCR, these criteria likely afforded less protection to such high-end consumers of fish and shellfish. Raising the FCR was assumed to offer added protection to populations, such as Native Americans, that consume greater quantities of fish or shellfish on a regular basis and also to specific subpopulations, such as children and women of childbearing age, who may be more susceptible to any chemical contaminants in fish and shellfish. One aspect of increasing the FCR was deciding whether to include consumption of anadromous fish, such as salmon, in the total ingestion rate. USEPA typically does not include salmon in ingestion rate estimates ''…on the assumption that adult salmon spend most of their lives in the open ocean and take up bioaccumulative and persistent contaminants almost exclusively via the food chain in that environment.'' (USEPA 2007). Nonetheless, as a matter of policy, these species were ultimately included in the data sets used to derive the Oregon FCR because they are of special interest and concern to Northwest Native American tribes (Matzke and Wigal 2011).

Water quality standards for protection of human health that are more stringent, because they are based in part on anadromous fish consumption data, create the expectation that their implementation will lead to lower contaminant levels in such fish. If exposure occurs in waters within the State's jurisdiction (''waters of the state''), then more stringent WQS generated by a higher FCR may reduce both contaminant loads in anadromous fish and risk to humans from subsequent consumption of these fish. This benefit of lower risk, and thus increased availability for consumption, would partially offset regulatory costs associated with what are significantly more stringent WQS. If, however, anadromous species are primarily contaminated in waters beyond the State's jurisdiction (e.g., in the open ocean), then more stringent WQS may simply impose economic and legal costs on the State's economy without the offsetting benefits of reductions in contaminant loads and associated risk. Thus the decision to include anadromous fish in a FCR calculation should be informed by some knowledge of where and when anadromous fish are most likely to be exposed to, and uptake, the majority of their contaminant burden.

Conceptually, contaminant concentration and body burden are a function of where and for how long the specific life stage of a fish and a contaminant are colocated relative to one another in the environment. Because of their anadromous life history, Pacific salmonids occupy 3 distinct habitat types during their lifetimes, each of which may present a different opportunity for exposure to a contaminant: a) freshwater habitats, where eggs hatch and fry develop, b) estuary habitats, where smolts enter marine waters to feed and reside for some time during migration to c) ocean habitats, where the fish spend the majority of their lives. An exposure scenario is defined by where a fish is in space (exposure location), the time it spends in each location (exposure duration), and the contaminant concentration in prey at that location (exposure concentration). A number of exposure scenarios have been advanced, in both the published literature and in anecdotal accounts, to explain the circumstances under which Pacific Northwest salmonids may acquire a contaminant load. Frequently discussed scenarios have contaminant uptake occurring when: a) juveniles are reared in a hatchery (Johnson et al. 2009), b) juveniles (fry, subyearling, yearling) are out-migrating through fresh or estuarine waters (Johnson, Ylitalo, Sloan, et al. 2007; Johnson, Ylitalo, Arkoosh, et al. 2007), particularly if they transit areas with known contamination (Meador et al. 2010), c) adults are in near-shore marine waters (Missildine et al. 2005; O'Neill and West 2009; O'Neill et al. 1998), d) adults are in the open ocean (Cullon et al. 2009; Ewald et al. 1998; Krümmel et al. 2003, 2005; Rice and Moles 2006), e) adults partake of a final ''feeding frenzy'' in marine waters just before entering freshwater to spawn (anecdotal), or f) adults migrate upriver to spawn (anecdotal). Note that scenario (f) differs from one where exposure is to a contaminant body burden, acquired elsewhere, that is mobilized during spawning (Debruyn et al. 2004). Because the FCR is only relevant to calculation of WQS for protection of human health, this study focused on where fish could acquire tissue residues that could pose a health risk if consumed by humans. It did not address either the protection of aquatic life or the effect of contaminant burdens on the health of anadromous fish, important issues that have been studied by others (Arkoosh et al. 1998; Spromberg and Meador 2005).

The primary objective of this study was to corroborate model estimates of contaminant tissue concentrations and body burdens for specific exposure scenarios with those observed in returning adult Pacific salmonids. Model corroboration considered both the magnitude and lifetime trajectories of both contaminant concentrations and body burdens. A scenario (or scenarios) corroborated by observations might be one that offers a possible explanation for the genesis of those observations. A secondary objective of this study was to identify exposure scenarios within which implementation of a WQS inclusive of anadromous fish might reasonably be expected to reduce contaminant levels in such fish. Because life histories of these anadromous fish are complex and varied, it did not seem possible to test the absolute plausibility of an exposure scenario for all combinations of salmon species, types, evolutionarily significant units (i.e., a population of organisms that is considered distinct for purposes of conservation), or individuals. It did appear feasible, however, to identify a plausible scenario (or scenarios) based on corroboration between scenario-specific model estimates and observed tissue concentrations and body burdens in a representative species of salmonid. Bioenergetics and toxicokinetic (bioaccumulation) models were used to estimate contaminant concentrations and body burdens at locations (spatial dimension) typically occupied by juvenile and adult life stages (temporal dimension) of an idealized individual salmonid.

METHODS

Overview

Figure 1 illustrates the conceptual approach to this study. For each simulated day {d} postemergence, a bioenergetics model was used to estimate the mass of invertebrate and vertebrate prey consumed by a fish on that day, for a total lifetime of 2040 d (≈5.5 y). This is likely an overestimate of lifespan, as most Fall chinook return at 3–4 y of age. The model runs for 2040 d to show the potential trajectory of bioaccumulation should a fish live for its theoretical maximum lifespan. Concurrently, the spatial location {y} of the fish on day {d} was estimated based on an individual's idealized life history. The contaminant concentration in prey was quantified at specific locations based on observed levels. A toxicokinetic (bioaccumulation) model was then used to combine estimates of contaminant concentrations in prey with estimates of prey consumption rates to make an estimate of contaminant levels (as both concentration and body burden) in a fish on day {d} at location {y} (Drouillard et al. 2009). Model estimates of tissue concentrations were then compared with those reported in the literature to assess the explanatory power of various exposure scenarios.

Representative salmonid

Pacific salmon have evolved many diverse strategies for juvenile migration, estuarine rearing, and adult migration and spawning (Allen and Hassler 1986; Groot and Margolis 1991; Healy 1991; Quinn 2004). Life histories of anadromous salmonids do, however, have some common traits. Adult fish spawn in freshwater streams, usually in late summer or fall. Their large yolky eggs are buried in the substrate, where embryonic development occurs. Juveniles emerge from the substrate the following spring as fry and are dependent on external food sources on emerging. Species life histories diverge at this point, with some species migrating to the estuary and others delaying their migration for months or years. After passing through the estuary, the fish carry out most of the growth in the ocean, spending, depending on the species and stock, between 1 and 6 years there. Adults then return to their natal streams or lakes to spawn and die shortly thereafter.

Fall chinook salmon (*Oncorhynchus tshawytscha*) were selected as the representative salmonid species because it is highly valued commercially, likely represents an important exposure pathway in the diet of peoples with subsistence lifestyles and high salmon consumption rates, is spiritually and culturally prized among certain Native American tribes, and is known to accumulate contaminants (Carlson and Hites 2005). With chinook, 2 distinct ''types'' have evolved. A ''stream-type'' (or Spring) is found most commonly in headwater streams of large river systems. This type has a longer freshwater residency and carries out extensive offshore migrations in the central North Pacific ocean before returning

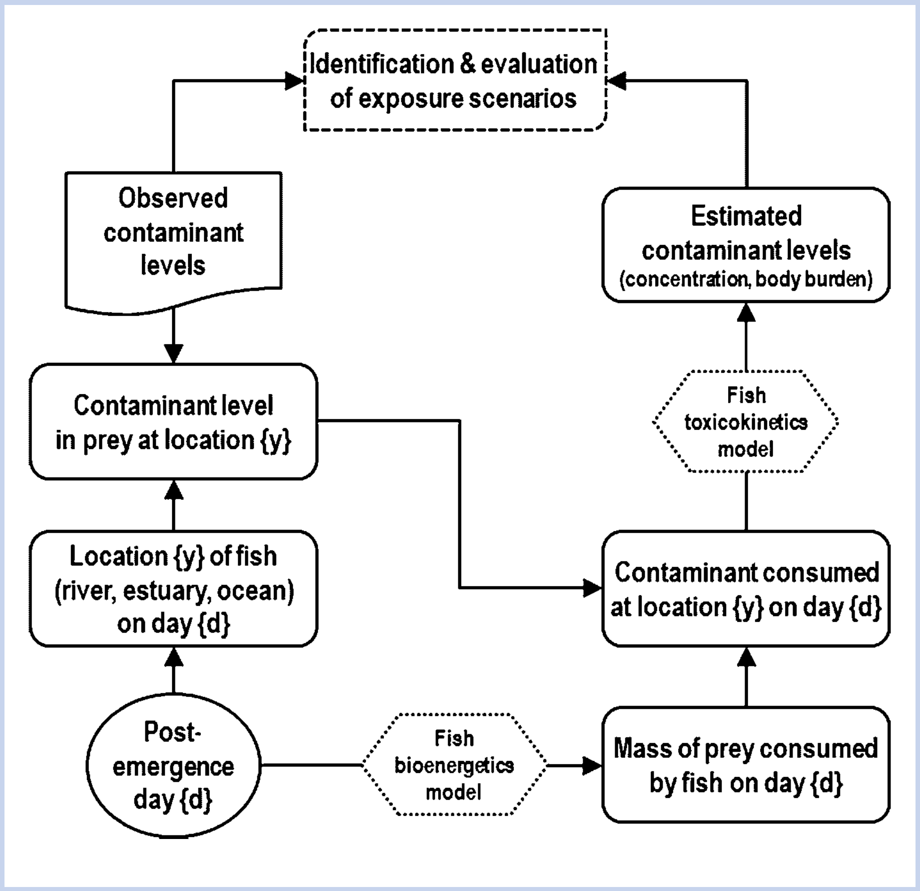

Figure 1. Conceptual model for conduct of this study.

to its natal streams in the spring or summer months. Juveniles migrate as yearlings after overwintering in the river environment. Stream-type juveniles are much more dependent on freshwater stream ecosystems because of their extended residence in these areas, but they spend little time in estuaries before moving to the ocean. They typically spend their first year at sea in near-shore waters before moving into the Gulf of Alaska and Northern Pacific Ocean for 2–4 years. An ''ocean-type'' (or Fall) is found commonly in coastal streams. Juveniles typically migrate to sea within the first 3 months of life, but timing of migration is quite variable (Reimers and Loeffel 1967). Some disperse to estuaries as fry immediately after emergence, some spend additional time in freshwater before entering the estuary, and some rapidly transit the estuary after short or long periods of residence in freshwater. Ocean-type spend more time in estuaries as juveniles than any other Pacific salmon but variation in timing and duration of estuarine residence is considerable (Hering 2009). After entering ocean waters, they tend to migrate along the coast, spend their ocean life in coastal waters (≈5–8 km offshore), and return to their natal streams or rivers principally as summer and fall runs. After 1–6 years in marine waters, both types return to their natal waters to spawn, the difference being that the ocean-type spawns almost immediately after reaching their natal stream whereas the stream-type typically spends several months in freshwater before spawning. Chinook from Alaska are almost entirely stream-type, whereas those from northern British Columbia are mixed stream- and ocean-types, and those further south in Puget Sound and Oregon waters are predominantly ocean-type (Healy 1991).

Representative contaminant

Polychlorinated biphenyls (PCBs) were selected as the representative persistent, bioaccumulative, and toxic (PBT) contaminant because their physicochemical behavior is well characterized, they have been detected in fresh and marine waters, in the tissues of various salmonid species, and in the tissues of salmonid invertebrate and vertebrate prey (Carlson and Hites 2005; O'Neill and West 2009). Empirical data on PCB concentrations in fresh and marine waters, in chinook salmon, and in their dietary items at various life stages, were drawn from the literature and are summarized in Table S1 (Supplemental Data). These data, although extensive and of good quality, nonetheless had some limitations. Ready comparisons between studies were challenged by PCB concentrations, particularly total concentrations, being reported as differing summations of various aroclors or congeners. Studies did not always report both wet weight and lipid-normalized concentrations, or data needed to convert from one to the other. Body burden estimates, an important adjunct to concentration measurements, were also rarely reported. There were also few measurements of PCB concentrations in adult fish caught at sea at known locations and apparently none of PCBs levels in the stomach contents of such fish. Many studies did not report ancillary data, such as type of salmon (Fall or Spring), weight, length, age, or lipid content, that would have been useful for comparative purposes.

A metaanalysis of the observations listed in Table S1 (Supplemental Data) suggested groups based on sampling location and tissue concentration. Wild fish in headwater (1st–3rd order) streams, including fish in headwater reaches of Puget Sound rivers and large rivers discharging to the ocean, and hatchery fish formed distinct groups, with wild fish in headwater streams having the lowest reported prey and tissue concentrations of all groups. Three groups were evident for Puget Sound: fish collected in the Sound itself, fish collected from contaminated estuaries, and fish taken from presumably un- or less contaminated, estuaries. Fish entering the ocean directly (i.e., not through Puget Sound) from large rivers and those that entered directly from small rivers formed 2 additional groups. Fish caught in the open ocean (e.g., Gulf of Alaska) or in coastal waters outside of Puget Sound (e.g., Johnstone Strait) formed a final group.

From the perspective of observed mean tissue concentrations in returning adults, fish could be placed, seemingly without regard to their type or exposure experience as out-migrating juveniles, into 1 of 3 concentration ranges: 1) a higher ''Sound'' range (mean tissue concentrations from 35 to 90 μg/kg, w/w) for returning adults whose natal river discharged into Puget Sound, 2) a middle ''Large River'' range (mean tissue concentrations from 10 to 40 μg/kg, w/w) for returning adults whose natal river discharged directly to the ocean from a watershed with significant urban land use and other anthropogenic impacts (e.g., Columbia River, Fraser River), or 3) a lower ''Ocean'' range (mean tissue concentrations from 10 to 20 μg/kg, w/w) for returning adults whose natal river also discharged directly to the ocean but from a watershed with few anthropogenic impacts (e.g., Salmon River, OR). This low range also included adults caught in the open waters of the North Pacific, Gulf of Alaska, or Bering Sea on the assumption that their natal rivers were also lightly impacted. Data for returning adults were sufficient to identify 2 ranges based on observed mean body burdens: a high range (200–400 μg/fish, w/w) for adults caught within Puget Sound and in the Duwamish, Deschutes, and Lower Fraser Rivers and a low range (30–100 μg/fish, w/w) for fish caught in the North Pacific Ocean, Gulf of Alaska, or Bering Sea. The differences between these high and low ranges for concentration (6–7-fold) and burden (7–10-fold) may be explained in part by the hydrology of Puget Sound, which is a deep, fjord-like estuary with a narrow connection to oceanic waters through the Strait of Juan de Fuca and shallow sills at Admiralty Inlet. These hydrological features tend to isolate its waters from less contaminated open ocean waters, reduce summer flushing time relative to that of the Strait of Georgia, and allow for contaminants to become entrained within it (Friebertshauser and Duxbury 1972; O'Neill and West 2009; Thomson 1994). This hydrology, combined with considerable urbanization on its surrounding lands, and the presence of several federal Superfund sites, may make the Sound a unique upper bound case for PCB contamination in Pacific Northwest coastal waters. These 5 ranges were used for corroboration purposes, in that a potentially explanatory exposure scenario would be one that placed its model estimates for both tissue concentration and body burden within either the higher or lower ranges observed in returning adult salmon.

Exposure Scenarios

Locations. In general, anadromous fish may be exposed to a contaminant while out-migrating as a juveniles through freshwater or estuarine environments, as adults in the marine environment, or in all 3 environments at different times. Within this general context, measurements summarized in Table S1 (Supplemental Data) were used to identify 16 specific exposure scenarios (Table 1). Because of the known ubiquity of PCBs in aquatic environments, a constant dissolved phased PCB concentration of 10 pg/L in both fresh and marine waters was assumed for all scenarios (Iwata et al. 1993). Seven scenarios (Scenarios 1–8) assumed that exposure occurred via water and prey consumption in only 1 specific location. Scenario 1 had exposure occurring only when wild juveniles out-migrate through river reaches with few, if any, significant anthropogenic impacts (e.g., Salmon River, OR), whereas Scenario 2 assumed exposure only when fish were reared on contaminated food in hatcheries. Exposures in estuaries within Puget Sound could occur when transiting (Scenario 3) a contaminated estuary (e.g., Duwamish Waterway) or another estuary that connects with the Sound (Scenario 4). Estuaries that enter open marine waters directly could be those for large rivers (Scenario 5) with urbanization in their watersheds (e.g., Columbia River, Fraser River), or small rivers (Scenario 6) with little urbanization in their watersheds (e.g., coastal rivers in Washington, Oregon, or Alaska). Exposures could also take place only in Puget Sound (Scenario 7) or only in unconfined coastal or the open marine waters (e.g., Gulf of Alaska) (Scenario 8). Although exposure in just 1 location is possible (e.g., only when transiting a contaminated estuary), fish have the potential, particularly with globally ubiquitous contaminants like PCBs, to be exposed in multiple locations. Eight scenarios (Scenarios 9–16) allowed for combined exposures via water and prey in multiple locations (Table 1). For example, Scenario 15 assumes that an out-migrating wild juvenile (Scenario 1) enters the open ocean (+ Scenario 8) through the estuary of a small river (+ Scenario 6), whereas Scenario 10 assumes that a hatchery-raised fish (Scenario 2) takes up residency in Puget Sound (+ Scenario 7) after entering it through an estuary with known contamination (+ Scenario 4). Although there is no empirical evidence to suggest that Pacific salmon indulge in a prespawning ''feeding frenzy'' (Higgs et al. 1995), the effect of any such behavior was evaluated by assuming that the consumption rate increased by 10 times for 30 days before the start of the spawning migration. Because Pacific salmon cease feeding during the spawning migration (Higgs et al. 1995), the only uptake of a contaminants during this portion of a salmon's life cycle would be from water via the gills.

Duration. Chinook in Puget Sound and Oregon waters are predominantly Fall or ocean-type (Healy 1991). Fall chinook may spend approximately 60–210 d postemergence in freshwater and approximately 10 and 90 d in an estuary. For this study, an idealized Fall chinook was assumed to have an exposure duration in freshwater for 130 d postemergence (median of the freshwater range), then in an estuary environment for 50 d (median of the estuary range), and the remaining 1860 d in the marine environment (Table 1), for a total lifetime of 2040 d (≈5.5 y). Median values were selected to explore what happens to a ''typical'' individual. Here the

Table 1. Summary of exposure scenarios, durations, and concentrations in Fall chinook

Scenario[a]	Exposure location	Exposure duration[c]	Exposure concentration (C_D, μg/kg, w/w)[b]	
			Juveniles[d]	Adults[d]
1	Freshwater: Wild (upstream of most anthropogenic stressors)	130	5 (5–23)	—
2	Freshwater: Hatchery	130	12 (10–14)	—
3	Estuary: Contaminated (Puget Sound)	50	450 (57–760)	—
4	Estuary: Other (Puget Sound)	50	34 (22–59)	—
5	Estuary: Large river	50	62 (20–115)	—
6	Estuary: Small river	50	10	—
7	Ocean: Puget Sound	1860	—	28[e]
8	Ocean: Open water	1860	—	6[e]
9 (1 + 3 + 7)	Wild > contaminated > Sound	Fall chinook resident in Puget Sound		
10 (2 + 3 + 7)	Hatchery > contaminated > Sound			
11 (1 + 4 + 7)	Wild > other > Sound			
12 (2 + 4 + 7)	Hatchery > other > Sound			
13 (1 + 5 + 8)	Wild > urban > Ocean	Fall chinook outside Puget Sound		
14 (2 + 5 + 8)	Hatchery > urban > Ocean			
15 (1 + 6 + 8)	Wild > non-urban >Ocean			
16 (2 + 6 + 8)	Hatchery > non-urban > Ocean			

[a] All scenarios assume a constant dissolved phase PCB concentration of 10 pg/L.

[b] Concentration as grand mean of means in Table 1 (minimum–maximum range of means).

[d] Concentration in stomach contents.

[e] PCB concentration in Pacific herring, assuming contaminated herring is 20% of total adult diet.

marine environment was either Puget Sound or the open ocean. A lifetime of this length is expected to overestimate exposure, as returns typically occur within 3–4 years of entering the marine environment.

PCB concentrations in prey. A key input to the toxicokinetic model is the PCB concentration in salmonid invertebrate and vertebrate prey (C_D), which is typically the PCB concentration in salmonid stomach contents. Each individual exposure scenario was assigned a different representative value for C_D, based on available dietary data as detailed in Table S1 (Supplemental Data) and summarized in Table 1. Its value in all scenarios was a point estimate representing a grand mean. For wild juveniles (Scenario 1), C_D was that for fish from the Salmon River (Oregon). For hatchery juveniles (Scenario 2), C_D was the mean PCB concentration in feed from various Oregon, Washington, Columbia River, and Columbia Basin fish hatcheries, exclusive of concentrations measured before 2000, as these appeared unusually high relative to more recent measurements. The C_D point estimate for a contaminated estuary (Scenario 3) was the mean of data from the Commencement Bay and Duwamish Waterway Superfund sites. That for a large river estuary (Scenario 5) was the mean of data from uncontaminated rivers entering Puget Sound, plus those for the lower Columbia and Fraser Rivers. All of these watersheds include urban lands subject to a variety of anthropogenic stressors, including chemical stressors. The Lower Columbia River, for example, is likely impacted at its confluence with the Willamette River by the Portland metropolitan area (Johnson, Ylitalo, Sloan, et al. 2007; Johnson, Ylitalo, Arkoosh, et al. 2007) and the Fraser River in Canada by its passage through the Vancouver (BC) metropolitan area. For a small river estuary (Scenario 6), C_D was the mean in the diet of fish in small, coastal rivers whose estuaries enter the ocean directly, without an intervening sound. Because of a paucity of data on PCB concentrations in adult stomach contents, the C_D for adults, in both Puget Sound (Scenario 7) and the open ocean (Scenario 8), was inferred from measured PCB concentrations in Pacific herring (*Clupea pallasi*), prey comprising 20%–60% of an adult's diet (Healy 1991; West et al. 2008).

Bioenergetic Model (Daily Consumption Rate)

As out-migrating juveniles in freshwater, wild chinook salmon typically feed on pelagic, drifting, and epibenthic larval and adult insects. In estuaries, their diet shifts toward pelagic zooplankton, epibenthic amphipods, and, as they grow larger, small fishes. In the marine environment, the diet of adult chinook is largely comprised of larval and juvenile fishes (principally Pacific herring [*Clupea*]), pelagic amphipods, and crab megalopa (Healey 1991; Schabetsberger et al. 2003). The Wisconsin bioenergetics model 3.0 (Hanson et al. 1997; Madenjian et al. 2004) was used, unmodified, to estimate the feeding rate (G_D), fecal egestion rate (G_F), and body weight (W) for juvenile (J) and adult (A) chinook salmon cohorts for each day of a 2040 d lifetime. The model's default values for chinook salmon were used to parameterize its physiological variables (Hanson et al. 1997; Stewart and Ibarra 1991). These included the allometric parameters for dependence of consumption and respiration on body mass, the most sensitive variables (i.e., those with the greatest influence on model predictions). Values for user-specified variables were: weight range (J: 0.1–80 g, A: 80–15 000 g), indigestible fraction of prey (J, A: 20%), prey energy content (J: 2000 J/g, A: 4000 J/g, wet body mass; energy densities of typical prey items (Hanson et al. 1997: see Appendix B), prey dietary fraction (1, unitless; because all prey had the same energy content and digestibility), predator energy content (4000 J/g, wet body mass), and water temperature (10° C, midpoint of optimal growth range [Allen and Haster 1986]).

Toxicokinetic Model (Contaminant Uptake and Retention)

Uptake from prey items and elimination via feces are the major pathways by which fish accumulate and eliminate persistent hydrophobic ($\log K_{OW} \approx 6$) organic contaminants such as PCBs (Qiao et al. 2000). Uptake of such contaminants from water via the gills is of less importance due to their generally low concentrations (pg/L) in fresh or marine waters (Gobas and Mackay 1987; Iwata et al. 1993). A mass balance contaminant accumulation model was implemented in STELLA^{TM} (Isee Systems) using variables and algorithms developed by Arnot and Gobas (2003, 2004) and Gobas and Arnot (2010). The 2 most sensitive variables in this model are $\log K_{OW}$ (that was a fixed value) and the concentration of a contaminant in prey items (C_D). Values for C_D (Table 1), as well as the day or days on which a fish is exposed, were varied to match the exposure scenario being evaluated. Table S2 (Supplemental Data) summarizes model variables and equations; relationships for these are shown in Figure S1 (Supplemental Data). This model provided estimates of tissue concentration and body burden resulting for uptake of PCBs from both surface water (via gill exchange) and prey (via consumption) for all, or any portion, of a fish's lifespan. Both estimates were necessary because for non- or poorly metabolized contaminants (such as PCBs) in a fast-growing species, decreases in concentration due mainly to growth dilution may be misinterpreted as reductions in burden (i.e., as a loss of contaminant mass). Burden is a better indicator of the difficult-to-reverse consequences of long term exposure to a recalcitrant contaminant.

RESULTS AND DISCUSSION

Scenarios

Observed and model estimated tissue concentrations are listed in Table 2; body burdens in Table 3. Scenario-specific model results, in relation to ranges observed in returning adults after 3–4 years in seawater, are shown in Figure 2 for concentrations and Figure 3 for body burdens. Trajectories through time of tissue concentrations, again in relation to observed ranges, are shown in Figures S2–S8 (Supplemental Material).

Individual scenarios. Exposures only in upstream freshwater habitats (Scenario 1 [Figure S2]) or only in a hatchery (Scenario 2 [Figure S2]), or only while transiting uncontaminated estuaries (Scenarios 4 and 6 [Figure S3]) all failed to produce estimates for returning adult fish within any of the observed concentration ranges. With the unusually high dietary concentrations reported before 1993 set aside, hatchery fish exposed to contaminated food (Scenario 2) would be indistinguishable from those exposed only in the open ocean (Scenario 8 [Figure S4]), which suggests that hatcheries may be an unlikely sole source of PCB loads in returning adults. Exposure only in Puget Sound (Scenario 7 [Figure S4]) or only in the open ocean (Scenario 8) was sufficient to generate concentrations and burdens within the Sound and Ocean ranges, respectively, for fish with 3–4 years in seawater and also at end-of-life (Figures 2 and 3). Exposure only in a large river estuary (Scenario 5 [Figure S3]) yielded

[h] Out-migrating juveniles collected in 1989, 1993, 2000 in the Duwamish River estuary, mean (1 SD) (Meador et al. 2002).

[i] Adults returning to the Lower Fraser River (BC) and Duwamish and Deschutes Rivers (WA) (Cullon et al. 2009).

[j] Adults collected in the Gulf of Alaska and North Pacific Ocean (Carlson and Hites 2005; Easton et al. 2002), in Johnstone Strait (Cullon et al. 2009), and off Vancouver Island (BC) (Ikonomou et al. 2007).

[k] 3 to 4 winters in seawater, as average of post-emergence days 1145 to 1510.

concentration estimates just below, but burden estimates at, the lower range, whereas short, intense exposures not unlike those achieved by passage through an estuary containing an in-water contaminated site (Scenario 3 [Figure S3]) generated concentration and burden estimates at the higher range. An estuary fed by a large river flowing through areas impacted by anthropogenic chemical stressors (e.g., the Columbia River at its confluence with the Willamette River is affected by the urban areas of Portland [OR] and Vancouver [WA], as well as a large in-water Superfund site) could produce such exposures.

Scenario 3, a single large exposure when out-migrant juveniles transit a contaminated estuary, produced tissue and burden estimates at the lower bound of those observed in 3–4-year-old adults (Figures 2 and 3). Tissue concentrations slowly declined but body burdens were recalcitrant, indicating that even a relatively brief (≤50 d) exposure to elevated prey concentrations may have lasting consequences in terms of increased PCB burdens carried by adults. Average and adjusted average contaminant concentrations in adults taken from Puget Sound after 1–4 years in salt water (O'Neill and West 2009) were compared to model estimated concentrations. Scenario 3 provided the closest approximation to these observations in terms of both magnitude of, and rate of decline in, concentration (Figure S9). Colloquially, a juvenile transiting a contaminated location appears to ''jump-start'' acquisition of a body burden of highly bioaccumulative contaminants such as PCBs. Scenario 7 did not suggest declines in tissue concentrations, suggesting that apparent declines, particularly in burdens, result from samples composed of individual fish with differing exposure experiences.

Absent a short, intense exposure to chemical stressors (e.g., Scenarios 3 and 5), simple residence in, or extended transit through, contaminated marine waters may be sufficient to generate the majority of the observed loads. The degree of loading may be a function of the extent of the time spent is residence or transit. Thus exposures before entering marine waters that do not involve intense exposures are unlikely to be the principal source of PCB loads observed in returning adults. This finding of a dominant role for exposure in open marine waters is consistent with reports by others (O'Neill and West 2009) and with the USEPA rationale for not including anadromous fish in exposure estimates (USEPA 2007).

Multiple scenarios. Exposure upstream, then in a contaminated estuary, then in Puget Sound (Scenarios 9 and 10 [Figure S5]), approximately doubled concentration and burden estimates over those for the Sound (Scenario 7) alone. Conversely, exposures upstream, then in an uncontaminated Puget Sound estuary, then in Puget Sound (Scenarios 11 and 12 [Figure S6]) did not produce concentration and burden estimates different than those in the Sound (Scenario 7) alone. This emphasizes the role played by short but intense exposures associated with a contaminated estuary. Exposure upstream, then in an large river estuary, then in open marine waters (Scenarios 13 and 14 [Figure S7]), also approximately doubled concentration and burden estimates over those for the open ocean (Scenario 8) alone. An initial spike in concentration (Figure S7) due to the large river estuary was subsequently ameliorated by a longer exposure to less contaminated prey in the open ocean, causing concen-

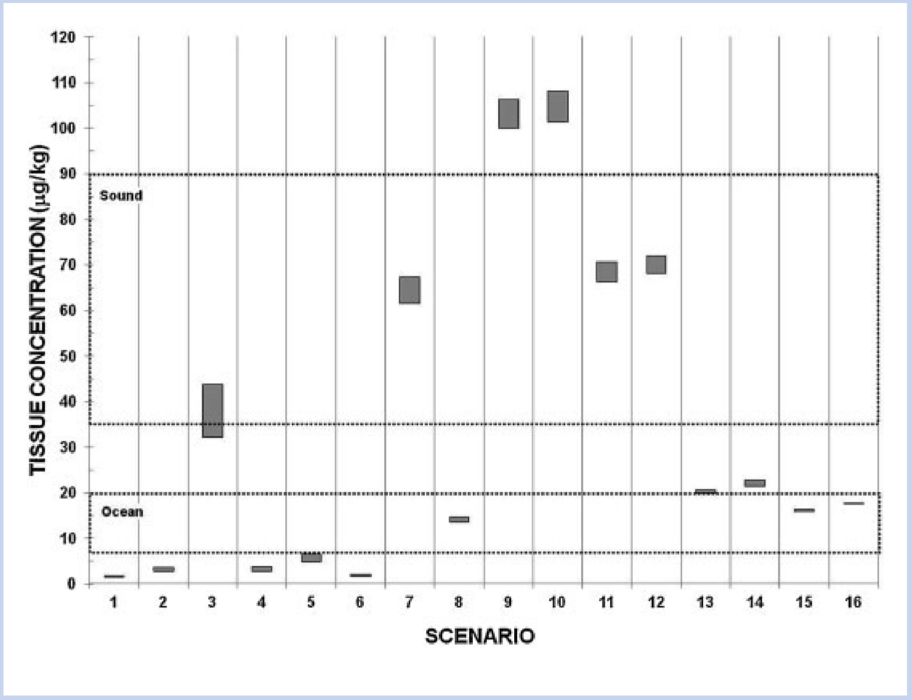

Figure 2. Comparison of tissue concentration estimates (µg/kg, w/w) by scenario (vertical bars) to observed tissue concentration ranges (boxes with dotted line borders) in adult fish at 3–4 y in marine waters.

tration and burden estimates to settle into the large river range between the Sound and Ocean ranges. However, exposures upstream, then in a small river estuary, then in the open ocean (Scenarios 15 and 16 [Figure S8]) did not produce concentration and burden estimates different than those in the open ocean (Scenario 8) alone.

Miscellaneous scenarios. Uptake from water was a small and comparatively inconsequential source of PCB concentrations and burdens, indicating that observed adult burdens could not be obtained only during the upstream spawning migration in freshwater. However, the ubiquity and persistence of legacy PCBs (and other legacy chemicals with similar

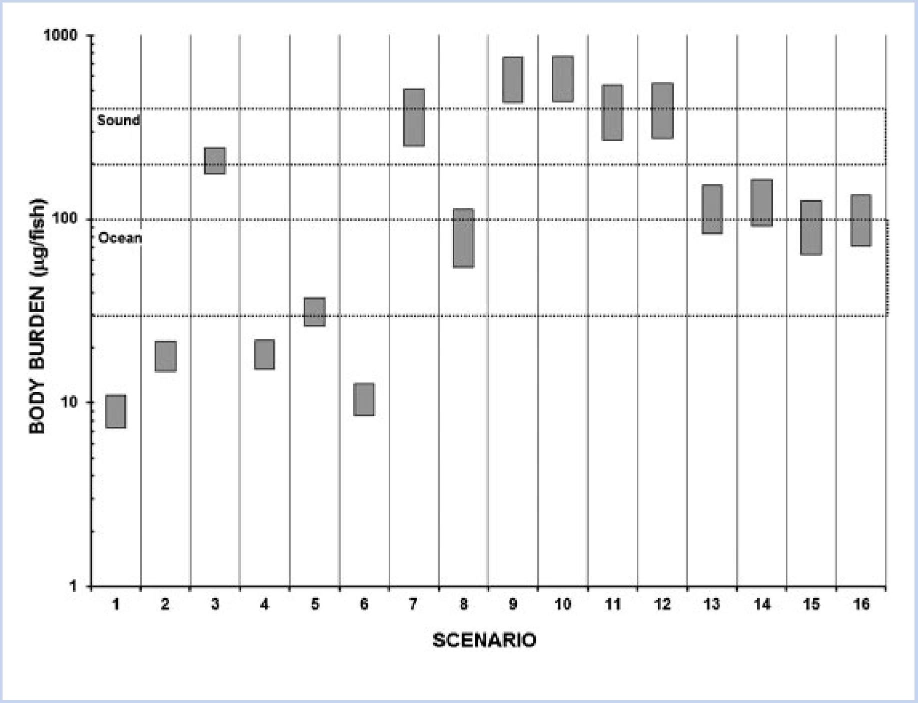

Figure 3. Comparison of body burden estimates (µg/fish) by scenario (vertical bars) to observed body burden concentration ranges (boxes with dotted line borders) in adult fish at 3–4 y in marine waters.

physicochemical properties) virtually guarantees that any fish, whether anadromous or resident, will have some small PCB burden (CTUIR 2007; Henny et al. 2003). The ''feeding frenzy'' scenario (a 10-fold increase in the consumption rate in the 30 d before the start of spawning) had no discernible effect on either concentrations or burdens estimated for any scenario. It is thus highly unlikely that an adult fish could acquire concentrations or burdens on the order of observed levels simply by sharply increasing its feeding near the end of its life.

Implications for WQS

This study focused on 1 type (Fall) of 1 species (chinook) of salmonid and on 1 PBT contaminant (PCBs), corroborated by a metaanalysis of available data on tissue concentrations and body burdens of that contaminant collected in the Pacific Northwest and Alaska by a number of researchers. It applied these data to models that are well established and whose behavior, including sensitive inputs, is well understood. However, these species, data, and models all embed uncertainties of various types, not all of which are readily identifiable or quantifiable. As a result, the results of this (or any) modeling study must be interpreted with caution; however, it may still provide insights into the efficacy of WQS for reducing contaminant loads in Fall chinook salmon. Note, however, that the specific applicability of these results to other salmonid species was not determined here. At a minimum, these results may be useful for dispelling assertions about exposure scenarios that are physiologically improbable and whose pursuit is unlikely to result in protective outcomes.

Results suggest that using WQS as waterbody target concentrations may yield only small ($\leq 2\times$) reductions in PCB levels (or of other ubiquitous legacy contaminants with similar PBT properties) in returning adult Fall chinook salmon because the majority of uptake likely occurs while adults are in marine waters beyond the state's jurisdiction. WQS would also have little effect on hatchery fish whose PCB load stems from consumption of contaminated feed (Scenario 2). Scenario 8 results suggest, as have others (O'Neill and West 2009), that PCB loads in fish either resident outside of Puget Sound or not in contact with a contaminated estuary likely stem primarily from exposure in open marine waters. Because states do not have jurisdiction over the open ocean, implementation of WQS will not occur in such waters.

Puget Sound is unique marine water body in that it is both poorly flushed and subject to contaminant loading from surrounding urban landscapes, which have been shown to be disproportionate contributors of chemical stressors (Black et al. 2000; Paul and Meyer 2001). It is also host to several major in-water contaminated sites, where WQS are currently being used to guide remediation efforts. Although addressing these sites is likely to eliminate excesses in concentrations and burdens (e.g., Scenarios 9 and 10), doing so is unlikely to result in large reductions in bioaccumulative contaminants in anadromous fish. Because of the known relationship between urban land use and chemical stressors (Black et al. 2000), use of WQS in controlling or reducing contaminants from nonpoint sources (e.g., runoff from impervious surfaces, nonpermitted stormwater flows, runoff of air deposition [Hope 2008]) will also be required (McCarthy et al. 2008). Because permitted and properly managed point sources (e.g., industrial, wastewater treatment, permitted stormwater) are no longer significant contributors of PCBs to watersheds, use of WQS to regulate such sources would not reduce chemical loadings throughout the Sound. Although implementation of WQS for all waters entering the Sound may, over time, yield lower contaminant levels within the Sound, there are likely to be practical limits on the affect WQS can have on globally distributed legacy contaminants such as PCBs.

Including anadromous fish in the FCR used for developing WQS for protection of human health creates the expectation that implementation of this WQS will significantly reduce bioaccumulative contaminants (e.g., PCBs, PBDEs, dioxins/furans) in such fish. Based on these model results, meeting WQS may lead to small reductions ($\leq 2\times$) only for returning Fall chinook salmon adults that were resident in a confined water body (e.g., Puget Sound) or who transited a highly contaminated estuary (e.g., Duwamish Waterway) as outmigrating juveniles. Otherwise, it may be unrealistic to expect attainment of WQS to result in reduced contaminant burdens in species who receive these burdens as adults in unconfined coastal or open marine waters. Where attainment of WQS can be physically linked to reductions in contaminant loads, benefits will typically out-weigh costs associated with its attainment. Conversely, any physical disconnects between attainment of WQS and expected reductions in contaminant loads creates a situation with costs but few, if any, off-setting benefits. Such a cost-benefit disparity can frustrate those seeking the protection of WQS and those legally required to implement controls designed to attain it.

Cancer risk management

A review of 132 federal regulatory decisions

Various federal agencies are responsible for promulgating regulations and standards to protect the public from exposure to environmental carcinogens. Although many factors are considered in the decision to regulate a carcinogen, one important issue concerns the probability that individuals in an exposed population will develop cancer.

What has not been clear, however, is the level of cancer risk that triggers regulation, or whether there is consistency within and between agencies in arriving at the risk decisions that underpin regulatory action. We have retrospectively reviewed the use of cancer risk estimates in prevailing federal standards and in withdrawn regulatory initiatives to determine whether any simple patterns emerge to correlate risk level with regulatory action. Our results show that there are definite patterns and a surprising degree of consistency in the federal regulatory process.

The sources of the data reviewed are notices of proposed or final regulations found in the *Federal Register* and in published and unpublished regulatory support documents, all of which are in the public domain. Three measures of risk are considered: *Individual risk* is measured as an upper-limit estimate of the probability that the most highly exposed individual in a population will develop cancer as a result of a lifetime of exposure. The *size of the population* exposed to the hazards is considered. Finally, *population risk* is measured as an upper-limit estimate of the number of additional incidences of cancer in the exposed population. Federal agencies compute population risks (as measured by the number of cancer deaths per year) by one of two methods: by multiplying maximum individual risk by population size or by accounting for variations in individual exposure levels and adding up the resulting figures for an entire population. Almost one-third of the population risk estimates reviewed here were calculated using the first method, although the second method is preferable.

Knowledge of two additional terms, de manifestis and de minimis, is important to understanding the patterns that emerge from the data. *De manifestis* risk, literally a risk of obvious or evident concern, has its roots in the legal definition of an "obvious risk"; one that is instantly recognized by a person of ordinary intelligence. *De minimis* risk has been used for a number of years by regulators to define an acceptable level of risk that is below regulatory concern. This term stems from the legal principle, *de minimis non curat lex;* "the law does not concern itself with trifles."

Table 1 lists 132 regulatory decisions for which at least one of these measures of risk was estimated prior to regulation of the substance in question. The methods used by federal agencies for estimating individual risk are generally considered to overestimate risk; they assume maximum exposure and a linear no-threshold dose–response function. For example, the population risk estimate for saccharin (Number 100 in Table 1) is listed as 1200 cancer deaths annually, although the Food and Drug Administration (FDA) states that this is an upper-limit risk estimate and the actual risk is between zero and 1200.

The published maximum risk estimates have been taken at face value; any errors in the estimates or interagency differences in the approach to risk analysis are not considered impor-

tant for our analysis. All that matters is that when the regulatory decision was made, risk managers were presented with these estimates as the best available upper-bound estimates.

Categories of risk

Figure 1 presents preregulatory levels of maximum individual risk for regulatory decisions involving public exposure to chemical carcinogens. Two patterns are apparent. First, every chemical with an individual risk above 4×10^{-3} (four chances in 1000 that a chronically exposed individual will develop cancer) was regulated. Second, except for one FDA decision (Number 44 in Table 1), no action was taken to reduce individual lifetime risk levels that were below 1×10^{-6}.

The Delaney Clause of the Federal Food, Drug and Cosmetic Act Food Additives Amendment of 1958 states: "No additive shall be deemed safe if it is found to induce cancer when ingested by man or animal." Despite this, in all 11 decisions made between 1980 and 1985 involving indirect carcinogenic food additives, FDA set standards but did not require existing risk levels to be reduced. FDA has recently argued that the Delaney Clause permits use of carcinogenic food additives with cancer risks below 1×10^{-6}; a decision that is being challenged in court. Our analysis shows that FDA's reasoning is consistent with historical practice.

Figure 2 presents 58 cases in which estimates of both individual risk and population size were available at the time a regulatory decision was made. Estimated exposed populations ranged from 9700 to 230 million, the latter for the total U.S. population. There does not appear to be a strong correlation between the size of the population exposed and the likelihood of regulation. This conclusion is contrary to that reached by Milvey, who stated that the de minimis risk level is a function of the size of the population at risk (*1*). To further investigate this question, we review estimates of individual and population risk.

Figure 3 presents decisions for which individual and population risk estimates were available at the time of regulation. Three categories of risk can be identified. De manifestis risks are those that are so high that agencies almost always acted to reduce them, and de minimis risks are so low that agencies almost never acted to reduce them (*2*). The risks falling into the area between these extremes were regulated in some cases but not in others.

Figure 4 shows 19 occupational decisions that have been added to Figure 3 to provide data on small populations at high individual risk; no other data exist for these cases. It is assumed that decisions to regulate occupational exposures can be used to aid in defining de manifestis and de minimis risk levels because public exposures to carcinogenic substances should be regulated at least as stringently as occupational exposures are.

Line A of Figure 4 defines the de manifestis level; above this line, federal agencies always acted to reduce risk. For exposures resulting in a small-population risk, the de manifestis level is approximately 4×10^{-3}. As population risk approaches 250 cancer deaths (which could only occur in a population the size of the entire United States) the de manifestis level drops to about 3×10^{-4}. Line B shows the de minimis level. Below this line, no action has ever been taken to reduce risk. Line B indicates that for small-population effects, regulatory action was never taken for individual risk levels below 10^{-4}. For effects resulting from exposures to the entire U.S. population, the level of acceptable risk drops to 10^{-6}. Line C is the area beyond which no data can fall. Figure 4 is essentially an analysis of the Reagan administration's regulatory decisions; only six decisions in Figure 4 occurred before 1980.

Figure 4 raises two questions. First, what justification is given by regulatory

FIGURE 2

Effect of individual risk vs. population size on chemical carcinogen regulations

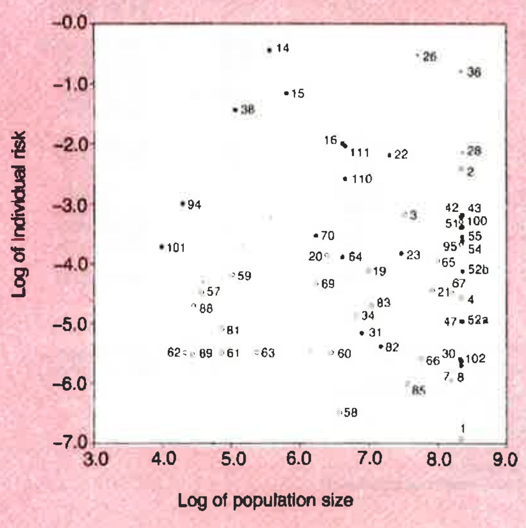

FIGURE 3

Effect of individual vs. population risk on chemical carcinogen regulation

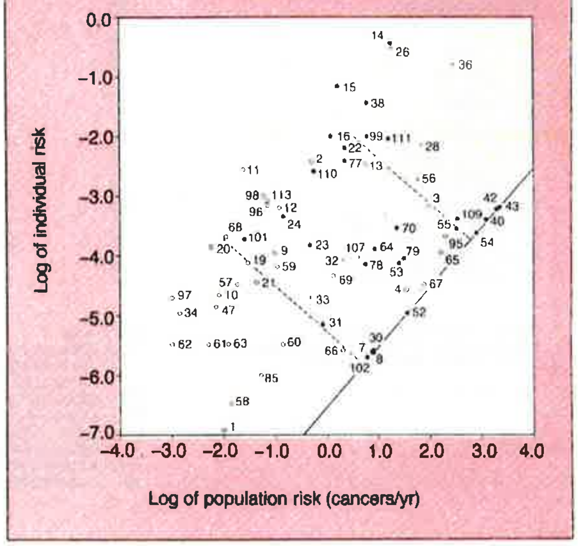

FIGURE 4
Effect of individual vs. population risk on chemical carcinogen regulation

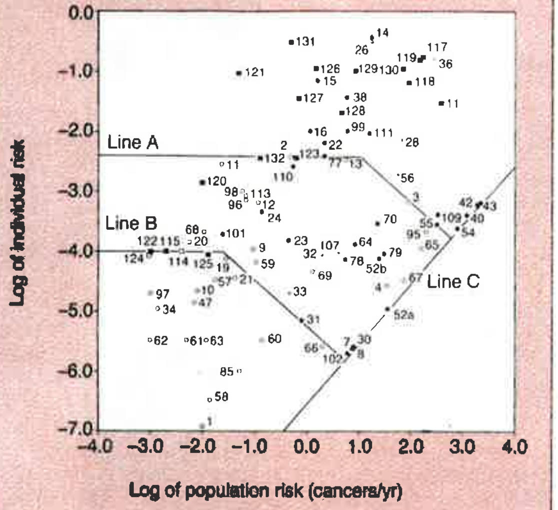

FIGURE 5
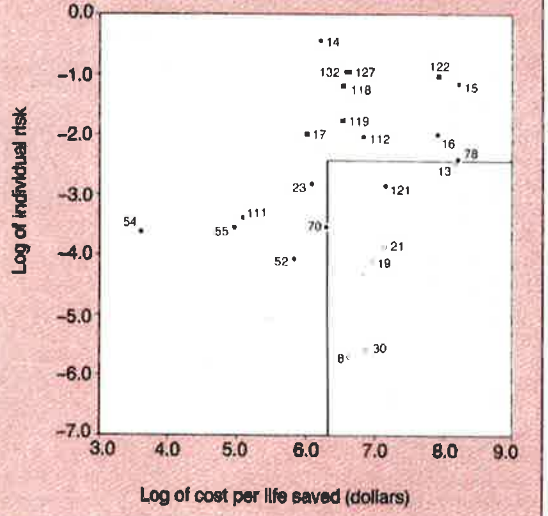
Effect of cost on the regulation of chemical carcinogens



agencies for not regulating chemicals in the de minimis category of risk? Second, what justification is given for regulatory decisions involving chemicals in the region between the de manifestis and de minimis levels? The primary answer given by federal agencies to the first question, as defined in Figure 4, is insignificant population risk. Table 2 shows those regulatory decisions that cited insufficient risk as the reason not to regulate. EPA's most explicit statement on the use of population effects in setting acceptable levels of risk is found in its decision on radionuclide standards (Table 1, Numbers 96–99).

In declining to regulate natural radionuclide emissions from elemental phosphorus plants (with an individual risk of 1×10^{-3}), the EPA decision states, "If risk to the most exposed individuals were the only criterion for judgment, this relatively high risk might well have led to a decision to regulate. However, this risk must be weighted against both the low aggregate risk [0.06 cancer deaths per year] and against other factors," such as cost (*3*).

Only two decisions in the de minimis region of Figure 4 consider factors other than small-population risk. Arsenic emissions from zinc smelters and benzene emissions from storage vessels are regulated by Section 112 of the Clean Air Act, the enforcement of which is heavily influenced by available technology. At the time of regulation, these two sources were already controlled with the best available technology (BAT), and further regulation could have resulted in shutdown of the industry (*4, 5*).

Analysis of regulatory decisions involving chemicals in the region between the de manifestis and de minimis levels indicates that cost effectiveness is the primary determinant of regulation. Figure 5 shows the cost effectiveness (cost per life saved) of regulating exposures to 23 chemicals vs. their preregulatory individual lifetime risk. Substances with individual risks above the de manifestis level were regulated regardless of cost.

In the region between the de manifestis and de minimis levels, substances with risk reduction costs of less than \$2 million per life saved were regulated; substances that cost more were not regulated. This conclusion is based on limited data, but it is consistent with EPA guidance suggesting that regulation is warranted if the cost per life saved does not exceed \$1.5 million (*6*).

The two major factors that influence the magnitude of cost, and by extension the decision to regulate, are the availability of substitutes (for example, decisions 8 and 30) and whether emissions currently are controlled by BAT (for example, decisions 9–13 and 19–21).

In reviewing the regulatory decisions of the past decade, two trends are apparent. First, there is an increased use of quantitative risk analysis, which extrapolates animal data to humans. Between 1976 and 1980, quantitative risk analysis was used in regulatory decisions involving only eight chemicals; from 1981 to 1985 the number of decisions increased to 53. Second, there are indications that the definition of de minimis is changing.

Prior to 1980, it was generally agreed that the de minimis risk was 10^{-6} per lifetime risk, regardless of population. Figure 4 indicates that for small-population risks, the de minimis risk is now considered to be a 10^{-4} lifetime risk. However, every decision in the de minimis region of Figure 4 was made after 1983.

Regulatory guidelines

The Environmental Protection Agency has specifically requested assistance in developing a quantitative rule for incorporating population risk into the decision-making process (*7*). EPA has suggested a de minimis individual lifetime risk level of 10^{-5} to 10^{-4} for small populations and 10^{-7} to 10^{-6} for large populations. Although no such explicit standard has been developed, we can see that there are simple rules that can be used to guide regulatory decisions. These guidelines incorporate individual risk, population risk, and cost effectiveness into a single framework, even though it is recognized that no absolute rules are possible.

Guideline 1. There is a de manifestis individual lifetime risk level that is a function of population risk, as shown in Line A of Figure 4. Above this level, regulatory action should be taken to reduce risk.

Guideline 2. There is a de minimis individual lifetime risk level that is a function of population risk, as shown in Line B of Figure 4. Below this line, regulatory action generally need not be taken.

Guideline 3. In the region between the de manifestis and de minimis levels, regulatory action should be taken if the

TABLE 2
Decisions citing insignificant population risk as the reason not to regulate

Chemical	Individual risk	Population risk (cancer/yr)	Agency comments
Arsenic			
Zinc oxide	3×10^{-3}	0.02	*Total cancer incidence, even on a national basis, is likely to be small compared to the incidence associated with smoking and diet.*
Secondary lead smelters	3×10^{-3}	6	
Primary lead smelters	1×10^{-4}	0.1	
Chemical manufacturing	6×10^{-4}	0.1	
Zinc smelters	2×10^{-5}	0.008	
Radionuclides			
Elemental phosphorus	1×10^{-3}	0.06	*This risk [10^{-3} individual risk] must be weighed against both the low aggregate risk and against other factors.*
Vinylidene chloride	8×10^{-4}	0.07	*Magnitude of the public health risk is small.*
Radionuclides			
Department of Energy facilities	7×10^{-4}	0.07	*[Population impact] insufficient to warrant regulation.*
Nuclear Regulatory Commission, non-DOE	2×10^{-5}	0.001	
Formaldehyde			
Teachers	7×10^{-5}	0.1	*[Population risk below one cancer risk per year, which is] insignificant risk of widespread harm.*
Students	3×10^{-6}	0.001–0.1	
Chlorinated benzenes	1×10^{-5}	0.007	*Health risk is not sufficient to warrant regulation.*
Epichlorohydrin	1×10^{-5}	0.001	*Relatively low aggregate risk.*

cost is below $2 million per life saved.

These guidelines have significant implications, for example, concerning remedial action at hazardous-waste sites. Most such sites pose risk to only a limited geographic area, where population risks presumably are small. Past regulatory actions by EPA indicate that 10^{-4} would be the de minimis risk level for these areas.

Perhaps the most surprising aspect of our study is the consistency found among federal agencies' methods in the use of cancer risk estimates for regulatory decisions. With the possible exception of FDA decisions concerning de minimis risks, the history of federal decision making indicates that all agencies are fairly consistent in their implicit definitions of de manifestis and de minimis levels of risk. If the above three guidelines were adopted explicitly, consistency with past decisions would be maintained and the process of regulatory decision making would be simplified considerably.

Regulatory Impact Analysis: A Primer

With this document, the Office of Information and Regulatory Affairs is providing a primer to assist agencies in developing regulatory impact analyses (RIAs), as required for economically significant rules by Executive Order 13563, Executive Order 12866, and OMB Circular A-4.[1]

In accordance with those requirements, agencies should include the information described below in their RIAs. This primer is limited to the requirements of Executive Order 13563,[2] Executive Order 12866,[3] and Circular A-4[4]; it does not address requirements imposed by other authorities, such as the National Environmental Policy Act, the Regulatory Flexibility Act, the Unfunded Mandates Reform Act, the Paperwork Reduction Act, and various Executive Orders that require analysis. Executive Order 13563, Executive Order 12866, and Circular A-4, as well as those other authorities, should be consulted for further information.

The purpose of this primer is to offer a summary of the requirements of OMB Circular A-4. The primer is not meant to be a substitute for the more detailed description in that Circular. Nothing in this primer is intended to alter existing requirements or policy.

A. Introduction

Executive Orders 13563 and 12866 require agencies to provide to the public and to OMB a careful and transparent analysis of the anticipated consequences of economically significant regulatory actions. This analysis includes an assessment and (to the extent feasible) a quantification and monetization of benefits and costs anticipated to result from the proposed action and from alternative regulatory actions. Executive Order 13563 specifically requires agencies "to use the best available techniques to quantify anticipated present and future benefits and costs as accurately as possible."

The purpose of the RIA is to inform agency decisions in advance of regulatory actions and to ensure that regulatory choices are made after appropriate consideration of the likely consequences. To the extent permitted by law, agencies should proceed only on the basis of a reasoned determination that the benefits justify the costs (recognizing that some benefits and costs are difficult to quantify). Regulatory analysis also has an important democratic function; it promotes accountability and transparency and is a central part of open government.

Important goals of regulatory analysis are (1) to establish whether federal regulation is necessary and justified to achieve a social goal and (2) to clarify how to design regulations in the most efficient, least burdensome, and most cost-effective manner. To that end, Executive Orders 13563 and 12866 require agencies to consider a range of regulatory alternatives, including the option of not regulating, and to design their regulations in the most cost-effective manner to achieve the regulatory objective. Agencies should select the alternative that maximizes net benefits, while also taking into consideration distributive impacts and qualitative benefits and costs, unless a statute requires another approach.

B. Key Elements of a Regulatory Impact Analysis

An RIA should include the following three basic elements:

A statement of the need for the regulatory action: An analysis should begin with a clear explanation of the need for the regulatory action, including a description of the problem that the agency seeks to address. Agencies should explain whether the action is intended to address a market failure or to promote some other goal, such as improving governmental processes, protecting privacy, or combating discrimination. If the action is compelled by statute or judicial directive, agencies should describe the specific authority and the extent of discretion permitted.

A clear identification of a range of regulatory approaches: If an agency has decided that Federal regulation is appropriate, it should identify and include in its RIA a range of alternative regulatory approaches, including the option of not regulating. Alternatives to Federal regulation include State or local regulation, voluntary action on the part of the private sector, antitrust enforcement, consumer-initiated litigation in the product liability system, and administrative compensation systems. Where relevant, agencies should consider flexible approaches that reduce burdens and maintain freedom of choice, such as warnings, appropriate default rules, and disclosure requirements. To the extent feasible, agencies should specify performance objectives, rather than specifying the behavior or manner of compliance that regulated entities must adopt.

An estimate of the benefits and costs—both quantitative and qualitative—of the proposed regulatory action and its alternatives: After identifying a set of potential regulatory approaches, the agency should conduct a benefit-cost analysis that estimates the benefits and costs associated with each alternative approach. The benefits and costs should be quantified and monetized to the extent possible, and presented in both physical units (e.g., number of illnesses avoided) and monetary terms. When quantification of a particular benefit or cost is not possible, it should be described qualitatively. The analysis of these alternatives may also consider, where relevant and appropriate, values such as equity, human dignity, fairness, potential distributive impacts, privacy, and personal freedom.

The agency's analysis should be based on the best available scientific, technical, and economic information. To achieve this goal, the agency should generally rely on peer-reviewed literature, where available, and provide the source for all original information. In cases of particular complexity or novelty, the agency should consider subjecting its analytic models to peer review.[5] In cases in which there is no reliable data or research on relevant issues, the agency should consider developing the necessary data and research. In addition, the agency should comply with the Information Quality Guidelines for the agency and with OMB's "Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by Federal Agencies."[6] Executive Order 13563 also provides that "[c]onsistent with the President's Memorandum for the Heads of Executive Departments and Agencies, 'Scientific Integrity' (March 9, 2009), and its implementing guidance, each agency shall ensure the objectivity of any scientific and technological information and processes used to support the agency's regulatory actions."

The agency should clearly document all of the assumptions and methods used in the analysis, discuss the uncertainties associates with estimates, and publicly provide the supporting data and underlying analysis (if possible on the Internet; see Executive Order 13563, section 2 (b)), so that a qualified third party reading the analysis could understand and reproduce the analysis. Regulatory analysis should also include a clear, plain language executive summary, including a table, that summarizes the benefit and cost estimates for each regulatory action and alternative under consideration, including the qualitative and non-monetized benefits and costs.[7]

C. Preparing a Regulatory Impact Analysis

This section provides a step-by-step guide to preparing an RIA. The three key elements discussed in the previous section are important; this section focuses primarily on the benefit and

---

[7] For additional discussion, see 2010 Report to Congress on the Benefits and Costs of Federal Regulations and Unfunded Mandates on State, Local, and Tribal Entities, page 51. Available at: http://www.whitehouse.gov/sites/default/files/omb/legislative/reports/2010_Benefit_Cost_Report.pdf

cost assessment of regulatory alternatives required by Executive Order 13563, Executive Order 12866, and Circular A-4.

Benefit -cost analysis (BCA) provides a systematic framework for evaluating the likely outcomes of alternative regulatory choices. It allows agencies to evaluate different regulatory options with a variety of attributes using a common measure – a monetary unit. When important benefits and costs cannot be expressed in monetary units or quantified in any manner, the BCA can provide useful information about the relative merits of regulatory alternatives, but the "net benefits" estimate, viewed in isolation, may be incomplete and misleading.

To provide a complete RIA, agencies should follow these steps:

- Describe the need for the regulatory action
- Define the baseline
- Set the timeframe of analysis
- Identify a range of regulatory alternatives
- Identify the consequences of regulatory alternatives
- Quantify and monetize the benefits and costs
- Discount future benefits and costs
- Evaluate non-quantified and non-monetized benefits and costs
- Characterize uncertainty in benefits, costs, and net benefits

Below we provide additional information for each of these steps.

Step 1: Describe the need for the regulatory action

As discussed in the previous section, an analysis should begin with a reasonably detailed description of the need for the regulatory action and should include an explanation of how the regulatory action will meet that need. The RIA should explain whether the action is intended to address a significant market failure (e.g., externality, market power, and inadequate or asymmetric information) or to meet some other compelling public need such as improving governmental processes or promoting values such as privacy or human dignity. If the regulation is designed to correct a significant market failure, the RIA should describe the failure both qualitatively and (where feasible) quantitatively. If a regulation is required by statute or judicial directive, the RIA should clearly explain the specific authority, extent of agency discretion, and permissible regulatory instruments.

Step 2: Define the Baseline

The baseline represents the agency's best assessment of what the world would be like absent the action. To specify the baseline, the agency may need to consider a wide range of factors and should incorporate the agency's best forecast of how the world will change in the future, with particular attention to factors that affect the expected benefits and costs of the rule. For example, population growth, economic growth, and the evolution of the relevant markets should all be taken into account. For regulations that largely restate statutory requirements, the analysis should use a pre-statutory baseline. For analyses supporting modifications to an existing regulation, a baseline assuming no change in the regulatory program generally provides an appropriate basis for evaluating regulatory alternatives.

The analysis should focus on benefits and costs that accrue to citizens and residents of the United States. Where the agency chooses to evaluate a regulation that is likely to have effects beyond the borders of the United States, these effects should be reported separately.

Step 3: Set the Time Horizon of Analysis

When choosing the appropriate time horizon for estimating benefits and costs, agencies should consider how long the regulation being analyzed is likely to have economic effects. The time frame for the analysis should cover a period long enough to encompass all the important benefits and costs likely to result from the rule. However, the agency should also consider for how long it can reasonably predict the future and should limit its analysis to that time period. Thus, if a regulation has no predetermined sunset provision, the agency will need to choose the endpoint of its analysis based on the foreseeable future or the agency's ability to forecast reliably. For rules that require large up-front capital investments, the life of the capital is also an option.

Step 4: Identify a Range of Regulatory Alternatives

The agency should consider a range of potentially effective and reasonably feasible regulatory alternatives. The relevant alternatives might involve different approaches, with distinct advantages and disadvantages. In considering which alternatives to discuss, an agency should reasonably explore which approaches are feasible and plausible ways of meeting the regulatory objective. An agency should give particular attention to identifying and assessing flexible regulatory approaches, including providing economic incentives to encourage the desired behavior, such as user fees or marketable permits, or providing information upon which choices can be made by the public.

Consistent with Executive Order 13563, section 4, an agency might consider flexible approaches that maintain freedom of choice. If, for example, an agency is considering banning the sale of a potentially unsafe product, it might consider instead requiring disclosure of health risks to the public. Once an agency identifies the least burdensome tool for achieving its regulatory objective, measuring the incremental benefits and costs of successively more stringent regulatory alternatives will allow an agency to identify the alternative that maximizes net benefits.

Agencies should consider any of the following, alone or in combination, to develop regulatory alternatives:

- *Deferral to state or local regulation.* Agencies should consider the option of deferring to regulation at the State or local level. To be sure, problems that affect interstate commerce or spill across State lines may best be addressed by Federal regulation. But more localized problems may be more efficiently addressed locally. In such situations, deferring to state and local regulation can encourage regulatory experimentation and innovation while also fostering learning and competition to establish the best regulatory policies.

- *Market-oriented approaches rather than direct controls.* Agencies should consider market-oriented regulatory approaches that use economic incentives to achieve regulatory goals and that afford entities greater flexibility in compliance. Such approaches include fees, penalties, subsidies, marketable permits or offsets, changes in liability rules or property rights, and required bonds, insurance, or warranties. In the domain of environmental protection, for example, emissions trading may deserve careful consideration as an approach that might achieve the same gain at a significantly lower cost.
- *Performance standards rather than design standards.* Performance standards express requirements in terms of outcomes, for example requiring achievement of a particular emissions level. By contrast, design standards specify the means to achieve those outcomes, for example requiring installation of a particular emissions control technology. Because they allow firms to have the flexibility to choose the most cost-effective methods for achieving the regulatory goal, and create an incentive for innovative solutions, performance standards are generally preferred to design standards.
- *Informational Measures.* If intervention is contemplated to address a market failure that arises from inadequate or asymmetric information or poor information processing, informational remedies will often be preferred. To the extent feasible, specific informational measures should be evaluated with reference to their benefits and costs.
- *Default rules rather than mandates.* Agencies should consider whether default rules are a better instrument than mandates for achieving regulatory objectives. If, for example, there is significant heterogeneity in the relevant population, a default rule may be preferable to a mandate because it allows people to act in ways that are suited to their own situations.
- *Enforcement Methods.* Alternative monitoring (e.g., Federal, State, or local authorities) and reporting methods (e.g., on-site inspections, periodic reporting, and noncompliance penalties) may vary in their benefits and costs.
- *Stringency.* Typically both the benefits and costs associated with a regulation will increase with the level of stringency. Agencies should study alternative levels of stringency to determine the level that maximizes net benefits.
- *Compliance dates.* The timing of a regulation can have an important effect on its net benefits. Agencies should consider various possible compliance dates, because (for example) a later date might, in some circumstances, promote predictability and significantly reduce compliance costs without greatly reducing benefits.
- *Requirements based on firm size.* If the expected costs or the expected benefits of compliance vary based on firm size, different requirements for large and small firms, based on these estimated differences, may be appropriate. Greater flexibility for small business, in the form of delayed compliance dates or partial or total exemptions, is worth careful consideration. At the same time, agencies should consider whether such differences in regulatory treatment provide one group of firms with a competitive advantage over others, create artificial incentives to keep firm sizes small (and thus deter hiring), or lead to foregone benefits that exceed the cost savings to exempted firms.

- *Requirements based on geographic regions.* Where there are significant regional variations in benefits and/or costs, agencies should consider setting different requirements for different regions to maximize net benefits.

At a minimum, agencies should compare, with their preferred option, a more stringent and less stringent alternative, and assess the benefits and costs of the three possibilities, with careful consideration of which achieves the greatest net benefits. And when the preferred option includes a number of distinct provisions, the benefits and costs of different regulatory provisions should be analyzed separately in order to facilitate consideration of the full range of potential alternatives.

Step 5: Identify the Consequences of Regulatory Alternatives

Benefits and costs. Agencies should identify the potential benefits and costs for each alternative and its timing. It may be useful to identify the benefits and costs in the following manner:

- Benefits and costs that can be monetized, and their timing;
- Benefits and costs that can be quantified, but not monetized, and their timing;
- Benefits and costs that cannot be quantified.

In addition to the direct benefits and costs of each alternative, the list should include any important ancillary benefits and countervailing risks. An ancillary benefit is a favorable impact of the alternative under consideration that is typically unrelated or secondary to the purpose of the action (e.g., reduced refinery emissions due to more stringent fuel economy standards for light trucks). A countervailing risk is an adverse economic, health, safety, or environmental consequence that results from a regulatory action and is not already accounted for in the direct cost of the action (e.g., adverse safety impacts from more stringent fuel-economy standards for light trucks). As with other benefits and costs, an effort should be made to quantify and monetize both ancillary benefits and countervailing risks.

Distributional effects. Those who bear the costs of a regulation and those who enjoy its benefits often are not the same people. The term "distributional effect" refers to the impact of a regulatory action across the population and economy, divided up in various ways (e.g., income groups, race, sex, industrial sector, geography).

The regulatory analysis should provide a separate description of distributional effects (i.e., how both benefits and costs are distributed among sub-populations of particular concern) so that decision makers can properly consider them along with the effects on economic efficiency (i.e., net benefits). Executive Order 13563 and Executive 12866 authorize this approach. Where distributive effects are thought to be important, the effects of various regulatory alternatives should be described quantitatively to the extent possible, including the magnitude, likelihood, and severity of impacts on particular groups.

Examples of distributional effects that could potentially be quantified include:

- Health benefits that accrue principally to low-income groups
- Regulatory costs that are imposed principally on low-income groups
- Reductions in sales by one business that are matched by increases in sales by another (transfer in economic activity from one business to another)
- Reductions in well-being for some consumers that are matched by increases for others (transfer of well-being among consumers)

Transfer payments. Distributional effects may arise through "transfer payments" that stem from a regulatory action as well. Transfer payments are monetary payments from one group to another that do not affect total resources available to society. For example, transfers payments include revenue collected through a fee, a surcharge in excess of the cost of services provided, and a tax.

Distinguishing between real costs and transfer payments is an important, but sometimes difficult, problem in cost estimation. A stylized example may help to clarify. Consider a regulation that taxes an air pollutant that is harmful to human health and is a by-product of some manufacturing process. In response to the tax, firms modify their manufacturing process to reduce (but not eliminate) the pollutant. The benefits of the regulation are reductions in premature death, illness, and disability resulting from the decreased emission of the regulated pollutant, as well as benefits to ecosystems, improvements in visibility, and so on. The cost of the regulation is equal to the cost to firms of modifying their production process (e.g., purchasing abatement technology). The taxes paid on the pollutant by the firm to the government are a transfer and have no effect on the net benefits of the regulation.

Examples of costs include:

- Goods and services required to comply with the regulation
- Reductions in consumer and producer well-being due to regulation-induced price or quantity changes
- Increases in premature death, illness, or disability (e.g., in the case where a regulatory proposal that would reduce certain safety and/or health risks would also have the consequence of increasing other safety and/or health risks).

Examples of transfer payments include:

- Changes in sales tax revenue due to changes in sales (monetary transfers from consumers to government)
- Payment by the Federal government for goods or services provided by the private sector (monetary transfers to the government to service providers, such as reimbursements by the Medicare program)
- Fees to government agencies for goods or services provided by the agency (monetary transfers from fee payers to the government—the goods and services are already counted as government costs and including them as private costs would entail double counting)

Step 6: Quantify and Monetize the Benefits and Costs

The agency should use the best reasonably obtainable scientific, technical, economic, and other information to quantify the likely benefits and costs of each regulatory alternative. Presenting benefits and costs in physical units in addition to monetary units will improve the transparency of the analysis. For example, the benefits of a regulation that reduces emissions of air pollution might be quantified in terms of the number of premature deaths avoided each year; the number of prevented nonfatal illnesses and hospitalizations; the number of prevented lost work or school days; improvements in visibility in specific regions; and improvements in ecosystem health as measured by specific indicators (e.g. lake acidification). Some costs – such as countervailing risks – may also be quantified in similar terms before they are turned into monetary equivalents.

As discussed in greater detail below, the agency should, to the extent feasible, estimate the monetary value of the benefits and costs of each regulatory alternative considered. Both benefits and costs are measured by the value that individuals place on the change resulting from a particular regulatory alternative. This value is typically and most easily measured in terms of the amount of money the individual would pay ("willingness to pay" (WTP)) or require as compensation ("willingness to accept" (WTA)), so that the individual is indifferent between the current state of the world (baseline), on the one hand, and the consequences of the regulatory alternative along with the monetary payment, on the other hand.

To the extent possible, agencies should estimate people's valuations of benefits and costs using revealed preference studies based on actual behavior. Revealed preference methods develop estimates of the value of goods and services — or attributes of those goods and services — based on actual market decisions by consumers, workers, and other market participants. If the market participant is well-informed and confronted with a real choice, and properly processes information, it may be feasible to determine accurately and precisely the monetary value of the changes associated with an alternative.

If the goods or attributes of goods that are affected by regulation — such as preserving environmental or cultural amenities — are not traded in markets, it may be difficult to use revealed preference methods. In such cases, the value of the goods or attributes may arise both from use and non-use. "Use values" arise where an individual derives satisfaction from using the resource, either now or in the future, for example by living in or moving to a neighborhood with clean air or water. "Non-use values" arise where an individual places value on a resource, good, or service even though the individual will not use the resource, now or in the future, for example by valuing wildlife in remote areas.

In the absence of an organized market, it is difficult to estimate use and non-use values. When studies are designed to elicit such values either though indirect market studies or stated preference methods, agencies should pay careful attention to characterization of the uncertainties. However, overlooking or ignoring these values may significantly understate the benefits and/or costs of regulatory action.

Agencies should include the following effects, where relevant, in their analysis and provide estimates of their monetary values:

- Private-sector compliance costs and savings;
- Government administrative costs and savings;
- Gains or losses in consumers' or producers' surpluses;
- Discomfort or inconvenience benefits and costs; and
- Gains or losses of time in work, leisure, and/or commuting/travel settings.

To improve the transparency of the analysis, monetary values of distinct benefits and costs should be presented separately, in addition to being summed and presented as total benefits and total costs.

Considerations in monetizing health and safety effects

In monetizing health and safety benefits, the agency should use the WTP measure (or, if appropriate, the WTA measure), rather than other alternatives (e.g., avoided cost of illness or avoided lost earnings). This is because WTP/WTA attempts to capture pain and suffering and other quality-of-life effects.

When monetizing nonfatal health effects, the agency should consider two factors: (1) the private demand for prevention of the nonfatal health effect, to be represented by the preferences of the target population at risk and (2) the net financial externalities associated with poor health, such as net changes in public medical costs and any net changes in economic production that are not experienced by the target population. Revealed-preference or stated-preference studies are necessary to estimate the private demand; health economics data from published sources can typically be used to estimate the financial externalities caused by changes in health status. If an agency uses literature values to monetize nonfatal health and safety risks, it is important to make sure that the values selected are appropriate for the severity and duration of health effects to be addressed by the alternative under consideration.

Since agencies often design health and safety regulation to reduce risks to life, evaluation of the benefits of reducing fatality risks can be the key part of the analysis. The goal of this analysis is to monetize the value of small changes in fatality risk – a measurement of WTP for reductions in only small risks of premature death. This concept is commonly referred to as the "value of statistical life" (VSL).[8] A considerable body of academic literature is available on this subject. Current agency practice provides a VSL ranging from roughly $5 million to $9 million per statistical life.

Another approach to express reductions in fatality risks is to use the life expectancy method, the "value of statistical life-years (VSLY) extended." If a regulation protects individuals whose average remaining life expectancy is 40 years, a risk reduction of one fatality is expressed as "40

---

[8] The term "value of life" is sometimes used to describe this concept. However, this term can be misleading because it suggests, erroneously, that the monetization exercise tries to place a "value" on individual lives. Use of VSL should not suggest that the value of any individual's life can be expressed in monetary terms. The sole purpose is to help estimate the likely benefits of a regulatory action that reduces the risks that people face.

life-years extended." Those who favor this alternative approach emphasize that the value of a statistical life is not a single number relevant for all situations. In particular, when there are significant differences between the effect on life expectancy for the population affected by a particular health risk and the populations studied in the labor market studies, they prefer to adopt a VSLY approach to reflect those differences. It is appropriate to consider providing estimates of both VSL and VSLY, while recognizing the developing state of knowledge in this area.

Step 7: Discount Future Benefits and Costs

The benefits and costs of a regulatory action typically take place in the future. Moreover, benefits and costs may not be distributed across time in the same manner. For example, a common challenge in evaluating alternatives that have health-related consequences is to quantify the time lag between when an action would take effect and when the resulting change in health status will be observed.

To provide an accurate assessment of benefits and costs that occur at different points in time or over different time horizons, an agency should use discounting. Agencies should provide benefit and cost estimates using both 3 percent and 7 percent annual discount rates expressed as a present value as well as annualized. These are "real" interest rates that should be used to discount benefits and costs measured in constant dollars. Unlike typical market interest rates, real rates exclude the expected rate of future price inflation.

The 7 percent rate is an estimate of the average before-tax rate of return to private capital in the U.S. economy, based on historical data. It is a broad measure that reflects the returns to real estate and small business capital as well as corporate capital. It approximates the opportunity cost of capital, and it is the appropriate discount rate whenever the main effect of a regulation is to displace or alter the use of capital in the private sector.

The 3 percent discount rate is based on a recognition that the effects of regulation do not always fall exclusively or primarily on the allocation of capital. When regulation primarily and directly affects private consumption, a lower discount rate is appropriate. The alternative most often used is sometimes called the "social rate of time preference." This term simply means the rate at which "society" discounts future consumption flows to their present value. If one assumes the rate that the average saver uses to discount future consumption is a measure of the social rate of time preference, the real rate of return on long-term government debt may provide a fair approximation. Over the last thirty years, this rate has averaged around 3 percent in real annual terms on a pre-tax basis.

Special considerations arise when comparing benefits and costs across generations. Although most people demonstrate time preference in their own consumption behavior, it may not be appropriate for society to demonstrate a similar preference when deciding between the well-being of current and future generations. Future citizens who are affected by such choices cannot take part in making them, and today's society must act with due consideration of their interests. Many people have argued for a principle of intergenerational neutrality, which would mean that those in the present generation would not treat those in later generations as worthy of less concern. Discounting the welfare of future generations at 7 percent or even 3 percent could create serious ethical problems.

An additional reason for discounting the benefits and costs accruing to future generations at a lower rate is the longer the horizon for the analysis, the greater the uncertainty about the appropriate value of the discount rate. Private market rates provide a reliable reference for determining how society values time within a generation, but for extremely long time periods no comparable private rates exist. As several economists (including Martin Weitzman[9]) have explained, for the very distant future, the properly averaged discount factor corresponds to the minimum discount rate having any substantial positive probability.

At the same time, some economists have cautioned that using a zero discount rate could raise intractable analytical problems. They have argued that with zero discounting, even a small improvement in welfare, if permanent, would justify imposing any cost on current generations since the benefits would be infinite.

If the regulatory action will have important intergenerational benefits or costs, the agency might consider a sensitivity analysis using a lower but positive discount rate, ranging from 1 to 3 percent, in addition to calculating net benefits using discount rates of 3 percent and 7 percent.

Step 8: Evaluate Non-quantified and Non-monetized Benefits and Costs

Sound quantitative estimates of benefits and costs, where feasible, are preferable to qualitative descriptions of benefits and costs because they help decision-makers to understand the magnitudes of the effects of alternative actions and compare across different types of consequences. However, some important benefits and costs (e.g., protection of human dignity, equity, or privacy, see Executive Order 13563, section 1(c)) may be difficult or impossible to quantify or monetize given current data and methods. Agencies should carry out a careful evaluation of non-quantifiable and non-monetized benefits and costs.

Benefits and costs that are difficult to monetize. If monetization is not possible, the agency should explain why and present all available quantitative information. For example, an agency may not be able to monetize a benefit in terms of privacy or dignity, but it may be able to quantify the number of beneficiaries. Alternatively, an agency may be able to quantify, but not to monetize, increases in water quality and fish populations resulting from water quality regulation. If so, the agency should attempt to describe benefits in terms of (for example) stream miles of improved water quality for boaters and increases in game fish populations for anglers. When estimates of monetized effects and quantified physical effects are mixed in the same analysis, the agency should describe the timing and likelihood of such effects, and should avoid double-counting of effects.

---

[9] Weitzman ML In Portney PR and Weyant JP, eds. (1999), *Discounting and Intergenerational Equity*, Resources for the Future, Washington, DC.

Benefits and costs that are difficult to quantify. If the agency cannot quantify a benefit or cost, the agency should explain why and present any available quantitative information. For example, the agency may not be able to quantify the number of individuals exposed to a risk but may be able to quantify the magnitude of the risk to those who are exposed. The agency should also provide a detailed qualitative description of any unquantified effects, such as ecological gains, improvements in quality of life, and aesthetic beauty. The agency should provide a discussion of the strengths and limitations of the qualitative information.

When the unquantified benefits or costs affect a policy choice, the agency should provide a clear explanation of the rationale behind the choice. Such an explanation could include detailed information on the nature, timing, likelihood, location, and distribution of the unquantified benefits and costs. The agency should include a summary table that lists all significant unquantified benefits and costs, highlighting (e.g., with categories or rank ordering) those that the agency believes are most important (e.g., by considering factors such as the degree of certainty, expected magnitude, and reversibility of effects).

Breakeven analysis. When quantification and monetization are not possible, many agencies have found it both useful and informative to engage in threshold or "breakeven" analysis. This approach answers the question, "How large would the value of the non-quantified benefits have to be for the rule to yield positive net benefits?" Suppose, for example, that a regulation that protects water quality costs $105 million annually, and that it also has significant effects in reducing pollution in rivers and streams. It is clear that the benefits of the regulation would exceed its costs if and only if those effects could reasonably be valued at $105 million or more. Once the nature and extent of the water quality benefits are understood, it might well be easy to see whether or not the benefits plausibly exceed the costs – and if the question is difficult, at least it would be clear why it is difficult. Breakeven analysis is an important tool, and it can provide insights when quantification is speculative or impossible.[10]

Cost-effectiveness analysis. Cost-effectiveness analysis (CEA) can provide a helpful way to identify options that achieve the most effective use of the available resources (without requiring monetization of all of the relevant benefits and costs). Generally, cost-effectiveness analysis is designed to compare a set of regulatory actions with the same primary outcome (e.g., an increase in the acres of wetlands protected) or multiple outcomes that can be integrated into a single numerical index (e.g., units of health improvement). This approach provides useful information about relative performance of regulatory alternatives (i.e., best 'bang for the buck'). At the same time, a comparison of monetized benefits and costs is necessary to determine which alternative maximizes net benefits.

When CEA is applied to public health and safety rulemakings, a measure of effectiveness must be selected that permits comparison of regulatory alternatives. Agencies currently use a variety of effectiveness measures. There are relatively simple measures such as the number of lives saved, cases of cancer reduced, or cases of paraplegia prevented. Sometimes these measures

---

[10] For additional discussion, see *2011 Report to Congress on the Benefits and Costs of Federal Regulations and Unfunded Mandates on State, Local, and Tribal Entities*, page 66-67. Available at: http://www.whitehouse.gov/sites/default/files/omb/inforeg/2011_cb/2011_cba_report.pdf

account only for mortality information, such as the number of lives saved and the number of years of life saved. There are also more comprehensive, integrated measures of effectiveness such as the number of "equivalent lives" (ELs) saved and the number of "quality-adjusted life years" (QALYs) saved. While OMB does not require agencies to use any specific measure of effectiveness, an Institute of Medicine report recommends that agencies use QALYs for all health and safety issues.[11] In any event, the regulatory analysis should explain why a measure was selected and how it was implemented.

Step 9: Characterize uncertainty in benefits, costs, and net benefits

Regulatory analysis requires forecasts about the future. What the future holds, both in the baseline and under the regulatory alternative under consideration, is typically not known for certain. The important uncertainties connected with the regulatory decision should be analyzed and presented as part of the overall regulatory analysis. The goal of the agency's uncertainty analysis is to present both a central "best estimate," which reflects the expected value of the benefits and costs of the rule, as well as a description of the ranges of plausible values for benefits, costs, and net benefits, which informs decision-makers and the public of the degree of uncertainty associated with the regulatory decision.

In developing an uncertainty analysis, agencies should follow these steps:

> *Specify potential scenarios*. As a first step, the agency should specify a set of plausible, mutually exclusive *scenarios* for both the baseline and for each regulatory alternative. Each scenario represents a complete description of a state of the world, including its evolution through time, that could arise. The goal is to specify scenarios that cover the full range of how the benefits and costs of the rule might vary. Typically this is done by specifying the set of factors that affect the benefits and costs of the regulatory alternatives.
>
> *Calculate the benefits and costs associated with each scenario.* Once the set of plausible scenarios has been specified, the agency can calculate the benefits and costs associated with each scenario. At this stage, the agency has all of the information it needs to conduct a *sensitivity analysis*. A sensitivity analysis examines how the benefits and costs of the rule change with key uncertain variables.
>
> *Construct a range of values.* When the agency cannot specify probabilities for the relevant scenarios, the agency should develop a central scenario for the baseline and for each regulatory alternative that reflects the agency's *best estimate* of the likely consequences of each regulatory alternative. The agency should use the benefits and costs of these best estimates to approximate the expected value of the benefits and costs of each regulatory alternative to use in its regulatory decision-making. The agency should also characterize ranges of *plausible* benefits, costs, and net benefits of each regulatory alternative. The goal is not to characterize the full range of *possible* outcomes, which

---

[11] IOM (2006). Valuing Health for Regulatory Cost-Effectiveness Analysis. The National Academies Press, Washington, DC.

> may turn out to be extremely large, but rather the range of *plausible* outcomes as in a confidence interval. The agency must use its judgment on the range of scenarios that such ranges should reflect. At a minimum, the range should include a "high" and a "low" scenario that provide plausible upper and lower bounds.

The approach to constructing a range outlined above should be thought of as the minimal analysis that agencies should conduct. When feasible, agencies should also:

> *Assign probabilities and calculate expected values*. Having specified the set of plausible scenarios, the benefits and costs associated with each scenario, and the probabilities of each scenario, the agency should calculate expected values of the benefits and costs for each regulatory alternative. In these cases, where probability distributions can be assigned to each scenario, the agency should conduct a formal uncertainty analysis in which it characterizes the distributions of benefits, costs, and net benefits.

Circular A-4 requires formal quantitative analysis of uncertainty for rules that exceed the $1 billion annual threshold in benefits or costs.

D. Summarizing the Regulatory Analysis

Regulatory analysis should include a clear, plain language executive summary. The summary should include one or more tables that summarize the benefit and cost estimates for each regulatory action and alternative under consideration as well as the qualitative and non-monetized benefits and costs.[12] The summary should include:

- *Alternative regulatory approaches.* At a minimum, one or more tables should generally be used to report the benefits and costs of both the agency's preferred option and at least one alternative that is less stringent (i.e., lower cost) and one alternative that is more stringent (i.e., higher cost). For each of the regulatory alternatives, the agency should calculate benefits and costs relative to a common baseline.

- *Categories of benefits and costs.* The agency should categorize the benefits and costs into three mutually exclusive and exhaustive categories: (1) quantified and monetized; (2) quantified but not monetized; and (3) neither quantified nor monetized. The agency should not include any benefit or cost in more than one of these categories. For example, if the agency has monetized fatalities averted by an alternative, it should report the dollar value as part of the quantified and monetized benefits, and should avoid double-counting the number of "lives saved" in the quantified but not monetized benefits category. (Of

---

[12] Circular A-4 states: "…you should present a summary of the benefit and cost estimates for each alternative, including the qualitative and non-monetized factors affected by the rule, so that readers can evaluate them." (P.3) In addition, it states: "Your analysis should also have an executive summary, including a standardized accounting statement." (P. 3). It further states, "You need to provide an accounting statement with tables reporting benefit and cost estimates for each major final rule for your agency." (P. 44). Circular A-4 includes an example of a format for agency consideration.

course, the agency may also choose to report the monetized benefits in physical units, but should do so in a way that clearly avoids double-counting).

- *Separate reporting of distributional effects, including transfers.* The agency should report distributional effects, including transfers, separately and avoid the misclassification of transfer payments as benefits or costs.

- *Rank qualitative impacts.* The agency should categorize or rank the qualitative effects in terms of their importance (e.g., certainty, likely magnitude, and reversibility). The agency should distinguish the effects that are likely to be significant enough to warrant serious consideration by decision-makers from those that are likely to be minor.

- *Transparency.* The agency should add notes to the bottom of the tables that enable readers to interpret the information in the tables correctly. For example, when there is significant uncertainty to estimates, a caveat describing the nature of the uncertainty should be provided in the notes.

Abstract

The Washington State Department of Ecology (Ecology) is conducting a series of technical studies that will inform strategies to control sources of toxic chemicals to Puget Sound. The studies come under the umbrella of the Puget Sound Toxics Loading Analysis (PSTLA). Phases 1 and 2 of the PSTLA developed loading estimates for toxic chemicals and used computer model simulations to predict outcomes of control actions. Ongoing Phase 3 studies are intended to reduce uncertainties associated with chemical loadings and model predictions.

For the present study, Ecology collected seasonal water samples at seven ambient marine sites throughout Puget Sound and its ocean boundary waters, and from the mouths of the five largest rivers flowing into Puget Sound. Samples were analyzed for a wide range of inorganic and organic chemicals of concern.

Many chemicals were seldom or never detected in marine water samples, but concentrations of metals and polychlorinated biphenyls (PCBs) were similar to previously reported values. Concentrations of organic carbon, copper, and PCBs were higher in outgoing Puget Sound waters than in incoming ocean waters. The opposite was true for cadmium. Ocean exchange estimates indicated that most target chemicals of concern appear to be exported from Puget Sound to the ocean.

River water samples contained measurable concentrations of conventional parameters, nutrients, metals, and some organic compounds. Concentrations were generally within ranges previously reported. Petroleum-related compounds, semivolatile organic compounds (BNAs), polycyclic aromatic hydrocarbons (PAHs), and chlorinated pesticides were seldom detected. Daily loads calculated for many chemicals can be compared to estimated loads from other studies and model simulations.

Suspended particulate matter (SPM) was also collected from deep marine waters and river waters, and samples were analyzed for a suite of chemicals similar to those analyzed for water samples. Results from the Hood Canal and South Puget Sound basins were used to estimate loss rates of toxic chemicals from the water column via sedimentation. Toxic chemicals such as PAHs were more often detected in river SPM than in river water.

Executive Summary

Introduction

The Washington State Department of Ecology (Ecology) is working in collaboration with the Puget Sound Partnership and other state and federal agencies on a multi-phase Puget Sound Toxics Loading Analysis (PSTLA). The purpose of the PSTLA is to quantify various sources of toxic contaminants entering Puget Sound and to better understand the behavior and fate of the contaminants within the ecosystem. Results of the PSTLA will form part of the technical basis for a comprehensive strategy to reduce and control toxic chemical releases to Puget Sound.

In Phase 1 of the PSTLA, existing data were used to estimate loadings of toxic chemicals released to Puget Sound via surface runoff, atmospheric deposition, permitted wastewater discharges, combined sewer overflows, and direct spills (Hart Crowser et al., 2007). Phase 2 of the analysis refined land-use classifications and roadway loadings to improve toxic chemical loading estimates for the entire Puget Sound basin (EnviroVision et al., 2008). Overall estimates of surface runoff loading were later recalculated (Herrera, 2010a).

Ecology expanded numerical modeling begun in Phase 2 to provide insights into the relative importance of various loading pathways. The resulting Puget Sound Toxics Box Model (Pelletier and Mohamedali, 2009) allowed managers to investigate the response of contaminant concentrations in the water, sediment, and biota of Puget Sound to various source-control strategies. Initial modeling exercises were performed for polychlorinated biphenyls (PCBs) due to the relative abundance of existing PCB data. Future modeling efforts will examine fate and transport of other toxic contaminants, including polybrominated diphenyl ethers (PBDEs).

Data Gaps

A review of readily available data collected since 1995 on selected toxic chemicals in Puget Sound and the Straits of Juan de Fuca and Georgia (Serdar, 2008) identified significant gaps and limitations in the existing data. With few exceptions, the available data were deemed inadequate for providing representative concentrations for Box Model input and analyses. Phase 2 simulations using the Box Model also indicated more data would improve the accuracy of predictions. The greatest sources of uncertainty for Box Model predictions were:

- Limited data from which to choose input values representing toxic chemical loading from surface runoff.
- Limited data on concentrations of toxic chemicals likely to be exchanged between Puget Sound and ocean boundary waters [1] (*ocean exchange*).

The authors of the modeling study recommended that Phase 3 studies should fill these data gaps and thereby address uncertainties.

---

[1] For purposes of this study, ocean boundary waters are defined as the sampling locations in the Straits of Juan de Fuca and Georgia that, although they do not reflect true oceanic waters, represent conditions at the ocean boundary used in the Box Model (external to Puget Sound proper).

Study Purpose

The present 2009-10 study was designed to collect data that would improve input values to the Puget Sound Toxics Box Model, thereby reducing uncertainty in model predictions. These data could also be used to calibrate the model. Specific objectives of the study were:

- Measure concentrations of target toxic chemicals and other water quality parameters in samples representing ocean boundary waters likely to enter and marine waters likely to exit the modeled portion of Puget Sound.
    - Whole water samples collected from the deep layer near the main ocean boundary (Strait of Juan de Fuca and Haro Strait).
    - Whole water samples collected from the surface layer of the four primary Puget Sound basins (Whidbey, Main, Hood Canal, and South Sound).
- Measure concentrations of target toxic chemicals and other water quality parameters in the five rivers having the greatest annual discharges to Puget Sound (Skagit, Snohomish, Nooksack, Stillaguamish, and Puyallup).
- Identify sources of variability in concentrations of target toxic chemicals and other water quality parameters.
- Determine concentrations of toxic chemicals associated with suspended particulate matter (SPM) in marine and river waters.

Study Findings

Marine Water and SPM

Major findings from the marine sampling portion of the 2009-10 study include:

- Suspended solids, organic carbon, metals, PCBs, and PBDEs in samples collected from the surface and deep layers of the marine water column were routinely detected but consistently low. Semivolatile organic compounds (BNAs) and chlorinated pesticides were rarely detected and polycyclic aromatic hydrocarbons (PAHs) were never detected in marine water samples.
- The range of total PCB concentrations measured for ambient marine waters was 6.1-75 pg/L (mean = 26.3 pg/L). The mean concentration in ocean boundary waters (20.4 pg/L) was significantly less than the mean for Puget Sound marine waters (30.7 pg/L). Both values were lower than the mean concentration previously reported for the Strait of Georgia (42 pg/l; Dangerfield et al., 2007).
- Total PCB concentrations in the deep marine waters were significantly higher than those in the surface waters. This was true for the ocean boundary waters and Puget Sound (Figure ES-1). A significant positive relationship between total PCBs and total suspended solids (TSS) suggested that sedimentation plays a key role in the fate of PCBs in the Sound.

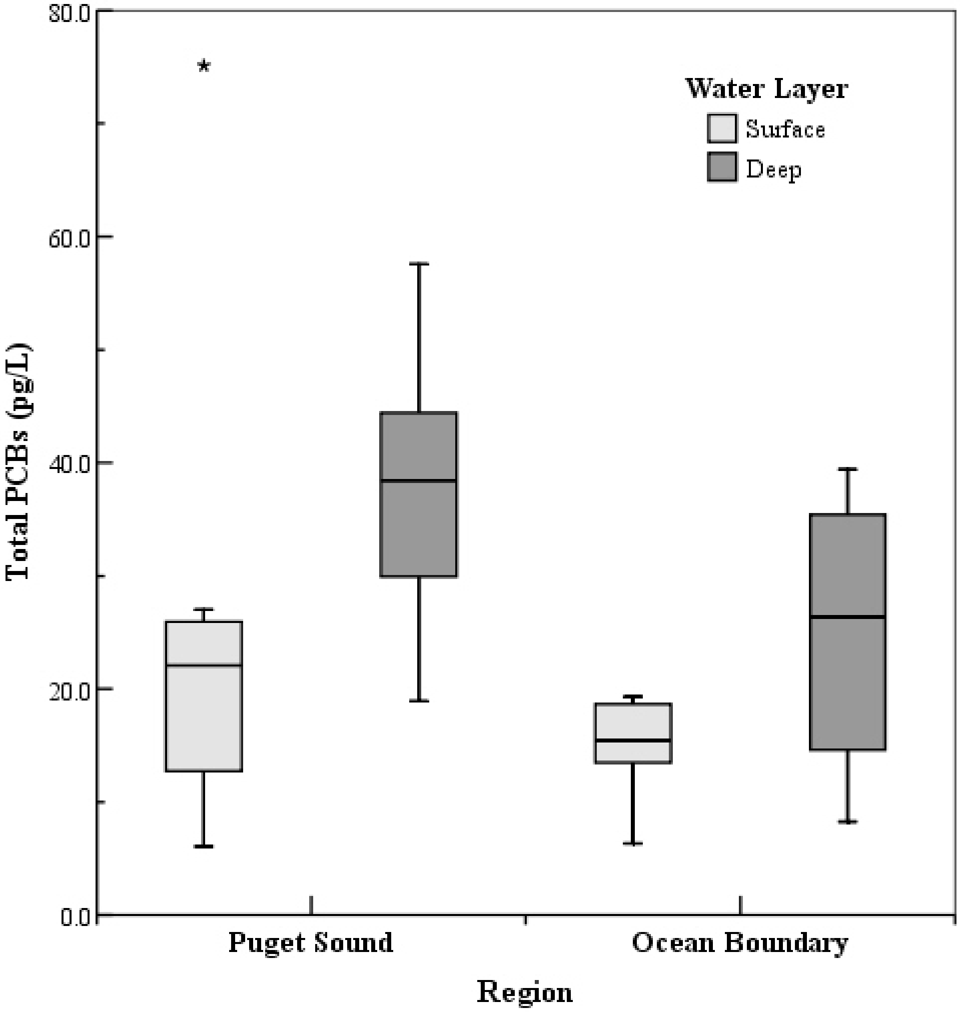

Figure ES-1. Total PCB concentrations in surface and deep marine waters.

- The range of detected total PBDE concentrations in marine waters (51 - 18,700 pg/L) was much wider than the range of total PCB concentrations. Total PBDEs concentrations were often 10 times higher in the present study than concentrations reported by Canadian researchers (Dangerfield et al., 2007). No evidence suggested the higher concentrations were due to sample contamination. Sources of high PBDE concentrations were not identified.
- Organic carbon concentrations in marine water samples resembled concentrations previously reported for the Strait of Georgia (Johannessen et al., 2008), but were substantially lower than marine water concentration records in Ecology's EIM database.
- Calculations of chemical exchange between Puget Sound and ocean waters, based on present study results, indicated most toxic chemicals are probably being exported out of Puget Sound. A notable exception was cadmium, which appeared to be imported into Puget Sound. This was due to incoming ocean waters having significantly higher concentrations than surface waters flowing out of the Sound to the ocean. The direction of net exchange for total PCBs and total PBDEs between the ocean and Puget Sound could not be estimated from the data collected.

- Samples of SPM collected from sediment traps deployed in Hood Canal and South Puget Sound (Case+Carr Inlets) contained similar concentrations of organic carbon, metals, and PBDEs. PCB concentrations in Case+Carr Inlet SPM were more than three times greater than those in Hood Canal.

River Water and SPM

Major findings from the river sampling portion of the study include:

- Concentrations of total suspended solids (TSS), organic carbon, nutrients, hardness, and metals were within the ranges reported from previous studies by Ecology and other monitoring programs (Inkpen and Embry, 1998; Wise et al., 2007).
- River water samples seldom contained detectable concentrations of petroleum-related compounds (oil and grease, TPH-D, and TPH-G), BNAs, PAHs, or chlorinated pesticides. River SPM collected by centrifugation in December 2009 and January 2010 contained detectable concentrations of many individual PAH compounds.
- The average concentration of total PCBs measured in surface water from the five rivers was 16.3 pg/L. The range of concentrations measured was 2.6 - 59 pg/L. This range is somewhat lower than the range reported by King County for the Green/Duwamish Rivers (83 - 814 pg/L; Willston, 2009) that flow through a more urban and industrial watershed.
- PBDEs were detected in less than half of the river water samples. Total PBDE concentrations were highly variable ranging from 10.9 - 265 pg/L, with an average of 55.6 pg/L.
- Total PAH concentrations in SPM (excluding retene) ranged from 32 - 210 μg/Kg, with an average of 120 μg/Kg. Concentrations of individual PAHs were <20 μg/Kg, except for retene which averaged 230 μg/Kg.
- Few other organic compounds (BNAs, TPH-D, chlorinated pesticides) were detected in SPM.
- Estimated daily loading of total PCBs from all five rivers ranged from 0.015 - 0.57 g/day.
- Estimated daily loading of total PBDEs from all five rivers ranged from 0.017 - 4.22 g/day.

Notable relationships between parameters include the following:

- TSS concentrations were significantly correlated with, and explained between 63% and 86% of the variability in, concentrations of total phosphorus and total metals.
- Organic carbon, total nitrogen, and nitrate+nitrite concentrations were significantly lower during July than during the other two sampling periods.
- Congeners belonging to the more polar PCB homolog groups (those with fewer chlorine atoms) were significantly correlated with many parameters in the dissolved phase (ortho-phosphate and dissolved metals). Congeners in the more hydrophobic PCB homologs (those with more chlorine atoms) were significantly correlated with TSS, total organic carbon (TOC), and parameters often found in particulate form (total nitrogen and total phosphorus).

Recommendations

Based on the findings of the present study, the following recommendations are made:

- Future sampling should focus on the collection and analysis of particulate samples to improve the detection frequency of hydrophobic compounds.
- More intensive water column sampling should be conducted near the ocean boundaries to Puget Sound proper (Admiralty Inlet sill and Deception Pass). Samples should be analyzed for a reduced suite of chemicals, with priority given to chemicals exhibiting high variability in the present study (e.g., PBDEs). This would improve current estimates of ocean exchange.
- Depth-integrated water sampling of large rivers should be conducted with focus on increased sampling frequency, a reduced suite of chemicals, and improved detection limits for organic contaminants. More frequent sampling during all phases of runoff-related events is needed to understand seasonal and other temporal patterns. This would facilitate a better characterization of loading during baseflow conditions and runoff-related events.
- Standard operating procedures (SOPs) for the collection and analysis of seawater samples for dissolved (DOC) and particulate organic carbon (POC) should be revised. For example, all equipment used for sample collection and processing should be made exclusively of glass or lined with Teflon.

Introduction

Puget Sound Toxics Loading Analysis

The State of Washington enacted legislation in 2007 to protect and restore the Puget Sound ecosystem by 2020. The Puget Sound Partnership, while developing the Puget Sound Action Agenda, identified the control of toxic chemical releases as a high priority.

To inform a comprehensive strategy to reduce and control toxic releases, the Washington State Department of Ecology (Ecology) and others [2] undertook a multi-year Puget Sound Toxics Loading Analysis (PSTLA). The PSTLA was intended to quantify various sources of toxic contaminants entering Puget Sound and to better understand the behavior and fate of the contaminants within the ecosystem. Results of the PSTLA will form the technical basis for a toxics control strategy.

Phase 1 of the PSTLA used existing data to estimate loadings of toxic chemicals to Puget Sound via surface runoff, atmospheric deposition, permitted wastewater discharges, combined sewer overflows, and direct spills (Hart Crowser et al., 2007). Phase 2 improved watershed loading estimates for the entire Puget Sound basin by using revised land-use classifications and incorporating roadway loadings (EnviroVision et al., 2008; Herrera, 2010a). Modeling efforts were also expanded to provide insights about the relative importance of various loading pathways. The resulting Puget Sound Toxics Box Model [3] (Pelletier and Mohamedali, 2009) was composed of three parts:

1. Water circulation and transport box model (Appendix B, Figure B-1).
2. Contaminant fate and transport mass balance model.
3. Food web transfer bioaccumulation model.

The Box Model was initially used to predict how concentrations of polychlorinated biphenyls (PCBs) in the water, sediment, and biota of Puget Sound might respond to various source-control strategies. In doing so, the model identified substantial uncertainties and data gaps.

Data Gaps and Recommended Actions

The greatest source of uncertainty about Box Model predictions was the input values used to represent toxic chemical loading to Puget Sound from surface runoff (river loading). Another major source of uncertainty was the limited information available on concentrations and loads of toxic chemicals exchanged between the ocean and Puget Sound (Serdar, 2008). The authors of the modeling study recommended Phase 3 investigations to address these uncertainties. These included the following targeted efforts:

---

[2] The Puget Sound Partnership, U.S. Environmental Protection Agency (EPA), and other federal, state, and local agencies.

[3] Hereafter, this report often refers to the Puget Sound Toxics Box Model simply as the Box Model.

- **Major tributaries.** Estimates of toxic chemical loadings from surface runoff should be improved by monitoring concentrations of toxic chemicals in rivers, streams, and discharges from publically-owned water treatment facilities (POTWs), especially in relation to land uses and flow regimes (baseflow or storm runoff).
- **Ocean boundary waters.** Estimates of toxic chemicals transported from ocean boundary waters into Puget Sound should be improved because they may:
    - Be similar in magnitude to toxics loadings from major land uses in Puget Sound watersheds.
    - Influence concentrations of toxics observed in Puget Sound and its biota.
- **Puget Sound water column.** Toxic chemical concentrations in major Puget Sound basins, and how they partition between suspended particulate matter (SPM) and water (dissolved), should be measured because they are important determinants of biological uptake.

Goals and Objectives

The principal goal of the present 2009-10 study was to provide concentration data for various toxic chemicals that could be used to address these data gaps. Specific objectives listed in the Quality Assurance (QA) Project Plan (Coots and Osterberg, 2009) included:

- Collect samples representing seawater entering and leaving the modeled portion of Puget Sound, especially:
    - Samples collected from the deep layer of ocean boundary waters (Strait of Juan de Fuca and Haro Strait) [4].
    - Samples collected from the surface layer of four Puget Sound basins (Main, Whidbey, South Sound, and Hood Canal) [5].
- Measure concentrations of the following parameters in seawater samples collected from above *and* below any density gradient (pycnocline) in ocean boundary waters and the four major Puget Sound basins:
    - Total suspended solids (TSS).
    - Total and dissolved organic carbon (TOC and DOC).
    - Total and dissolved fractions of five metals (arsenic, cadmium, copper, lead, and zinc).
    - Semivolatile organic compounds (BNAs).
    - Polycyclic aromatic hydrocarbons (PAHs).
    - Chlorinated pesticides.
    - Polychlorinated biphenyl (PCB) and polybrominated diphenyl ether (PBDE) congeners.

---

[4] Samples collected from the western end of the Strait of Juan de Fuca would be less representative of seawater entering Puget Sound.

[5] Samples collected from surface layer waters of the Straits of Juan de Fuca and Georgia could include toxic chemicals originating outside of Puget Sound and therefore be less representative of leaving Puget Sound.

- Measure concentrations of the same chemicals of concern *plus* the following parameters in the five rivers with the greatest annual discharges to Puget Sound (Skagit, Snohomish, Nooksack, Stillaguamish, and Puyallup):
    - Hardness.
    - Nutrients (total nitrogen [TN], nitrate+nitrite nitrogen, ammonia nitrogen, total phosphorus [TP], and ortho-phosphate).
    - Petroleum-related compounds.
        - Oil and grease.
        - Diesel and gasoline fractions of petroleum hydrocarbons (TPH-D and TPH-G).
- Identify variability in concentrations of target toxic chemicals and other water quality parameters.
- Determine concentrations of toxic chemicals associated with SPM in marine and river waters.

Outcomes

Results of the present study include the following:

- Concentration ranges for target chemicals in ocean boundary waters and the major Puget Sound basins.
- Estimates of chemical exchange between ocean boundary waters and Puget Sound.
- Concentration ranges for target chemicals near the mouths of five major rivers discharging to Puget Sound.
- Estimates of daily chemical loads from the same rivers to Puget Sound.
- Some indications of spatial and temporal variability in chemical concentrations in the marine water column and near the river mouths.

Study results also provide data for calibrating the existing Puget Sound Toxics Box Model and using it to predict the transport and fate of other toxic chemicals. Consequently, the study contributes to developing a control strategy for toxic chemicals entering Puget Sound.

Study Design

The QA Project Plan (Coots and Osterberg, 2009) described the study design in detail. The following section summarizes the major project elements:

Ocean Exchange of Toxic Chemicals

Ecology collected samples from ocean boundary waters (Strait of Juan de Fuca and Haro Strait) and major Puget Sound basins (Whidbey, Main, South Sound, and Hood Canal) to determine water column concentrations of a suite of chemicals of concern (Figure 1). At each location, samples were collected from two depths representing the surface and deep layers simulated by the Box Model (Table 1). Temporal variability was addressed by sampling the water layers over three seasons. Ecology used the results to estimate the annual mass transport of target chemicals into and out of Puget Sound at the main ocean boundaries (Admiralty Inlet and Deception Pass).

River Loading of Toxic Chemicals

Ecology sampled the five rivers with the greatest mean annual flow near their mouths but upstream of any likely intrusion of marine (salt) water (Figure 1). Each river was sampled on three occasions intended to represent:

- Summer baseflows.
- Fall runoff or storm-related flows.
- Winter baseflows.

Water samples collected using depth-integrated methods were analyzed for the same toxic chemicals as marine waters, plus nutrients and hardness. Surface grab samples were also collected and analyzed for petroleum-related compounds. Instantaneous loads were calculated using measured concentrations of the various parameters and the mean daily flows.

Toxic Chemicals Associated with Particulates

Ecology measured concentrations of toxic chemicals associated with SPM in samples collected during the winter season from the marine water column and from near the five river mouths. Sediment traps were deployed at five locations to collect SPM from the marine water column (Figure 1). Centrifuges were used to concentrate SPM pumped from each river at nearly the same time that whole water samples were collected.

Sampling Methods

Marine Water Column

Ecology chose the marine water column sampling sites shown in Figure 1 to represent ambient conditions in the four major Puget Sound basins and near the main ocean boundaries (Admiralty Inlet and Deception Pass). Sites were established at the deepest location near the centroid of each basin. Two sites in the Strait of Juan de Fuca and one in Haro Strait were chosen to represent boundary waters. All sampling sites were located away from river mouths and nearshore influences. The geographic coordinates for each sampling site are listed in Table 1.

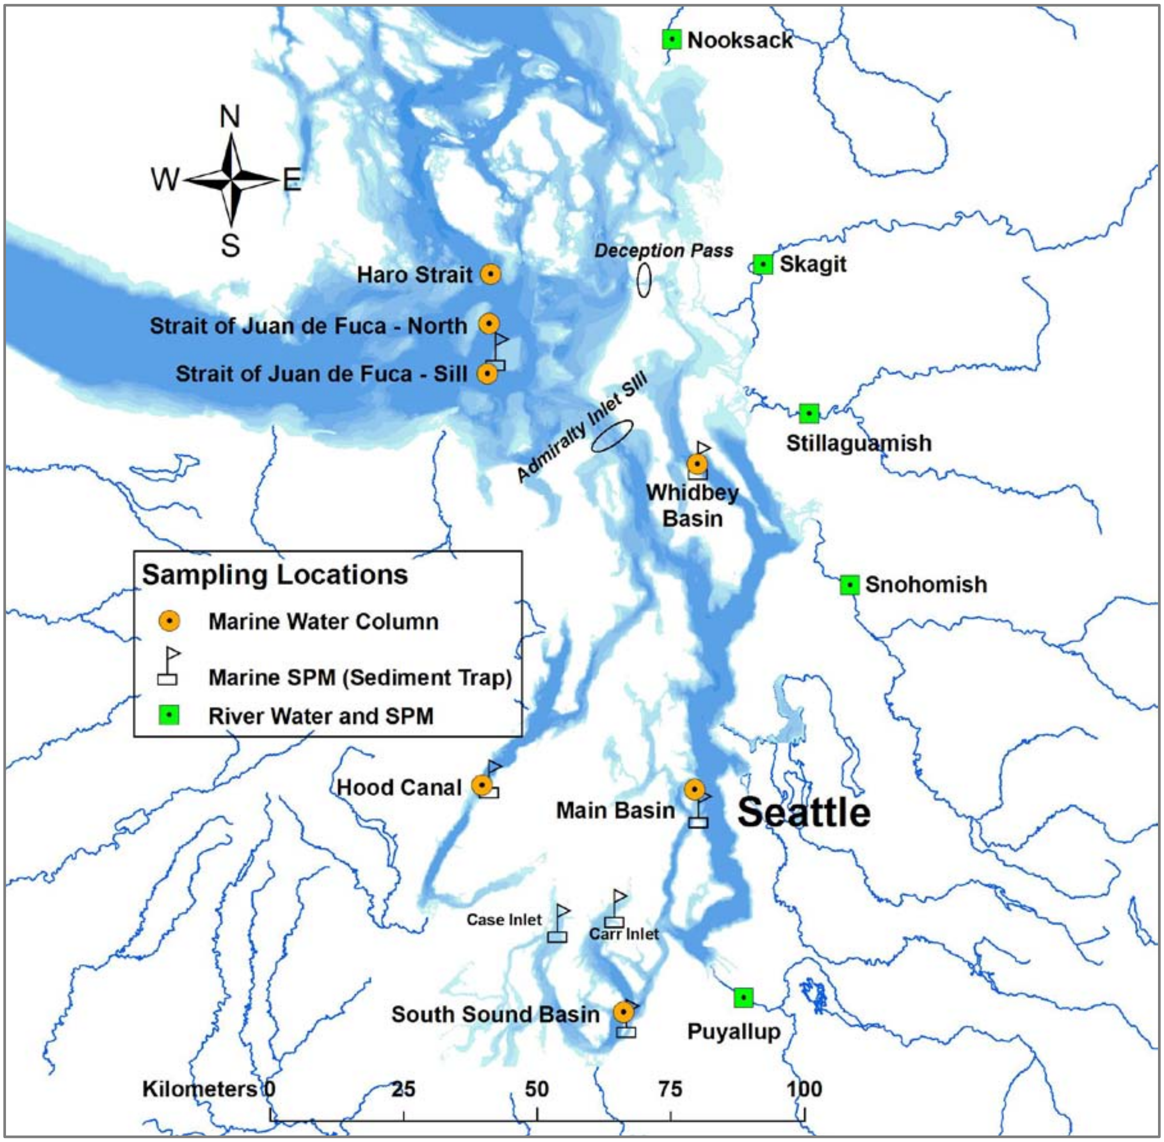

Figure 1. Marine water column and river sampling locations.

Puget Sound Toxics Box Model marine boundaries are shown in italics. Also shown are locations where sediment traps were deployed in Carr and Case Inlets during 2008 (see Results).

Table 1. Marine water column sampling site information.

Coordinates are listed for each sampling site chosen to represent Puget Sound Toxics Box Model regions. Also listed are depths used by the Box Model to divide surface from deep water layers.

Sampling Site ID	Latitude	Longitude	Box Model Region	Depth (meters) Dividing Water Layers
	(Decimal degrees; NAD83)			
Hood	47.5589	-123.0048	Hood Canal South	13
South Sound	47.1847	-122.6378	Puget Sound South	30
Main	47.5616	-122.4759	Puget Sound Main	50
Whidbey	48.1083	-122.4900	Whidbey Basin	9
SJdF at Sill	48.2500	-123.0250	Boundary Conditions	50
SJdF North	48.3333			
Haro Strait	48.4167			

SJdF = Strait of Juan de Fuca.

The circulation and transport component of the Puget Sound Toxics Box Model (Pelletier and Mohamedali, 2009; Babson et al., 2006) divided each basin vertically into surface and deep water column layers, as shown in Table 1. To provide chemical concentration data for model input and calibration, water samples were collected from within the surface and deep layers at the seven sampling locations. To assess the seasonal variability of water column concentrations, each site was sampled on three occasions (July 2009, October 2009, and January 2010).

The platform for marine sampling activities was the research vessel (R.V.) *Skookum*, an aluminum hull vessel with no antifouling coat. The *Skookum* was positioned by GPS within 100 feet of target coordinates, and the engine was off for at least five minutes prior to sampling. All sampling activities were conducted on the windward side to minimize contamination from shipboard sources.

Prior to sampling the water column at each site, a Conductivity/Temperature/Depth profiler (CTD; Model SBE25, Sea-Bird Electronics, Inc.) was deployed to measure temperature, salinity, and density throughout the water column. CTD deployments were conducted according to manufacturer protocols (Sea-Bird, 2009a and 2009b). Density profiles were assessed in the field to evaluate whether the water column was stratified (i.e., a less dense surface layer overlying a more dense deep water layer) and to accordingly select water sampling depths as follows:

- If density stratification was present, sampling depths targeted the approximate middle of the observed surface and deep layers.
- Absent stratification, sample collection targeted depths at the approximate middle of Box Model-defined surface and deep layers (Table 1).

Actual sampling depths are documented in Appendix B (Tables B-1 and B2; Figures B-2 through B-8). CTD data were later post-processed using recommended protocols, standard oceanographic equations, and manufacturer software (Sea-Bird, 2009c and 2010).

Water column samples were collected using a pair of 10-liter, Teflon-coated GO-FLO discrete samplers (General Oceanics, Inc.; Figure 2). Mounted on a non-metallic Vectran rope, the two samplers were deployed simultaneously to collect 20 liters from a targeted depth. Collection of samples from the deep layer preceded surface layer sampling at all locations. To prevent contamination of water samples expected to contain very low concentrations of target chemicals, strict protocols were employed for GO-FLO deployment and sample decanting. These protocols were based on EPA *clean hands / dirty hands* techniques (EPA, 1996), and are documented in Appendix C.

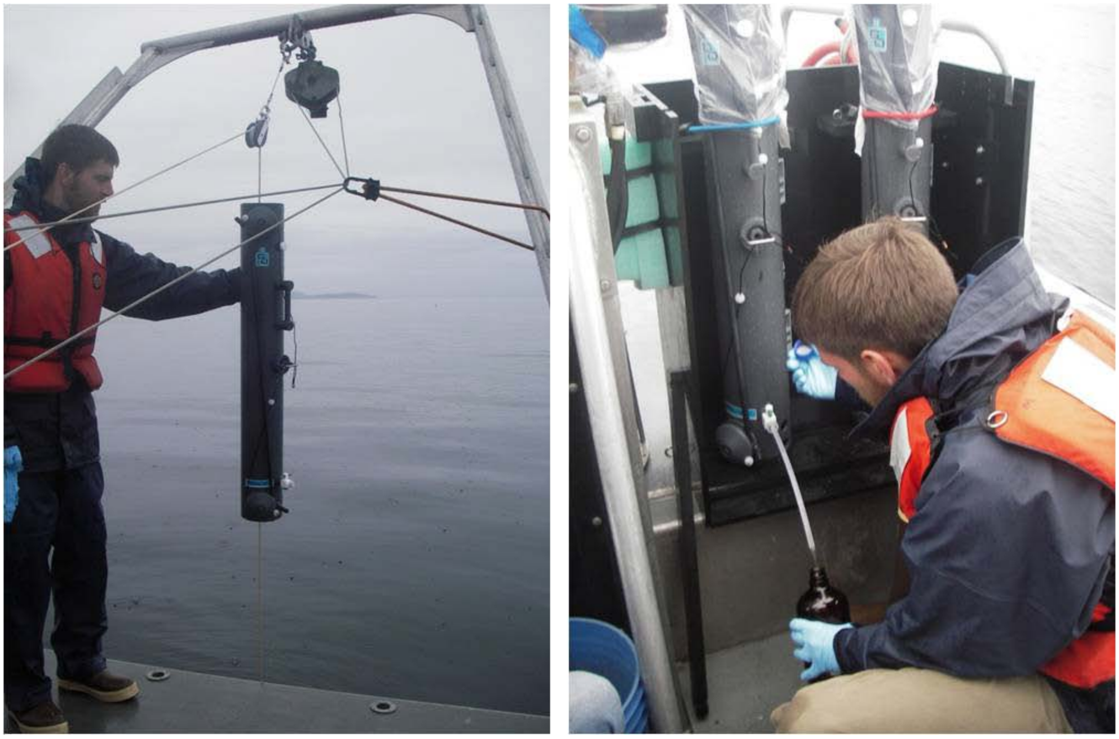

Figure 2. Collecting samples from the marine water column using GO-FLO samplers.

After retrieval, sample water was drained from the GO-FLO samplers through clean Teflon tubing to pre-rinse and then fill certified, pre-cleaned containers. Subsamples were filled in the following order: TSS, particulate organic carbon (POC) and DOC, PCB congeners, PBDE congeners, chlorinated pesticides, PAHs, BNAs, and total and dissolved metals. The volume, container, preservation, and holding times for each of these analytes are listed in Appendix C (Table C-1). Atmospheric exposure of the sample water during a typical bottle fill was minimal, occurring over a distance of approximately one inch (between the end of the Teflon tubing and the receiving bottle) for only 5 to 30 seconds.

Notable modifications to subsampling protocols from those presented in the QA Project Plan included:

- Salinity was not measured to confirm sample collection depth.
- A portable glove box was not used for transferring water to sample bottles (to eliminate exposure of samples to ambient air) because deck space was limited.

No seawater samples were collected for analysis of organic carbon during the first sampling event (July 2009) because previously available methods (Stutes and Bos, 2007) were inadequate for the purposes of this study. New field protocols were developed based on SOPs used by the University of Maryland's Horn Point Environmental laboratory (Lane et al., 2000) and others (Johannessen et al., 2008). The new procedures used an all-glass filtration apparatus and 0.7-µm pore-size glass fiber filters, with the filters and filtrate analyzed for POC and DOC, respectively (see Appendix C for details). Sampling for organic carbon resumed in October 2009 and was conducted at all locations and depths during the final two sampling events.

Various field quality control (QC) samples were also collected during each seasonal sampling. Results were used to assess environmental variability, replicability of sampling and analytical methods, and the potential for sample contamination by sampling equipment and procedures. Appendix D describes the purpose of each type of field QA sample and a description of how it was created in the field. Appendix D also presents field QA data and discusses how these data influenced interpretation of water column sample results.

Marine SPM

Ecology collected samples of SPM settling through the marine water column using moored sediment traps. A total of five moorings were deployed, each equipped with multiple traps. Sampling targeted the four Puget Sound basins where water column sampling was conducted, as well as a single location in the Strait of Juan de Fuca to collect SPM from the ocean boundary waters. All moorings were anchored in water no deeper than 50 meters and located as near as possible to water sampling stations (Figure 1).

Sediment trap moorings were deployed during October 2009. At sites where water column stratification was observed, traps were positioned to collect SPM from both the surface and deep water layers (two traps within each layer). At sites where the water column was completely mixed at the time of deployment, multiple traps were mounted within a single mid-depth zone. The configuration of each site's mooring is presented in Appendix B (Figure B-9).

Individual sediment traps consisted of paired straight-sided glass collection cylinders, each 50 cm tall by 10 cm diameter (5H:1W; 78.5 cm^2 opening area). A schematic of the construction details of the traps and their moorings is presented in the QA Project Plan (Coots and Osterberg, 2009), and further discussion can be found in Norton (2001 and 1996). At deployment, collection cylinders were filled with two liters of high salinity water (4% NaCl) and sodium azide (2% NaN_3) as a preservative to reduce microbial degradation of the samples.

Traps were intended to be deployed for a period of two to three months, collecting SPM between the fall and winter water column samplings. However, efforts to recover the traps during January and February 2010 were mostly unsuccessful, with moorings having either failed or drifted down slope too far to locate. Only the mooring in the Hood Canal was located; unfortunately, it had been disturbed and most of the collection cylinders were damaged. The SPM collected by the deepest (40 meters) sediment trap from the Hood Canal was intact and visibly undisturbed, and was deemed usable.

Upon retrieval, overlying water was removed from the two Hood Canal cylinders using a peristaltic pump. The salinity of the water immediately above the SPM in each cylinder was measured with a refractometer to verify that preservative remained. The SPM from the two cylinders was slurried, combined in a glass sample jar, and allowed to settle overnight. It was then concentrated by laboratory centrifugation (2000 rpm for at least 10 minutes), homogenized, and weighed. Total dry mass was estimated from the measured wet mass and approximate percent solids. Based on the estimated dry mass, chemical analyses were prioritized and subsamples were apportioned into certified, pre-cleaned glass sample containers for each analysis.

The Hood Canal trap yielded enough SPM to analyze a subset of the planned suite of parameters, including percent solids, TOC, five metals, PCB congeners, and PBDE congeners. To supplement these analytical results, archived sediment trap material from a recent Ecology study was also analyzed. The archived SPM had been collected by mid-water column sediment traps (identical to those employed in the present 2009-10 study) moored at sites in the Case and Carr Inlets (Figure 1) between March and June 2008 (Norton, 2009). Archived SPM from the Case and Carr traps was thawed [6], combined, and homogenized. Subsamples were distributed into sample jars for analysis of percent solids, metals, and PCB and PBDE congeners.

River Water

Ecology sampled five rivers contributing the greatest annual discharge to Puget Sound from bridges located beyond the normal upper extent of saline water intrusion. All bridges were near U.S. Geological Survey (USGS) or Ecology gaging stations (Figure 1 and Table 2). Additional details about sampling sites and sampling activities are presented in Appendix B (Table B-3 and Figures B-11 to B-15).

Sampling occurred at times intended to capture three river conditions:

- Baseflows during the dry season (July).
- Flows related to “first fall flush” or storm-related runoff (October).
- Baseflows during the wet season (December/January).

Depth-integrated samples were collected using Teflon one-liter sample bottles fit with Teflon nozzles sized for expected current velocities. Bottles and nozzles were pre-cleaned to priority pollutant standards using laboratory soap, tap water, 10% nitric acid, de-ionized water, acetone, and hexane. Similar cleaning procedures are described elsewhere (PSEP, 1997; Ecology, 2006 and 2008).

---

[6] Particulate material from Case and Carr Inlet traps had been frozen and stored in glass jars for approximately 18 months.

Table 2. Sampling locations near mouths of the five largest rivers discharging to Puget Sound.

River Name	Watershed Area [1] (km^2)	Annual Flow (Period of Record)		Sampling Location (Decimal degrees, NAD 1983)		Location Description	River Mile (RM)	Nearest Gaging Station
		cfs	cms	Latitude	Longitude			
Skagit	8,010	16,530 (69 yrs)	468	48.4450	-122.3354	Old Hwy 99 Mt. Vernon	15.7	USGS 12200500

[1] Area of watershed upstream of gaging station where samples were collected.

[2] Mean annual flow based on two USGS gaging stations (12150800 - Snohomish R.; 12155300 Pilchuck River) is 9,993 cfs.

[3] Mean annual flow based on USGS gaging station 12213100 at RM 5.8 is 3,825 cfs.

[4] USGS gaging station is located at RM 6.6, approximately 0.8 miles upstream.

The sampling bottle with nozzle was attached to a US DH-95 sampler (FISP, 2000) that was suspended by steel cable from each bridge deck (Figure 3a). Sampling followed USGS protocols (USGS, 2005) except that water was collected and composited from only three quarter points in the channel. Near-surface grab samples were collected for analysis of petroleum products (oil and grease, TPH-D, and TPH-G), as shown in Figure 3b.

Ecology conducted sample collection and processing activities according to EPA *clean hands / dirty hands* methods (EPA, 1996) to the extent possible to minimize the risk of contamination. However, a portable glove box was not used while compositing and filtering samples because it proved to be cumbersome.

Field QA samples collected during river water sampling are described in Appendix D, which also includes QC sample results and discussion of how these QC samples affected data quality.

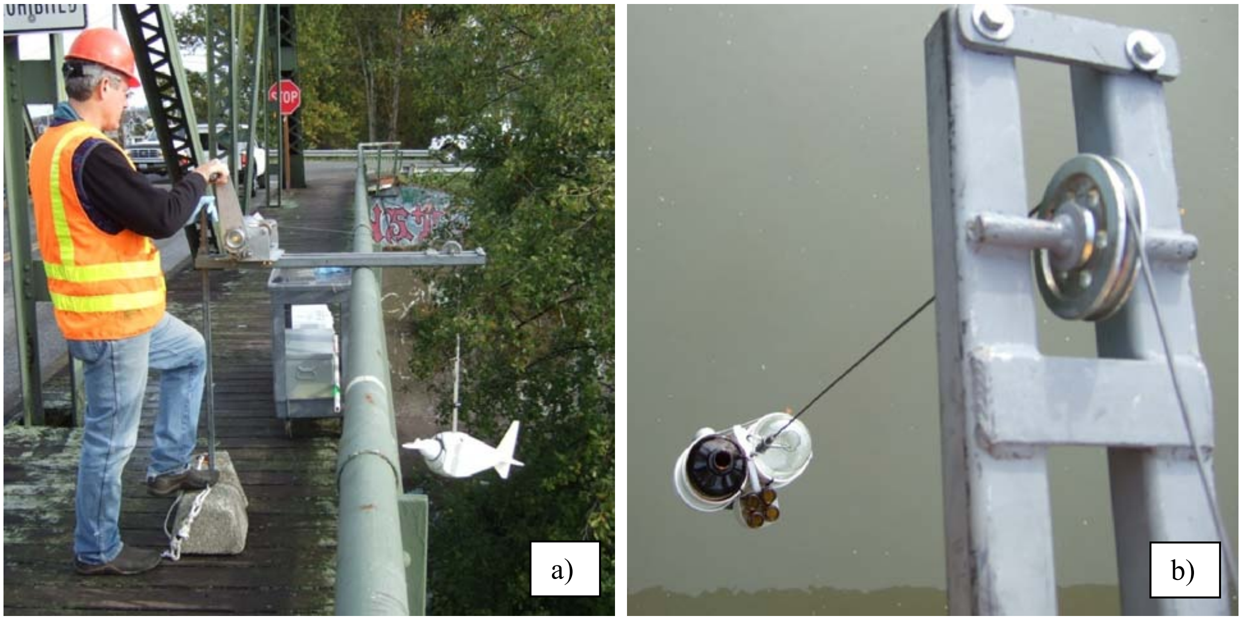

Figure 3. Collecting depth-integrated water samples and surface grabs.

River SPM

Ecology collected SPM from the five rivers only during the winter, as specified in the QA Project Plan. This was done by pumping mid-channel water through continuous-flow centrifuges in which solid material was retained. Sampling occurred within 24 hours of collecting discrete river water samples. A brief description of pump-and-centrifuge field methods follows (also see Coots and Osterberg, 2009; Gries and Sloan, 2009).

A Grundfos groundwater/well pump (Model SP4) was deployed and maintained at about 6/10 maximum mid-channel depth in each river. Water was pumped at about 2.8 gpm through Teflon-lined tubing to two Alpha Laval centrifuges (Sedisamp II, Model 101L). During this process, three discrete samples were collected from both inflow and outflow waters. The samples were composited and analyzed for TSS to assess the efficiency of centrifuges at retaining SPM [7].

After 16 - 22 hours, pumping ceased and centrifuges were shut off. The centrifuged SPM was collected while still at the sampling site. Residual water in the centrifuge bowls was removed using pre-cleaned glass syringes. Solids were collected using stainless steel spoons and Teflon-coated spatulas. Water and solids were placed in separate certified, pre-cleaned glass sample containers. Solids in the bowl water were later concentrated by laboratory centrifugation (approximately 2,000 rpm for at least 20 minutes) and added to the main mass of field-centrifuged solids. The total wet weight of solids collected was recorded. Subsamples were weighed and placed into separate jars for different analyses.

---

[7] % Efficiency = $[(TSS_{inflow}-TSS_{outflow})/TSS_{inflow}]*100$

Prior to the first river sampling:

- The stainless steel pump was soaked for 48 hours in de-ionized water.
- All tubing and centrifuge parts were cleaned using a 10% solution of nitric acid, de-ionized water, acetone, and hexane.

Between river sampling events, centrifuge parts were cleaned similarly. However, tubing was cleaned using only laboratory detergent, 10% nitric acid, and copious de-ionized water. Water from each river was also pumped through the tubing for at least 15 minutes (>150 liters or >40 gallons) before collecting SPM.

Analytical Methods

This section provides a summary of the analytical methods used for the present study. Additional details can be found in Appendix C, the QA Project Plan (Coots and Osterberg, 2009), and Ecology's Manchester Environmental Laboratory (MEL) *Lab Users Manual* (MEL, 2008).

Marine and River Water

Standard preparation, cleanup, and analytical methods were used to measure the parameters listed in the *Goals and Objectives* section. Table 3 describes the methods used by laboratories to analyze the parameters in the different samples that were collected. The following should be noted:

- The fractions of organic carbon that the Horn Point Lab measured in marine water (DOC and POC) differed from those MEL measured in river water (DOC and TOC).
- MEL measured phosphorus in strong acid extracts of river water samples using a colorimetric method comparable to most nutrient monitoring studies.
- Frontier Geosciences measured concentrations of five metals in marine water samples using methods similar those MEL used to measure the same metals in river water samples.
- The detection limits and reporting limits for oil and grease in river water were based on a grab sample size of one liter.
- MEL's organic chemical analyses provided results for as many as 32 chlorinated pesticides, 55 semivolatile organic compounds (BNAs), and 22 individual PAHs.
- Analytical Perspectives reported concentrations for 209 PCB congeners, and Pacific Rim Labs reported concentrations for 36 PBDE congeners.

SPM from the Marine Water Column and Rivers

Material from the Hood Canal sediment traps was analyzed for percent solids, TOC, five metals, PCBs, and PBDEs. Sediment that was combined from traps previously recovered from Carr and Case Inlets was analyzed for the same metals, PCBs, and PBDEs. Samples of SPM collected from each of the rivers were analyzed for percent solids, TOC, the same five metals, PCBs, and PBDEs. Enough suspended sediment was centrifuged from four of the rivers to also be analyzed for TPH-D, BNAs, PAHs, and chlorinated pesticides. Laboratory methods used for the various analyses are included in Table 3.

LEGEND:

Analytes or Parameters

BNAs = base/neutral/acid extractable, semivolatile organic compounds
DOC = dissolved organic carbon
PAHs = polycyclic aromatic hydrocarbon compounds
PCBs = polychlorinated biphenyls
PBDEs = polybrominated diphenyl ethers
TOC = total organic carbon
TPH-D = total petroleum hydrocarbons - diesel fraction
TPH-G = total petroleum hydrocarbons - gasoline fraction
TOC = total organic carbon
TSS = total suspended solids

Sample Type

F = freshwater (river samples)
S = seawater (ocean boundary and Puget Sound water samples)
SPM = suspended particulate matter (trap and centrifuge samples)

Method

ECD = electron capture detection
ECY = Washington State Department of Ecology (method number)
EPA = U.S. Environmental Protection Agency (method number)
FID = flame ionization detection
GC = gas chromatography
HR = high resolution
ICP = inductively-coupled plasma detection
MS = mass spectrometric confirmation
PSEP = Puget Sound Estuary Program Protocols and Guidelines (PSEP, 1986; PSEP, 1997)
SIM = selective ion monitoring
SM = Standard Methods (APHA, 2005)

Laboratories

AP = Analytical Perspectives, Inc.
FGS = Frontier GeoSciences, Inc.
Horn = University of Maryland Environmental Laboratory, Horn Point, Maryland
MEL = Manchester Environmental Laboratory
PRL = Pacific Rim Laboratories, Inc.

Data Quality

Data Verification

Laboratory chemists, MEL's QA Officer, and project staff conducted data quality reviews. The reviews evaluated the acceptability of sampling and analytical results based on the measurement quality objectives (MQOs) outlined in the QA Project Plan. This section describes the data quality review process and summarizes the findings. Additional details can be found in Appendix D.

Field Data Quality Review and Findings

Project staff reviewed field notes and found that measurements were made consistent with methods described in the QA Project Plan, except as noted in the *Sampling Methods* section. Three minor data quality concerns were identified:

- Some salinity results from marine water column CTD profiles were flagged as suspect.
- Water depths recorded for river samplings (quarter points and pump intake depths) were only accurate to ± 1 foot due to water levels that changed with tides or flows.
- Flow rates and the water volume pumped to collect SPM from the Puyallup River (December 2009) were uncertain because debris sometimes accumulated in the tubing and impeded flow.

Analytical Data Quality Review and Findings

MEL and contract laboratory chemists conducted initial QA reviews to verify that samples were handled and analyzed according to QA Project Plan requirements. The reviews focused on:

- Sample storage conditions and holding times.
- Sample preparation, extraction, and analytical methods.
- Instrument calibrations.
- Method detection limits (MDLs) and reporting limits (RLs).
- Lab QC sample results.

MEL staff found that the results, with few exceptions, reflected the storage conditions, holding times, and analytical methods listed in the QA Project Plan. Results that met all MQOs were accepted without qualification.

Results were assigned a "J" qualifier code (indicating an estimated value) if the detected concentrations were less than the RL, or if one or more lab QC samples failed to meet MQOs. For example, chemical concentrations were qualified with a "J" if spiked QC samples showed consistently low recovery. However, the number of "J" qualifier codes assigned for different reasons was not easily quantified. Ecology's QA Officer assigned an "N" qualifier code for PCB and PBDE congeners that could only be tentatively identified (or "NJ" if also below reporting limits). A "UJ" qualifier code was assigned to sample results for various reasons but usually because concentrations were less than ten times (<10 X) those measured in batch-specific method blanks. This indicated potential contamination from sample handling and analysis in the laboratory. Analytes for which this occurred were lead, zinc, Lindane, di-N-butyl phthalate, PCB-011, PBDE-047, PBDE-099, and PBDE-100. Consistent with laboratory best practices (EPA and MEL), results assigned "N", "NJ", "U" and "UJ" qualifiers were not used in analyses unless stated otherwise.

Analytical results were rarely rejected (0.5% of all individual chemical concentrations reported). The chemicals for which concentrations were sometimes assigned a "REJ" qualifier code were 2-chloronaphthalene, 3-nitroaniline, 4-chloroaniline, acenaphthylene, benzoic acid, n-nitroso-diphenylamine, PBDE-007, PBDE- 010, and PBDE-015.

In terms of traditional measures of data quality:

- *Accuracy* of results was ensured by verifying calculations of final concentrations. Only a few corrections were required. The accuracy of metals results for marine water samples was also assessed by analyzing certified reference materials (CRM) [8]. CRM results were generally within the range of acceptable values, with exceptions often close to the limits of the acceptable range. Sample results were not qualified based on CRM analyses.
- *Bias* was evaluated by examining the recoveries of parameters spiked into de-ionized water or samples. Concentrations in laboratory control samples, matrix spikes, surrogate spikes, and internal standards were generally recovered within MQOs for the different parameters. Sample results were assigned a "J" when results for more than one QC sample were outside the MQOs. The nature of any potential analytical bias (high or low) was not preserved in this report or in Ecology's EIM database.
- *Precision* was assessed by analyzing laboratory and matrix spike duplicates. A relative percent difference (RPD) between concentrations in duplicates and their associated field samples that did not meet the relevant MQO was cause to assign a "J" qualifier [9].

MEL summarized data quality review findings in laboratory narratives and compiled final analytical results in printed-copy format and electronic data deliverables (EDDs) [10]. Project staff used these to conduct a similar data quality review and to apply study-specific data quality rules, as documented in Appendix D. This review resulted in some changes to laboratory-assigned qualifier codes and to reported concentrations. Important modifications included:

- Results for TSS, organic carbon, nutrients (nitrogen and phosphorus compounds), hardness, metals, and oil and grease were reported down to the MDL.
- Sample results were assigned a "UJ" only if they were less than or equal to three times (≤ 3X) the batch-specific method blank concentration.
- Concentrations of DOC and POC in marine water samples were adjusted to account for concentrations detected in method and field blanks.

---

[8] National Research Council Canada CASS-4 and NASS-5 CRMs were the only reference materials analyzed during this study.

[9] Relative standard deviation (RSD) control limits applied to results for more than two lab replicates.

[10] Copies of laboratory narratives may be requested from the authors.

- Concentrations of metals in marine water samples were recalculated (the contract laboratory had subtracted the mean method blank concentration).

Rules pertaining to each of the modifications listed above are described in Appendix D. The number of each type of revision made by project staff to laboratory qualifier codes is shown in Tables D-1 to D-4. Reporting down to the MDL (instead of the RL) did not affect any marine water column data, but 62 river water sample results (1.2% of freshwater samples) were changed from nondetects ("U") to "J"-qualified or unqualified results. Of more than 19,000 individual chemical analyses of marine and river water samples, project staff assigned "UJ" or "J" qualifiers codes to 432 results received from MEL (2.3%) due to parameter concentrations in the lab method blanks.

Field Quality Assurance Sample Review and Findings

The various field QA samples from marine and river water sampling are described and discussed in Appendix D. Field QA sample results are presented in Tables D-5 through D-14.

Results for the field replicates and duplicates usually indicated a homogeneous environment and repeatable analytical results (Tables D-5 to D-8, D-11, D-13, and D-14). No chemical qualifier code was assigned to field replicate results that were substantially different because there were no pre-defined MQOs for such samples and the results may reflect spatial or temporal variability.

Bottle, filter, transfer, and equipment blanks sometimes contained measurable concentrations of copper, dissolved lead, zinc, PCB congeners, and PBDE congeners (Tables D-9, D-10, D- 12, and D-14). This indicated potential for marine and river water samples to become contaminated with low concentrations of these parameters during routine sampling, handling, and analysis. Field blank concentrations exceeding those in method blanks appeared to implicate sampling equipment and the sampling process as sources of contamination. Similar concentrations in field and method blanks indicated contamination likely occurred in laboratory settings.

Chemical concentrations in field blanks were not subtracted from sample results. Despite attempts to mimic marine water column and river water sampling procedures described in *Sampling Methods*, field blanks could not be created in exactly the same manner. Field blanks were exposed to sources of contamination longer than were marine and river water samples. For example, marine water was only exposed to ambient air while clean sample containers were being filled, whereas the associated field blanks were also exposed to air while being created. There was also evidence that rinsing sampling devices with ambient marine or river water eliminated or at least reduced contamination from the cleaning, storage, and handling processes. Therefore, subtracting field blank concentrations would inappropriately underestimate sample concentrations. Further discussion can be found in Appendix D.

Data Usability

Field measurements were nearly all usable. CTD results flagged as "suspect" did not affect interpretation of water column profiles because the suspect results always represented a single depth or limited depth range. Uncertain pumping rates and volumes pumped did not prevent calculation of centrifuge efficiency or alter chemistry results for samples of SPM.

In terms of traditional descriptions of data usability:

- *Representativeness*. Marine water column samples were collected from locations representing ocean boundary and main basin waters and from depths representing layers defined by the Box Model. River water samples were depth-integrated and SPM samples were time-integrated. Whether the results for marine and river water samples collected during three seasons represented average seasonal or annual conditions could not be determined.
- *Completeness*. The total number of water samples collected, the number of SPM samples collected from rivers, and the total number of QC samples created were similar to what was planned. The total number of analyses conducted using these samples also reflected plans. Only the deepest sediment traps deployed in Hood Canal were recovered, so the number of marine SPM samples and analyses failed to meet targets.
- *Comparability*. Sampling and analytical methods were chosen based on their history of previous use within and outside of the region. With the exception of oil and grease, analytical detection and reporting limits were similar to ones achieved for other studies. Limits for oil and grease were elevated relative to a related study (Herrera, 2010b) because these limits were based on a one-liter sample size instead of four liters.

Based on all data quality reviews, this study collected samples that were reasonably representative of environmental conditions, stored and handled appropriately, and analyzed for parameters of interest using methods comparable to other regional studies. Most laboratory results met study MQOs. Those that did not were appropriately qualified. All analytical results were deemed usable for the purposes of the present study except for:

- A few results for individual BNA and PAH compounds that were rejected.
- Some results for several PCB and PBDE congeners qualified with "N" and "NJ".
- Results for dissolved lead and zinc concentrations in marine water column samples (discussed below).

Marine water column samples sometimes contained dissolved metal concentrations greater than the associated total metal results. In most cases, the dissolved form was within 100% - 120% of the total concentration. This indicated a high fraction of the total metal concentration was in dissolved form and that the analysis could not distinguish between two low concentrations. However, some dissolved metal results were as much as 250% of the total. These samples appeared to reflect contamination of the dissolved sample at some stage of collection and handling. The marine water column data for metals were handled as follows:

- Arsenic and cadmium concentrations in marine water column samples were low, and it was often difficult to distinguish between them [11]. There was no evidence of sample contamination from filter blank results (Table D-9, Appendix D). Dissolved concentrations were included in summary statistics and data analyses.
- The dissolved copper concentration exceeded the corresponding total concentration in only two marine water column samples. The ratios of dissolved to total copper were 109% and 123%. All dissolved copper data were considered usable.
- Dissolved lead and zinc concentrations were more variable than those of the other metals and sometimes were more than two times the corresponding total concentration. For these reasons it was difficult to determine which dissolved results were analytically indistinguishable from total results and which reflected field or lab contamination. Therefore, descriptive statistics for dissolved lead and dissolved zinc are not presented in this report, and dissolved concentrations of these chemicals were not used in analyses.

Overall, perhaps the three greatest limitations on data usability are:

- Concentrations of organic chemicals detected in less than 50% of all samples (e.g., oil and grease in river water) or that were highly variable when detected (e.g., PBDEs in marine water samples) may not represent the normal range and variability. Uncertainty associated with estimates of loading or ocean exchange for these chemicals is relatively high.
- Concentrations of some organic chemicals (TPH, BNAs, chlorinated pesticides) were seldom detected in marine water column or river water samples. Consequently, transport estimates for these chemicals based on one-half the RL or MDL are likely biased high and also uncertain.
- Data for toxic chemicals associated with marine SPM collected during this study were limited because of the failure to recover most sediment traps. Estimates of the downward flux of toxic chemicals due to sedimentation will be limited and difficult to apply to other areas of Puget Sound and the ocean boundary.

---

[11] For 21 arsenic results where the dissolved concentration exceeded the total, the average ratio was 1.05 (max=1.13). For 16 cadmium results, the average exceedance ratio was 1.08 (max=1.25).

Results

Marine Water Column

Ecology collected marine water column samples at seven sites during three seasonal sampling events (July 2009, October 2009, and January 2010). Sampling depths targeted surface and bottom waters, the division between layers being determined by CTD profiles and Box Model-defined boundaries. Details of sampling activities and water column conditions are provided in Appendix B, Tables B-1 and B-2. Collection depths from each location and sampling event are shown with vertical water density profiles and Box Model layers in Figures B-1 through B-7 of Appendix B.

Density profiles revealed that water column stratification at the three ocean boundary water sites varied seasonally. Stratification at these sites was strongest during July, became slightly degraded in October, and was absent in January apart from a near-surface freshwater lens. The stratification depths observed at the four Puget Sound basin sites did not differ markedly between the sampling events and were consistent with divisions defined by the Box Model. Stratification in the South Sound basin was always weak-to-absent, except for a shallow lens of freshwater from recent heavy rains was present at the surface in January 2010.

For each sampling location, the total number of samples collected and analyzed is summarized in Table 4. Nearly 500 analyses were conducted by a total of five laboratories. This section summarizes the marine water column results, with complete results tabulated in Appendix E and available from Ecology's EIM database.

Conventional Parameters

The TSS results from marine water column sampling are summarized in Table 5. With the exception of several elevated TSS concentrations in the Whidbey basin and at the San Juan de Fuca (SJdF) North station, values at all sites were between 0.8 and 2.3 mg/L over the course of the three sampling events. The average concentration of TSS was significantly lower in samples collected during October than in samples collected at other times. Results of various statistical analyses are presented in the *Discussion* section.

Organic carbon concentration results for samples collected during October 2009 and January 2010 are also summarized in Table 5. Measured DOC and POC concentrations were summed to represent TOC concentrations.

The concentration of DOC averaged 0.76 mg/L (63.1 µM) across all samples and showed little variability (CV = 0.12). Concentrations differed little between the seven sampling sites and between the surface and deep water layers. The average DOC concentration was greater at Puget Sound basins sites than at ocean boundary water sites. Concentrations were also greater in October than in January, but the apparent temporal difference was small (< 0.20 mg/L).

Table 4. Inventory of marine water column samples collected and analyzed.

Parameter → Marine Site ↓	TSS	POC	DOC	Metals – Total [1]	Metals – Dissolved [1]	BNAs [2]	PAHs [3]	Chlor. Pesticides [4]	PCBs [5]	PBDEs [6]	Total

POC	28	100	0.03	0.05	0.06	0.13	2.44	0.09	1.78
TOC *	28	100	0.66	0.75	0.81	0.89	0.43	0.87	2.75
Ocean Boundary Stations (3)									
TSS	18	100	1.0	1.2	1.6	1.9	0.59	2.2	6.0
DOC	12	100	0.61	0.66	0.70	0.70	0.09	0.71	0.81
POC	12	100	0.04	0.04	0.05	0.06	0.35	0.07	0.11
TOC *	12	100	0.66	0.73	0.75	0.76	0.08	0.77	0.89
Puget Sound Stations (4)									
TSS	24	100	0.8	1.2	1.4	1.7	0.61	1.7	5.5
DOC	16	100	0.71	0.75	0.78	0.80	0.10	0.84	0.97
POC	16	100	0.03	0.05	0.07	0.19	2.25	0.12	1.78
TOC *	16	100	0.74	0.81	0.85	0.99	0.48	0.99	2.75

CV = Coefficient of variation.
* Values for TOC are calculated as the sum of DOC and POC concentrations.

The average POC concentration was 0.13 mg/L (11 µM). Concentrations in surface waters of Puget Sound basin sites during October were the most variable (Figure 4) and exceeded concentrations measured in ocean boundary waters. The average POC concentration was greater in October samples than in January samples.

The pool of organic carbon was dominated by the dissolved fraction, with DOC averaging more than 90% of TOC. The October Whidbey Basin surface water sample was an exception. It contained an unusually high POC concentration (Figure 4) that was 65% of TOC.

As was true for DOC, average TOC concentrations were greater in Puget Sound basins than in boundary waters, and greater during the fall than in the winter. TOC concentrations in surface water samples collected in October exceeded those in the deep waters by an average of nearly 0.6 mg/L. However, by January, TOC concentrations at the two depths differed little.

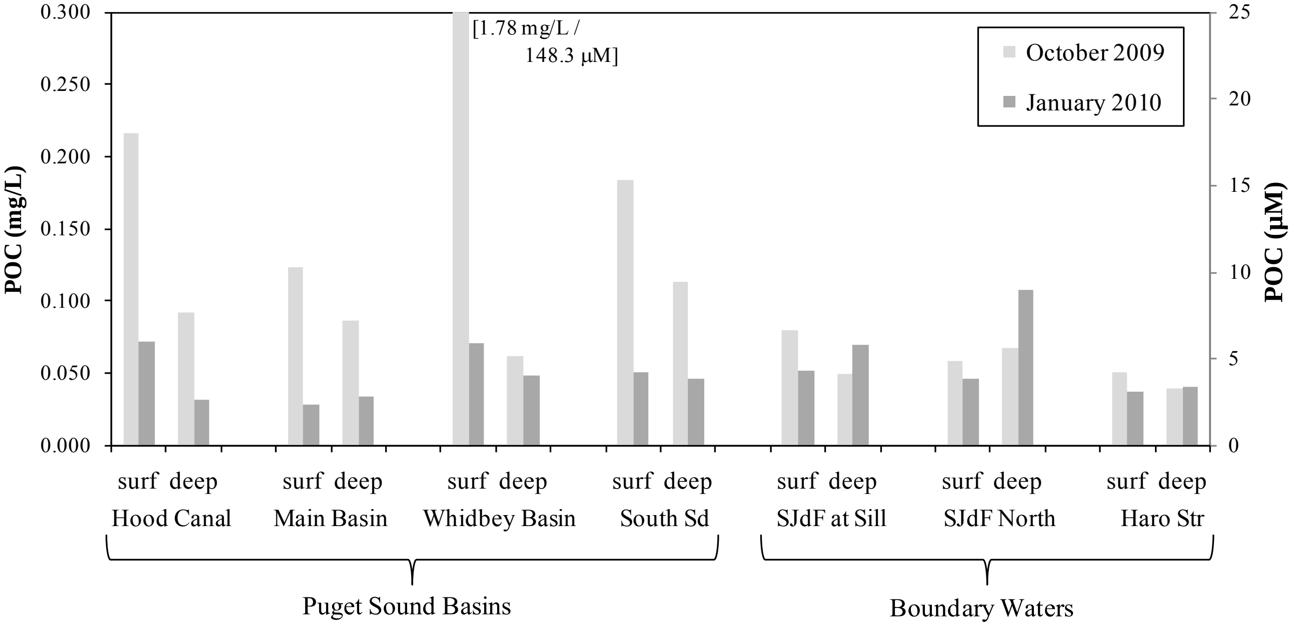

Figure 4. Summary of marine water column POC results.

Metals

Marine water column samples were analyzed for total and dissolved forms of arsenic, cadmium, copper, lead, and zinc. Summary statistics for marine metals are presented in Table 6, and complete results can be found in Table E-1 of Appendix E.

Dissolved metal results sometimes exceeded their corresponding total concentration. For the purposes of this project, all dissolved results for arsenic, cadmium, and copper were deemed usable. However, uncertainties associated with the results for dissolved lead and dissolved zinc caused these data to be excluded from analyses. See *Data Usability* section.

Table 6. Summary statistics for total and dissolved metals in the marine water column.

***** Summary statistics for concentrations of dissolved lead and zinc are not presented here. Dissolved concentrations often exceeded total concentrations to a degree that complicated distinguishing valid results from ones that reflected field or laboratory contamination.

Arsenic

The range of total arsenic concentrations measured in regional marine waters was 1.16 - 1.56 µg/L (Figure 5). The overall average concentration was 1.42 µg/L. Total arsenic concentrations were greater in January than in October and also greater in deep waters than in surface waters.

Results for dissolved arsenic are shown in Figure 6. Dissolved arsenic averaged 96% of the total concentration in one-half of all samples (21/42). However, the dissolved fraction marginally exceeded the total concentration in the remaining 21 samples. Filter blanks showed no evidence of contamination. Therefore, these apparently anomalous results were attributed to the analytical difficulty of differentiating between dissolved and total forms at such low concentrations.

Cadmium

Total cadmium concentrations, shown in Figure 7, ranged from 0.059 - 0.112 µg/L. The average concentration at all locations and depths was 0.085 µg/L. Ocean boundary water concentrations were greater than those in Puget Sound. In addition, the average deep water concentration exceeded that for surface waters.

Like arsenic, dissolved cadmium was the predominant form. In 23 samples, dissolved cadmium averaged 91% of the total concentration. The dissolved form exceeded the total concentration in the remaining 19 samples. Filter blanks again showed no evidence of contamination (similar to the arsenic results) so these exceedances were also attributed to difficulties distinguishing between the dissolved fraction and the total at low concentrations.

As with total concentrations, dissolved cadmium was greater in ocean boundary waters than in Puget Sound. Surface water dissolved concentrations at all sites except SJdF Sill increased from July to October and again from October to January (Figure 8). Dissolved cadmium was greater in deep waters than in surface waters during July and October. This was especially true for ocean boundary sites, where concentrations exceeded those in surface waters by as much as 0.028 µg/L. However, by January the ocean boundary sites had higher dissolved cadmium concentrations in the surface waters than in deep waters.

Copper

Total copper concentrations in the marine water column ranged from 0.19 - 1.37 µg/L (Figure 9) and were more variable than dissolved concentrations (Figure 10). Elevated total copper concentrations occurred on one occasion at the Hood Canal, Main Basin, SJdF North, and Haro Strait sites. The elevated results did not appear to be associated with any spatial or temporal pattern. Dissolved copper concentrations ranged from 0.16 - 0.51 µg/L, representing 30% to 100% of the total (average of 80%). Dissolved copper was greater than the total in only two samples.

The waters of Puget Sound contained greater concentrations of total and dissolved copper than did ocean boundary waters. For example, dissolved copper in Puget Sound ranged from 0.28 - 0.51 µg/L while boundary waters contained 0.16 - 0.28 µg/L. Total and dissolved copper concentrations were lowest in October in all but one location. The maximum observed total and dissolved copper concentrations were in the deep water sample collected from Hood Canal in July.

Lead

Total lead in the marine water column, shown in Figure 11, ranged from 0.015 - 0.230 µg/L. Total lead concentrations in the deep waters usually exceeded those in surface waters. October concentrations of total lead in five samples (SJdF North, surface; SJdF Sill, surface and deep; South Sound, surface and deep) were within three times the concentration in the associated laboratory method blank. These results were qualified as "UJ" (as described in Appendix D). Dissolved lead results were not usable for the purposes of this project (see *Data Usability*).

Zinc

The range of total zinc concentrations in the marine water column was 0.41 - 7.44 µg/L (Figure 12). The average for all locations, seasons, and depths was 0.86 µg/L. Total zinc concentrations in deep waters were often greater than in surface waters, especially during October and January. Dissolved zinc results were not usable for the purposes of this project (see *Data Usability*).

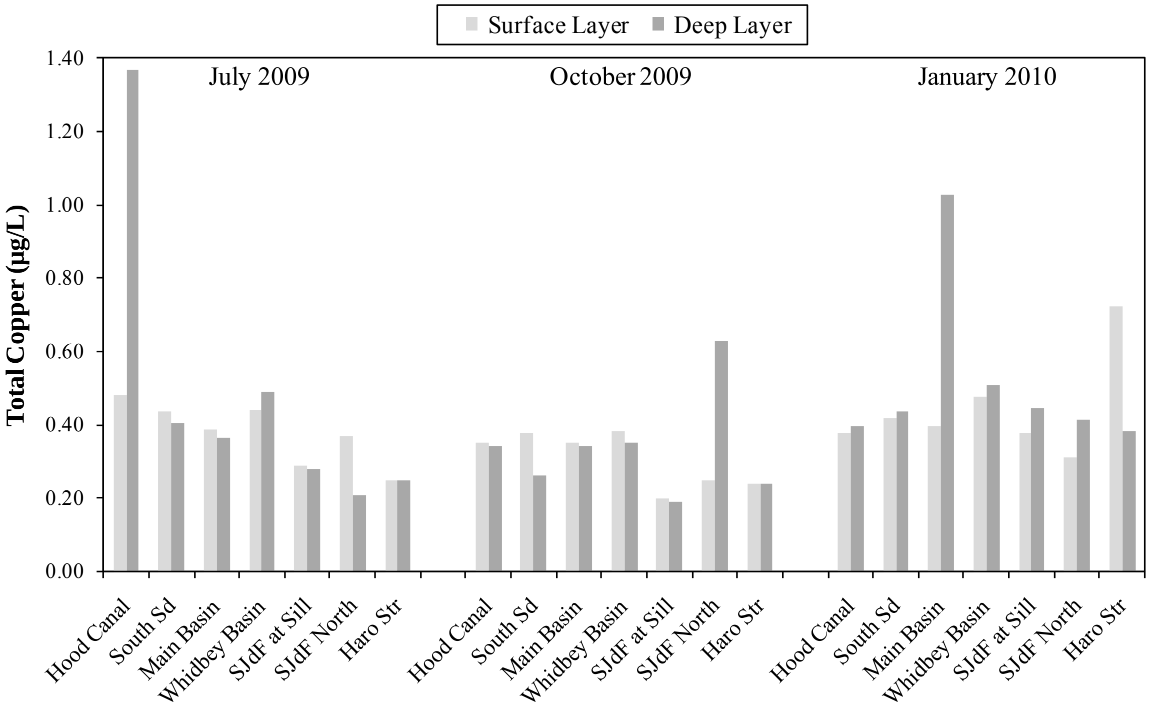

Figure 9. Concentrations of total copper in the marine water column.

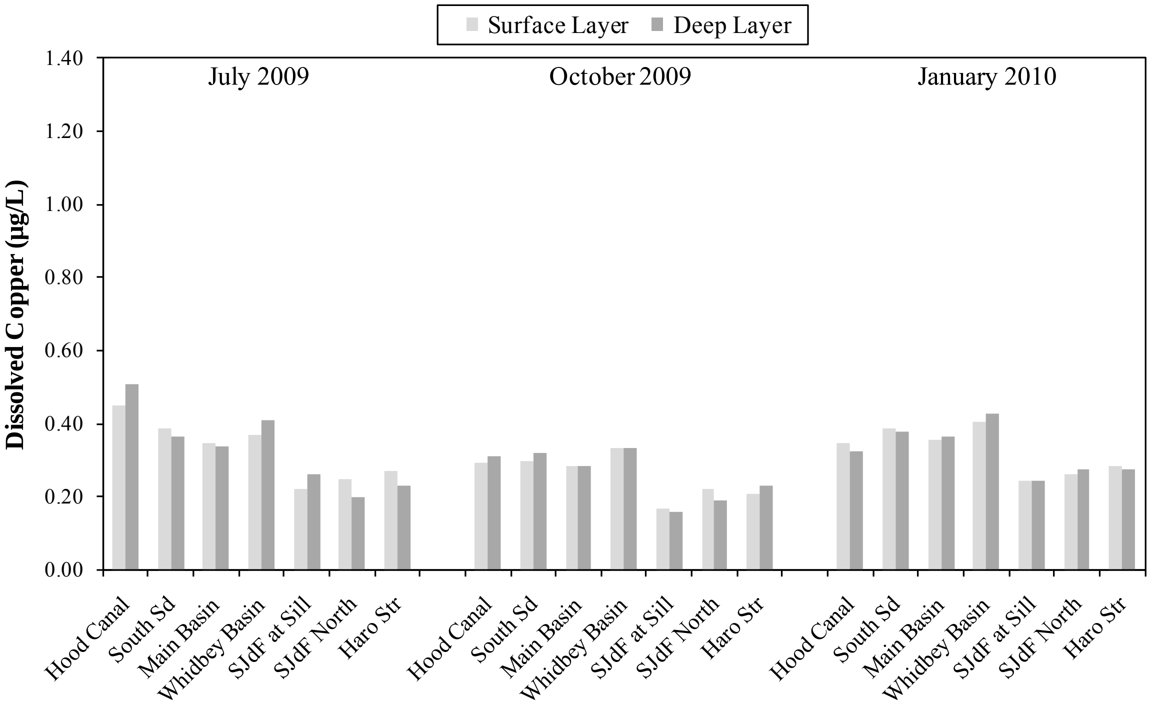

Figure 10. Concentrations of dissolved copper in the marine water column.

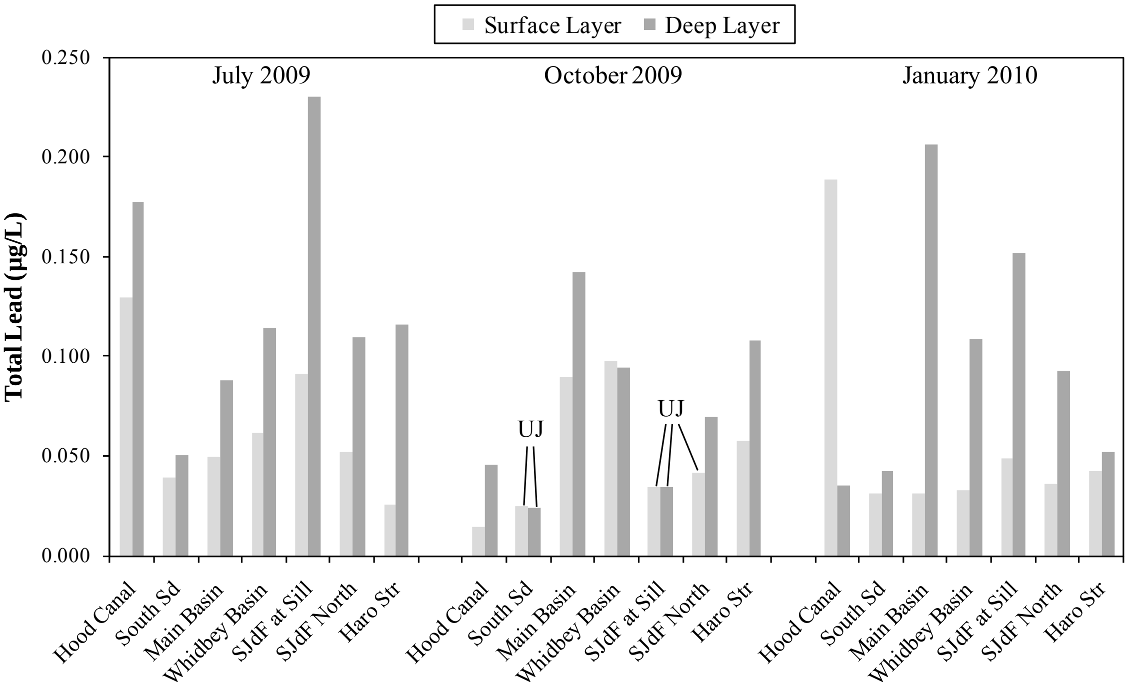

Figure 11. Concentrations of total lead in the marine water column.

Samples collected during October qualified as "UJ" were within three times the laboratory method blank concentration. Dissolved lead results not shown (see Data Usability).

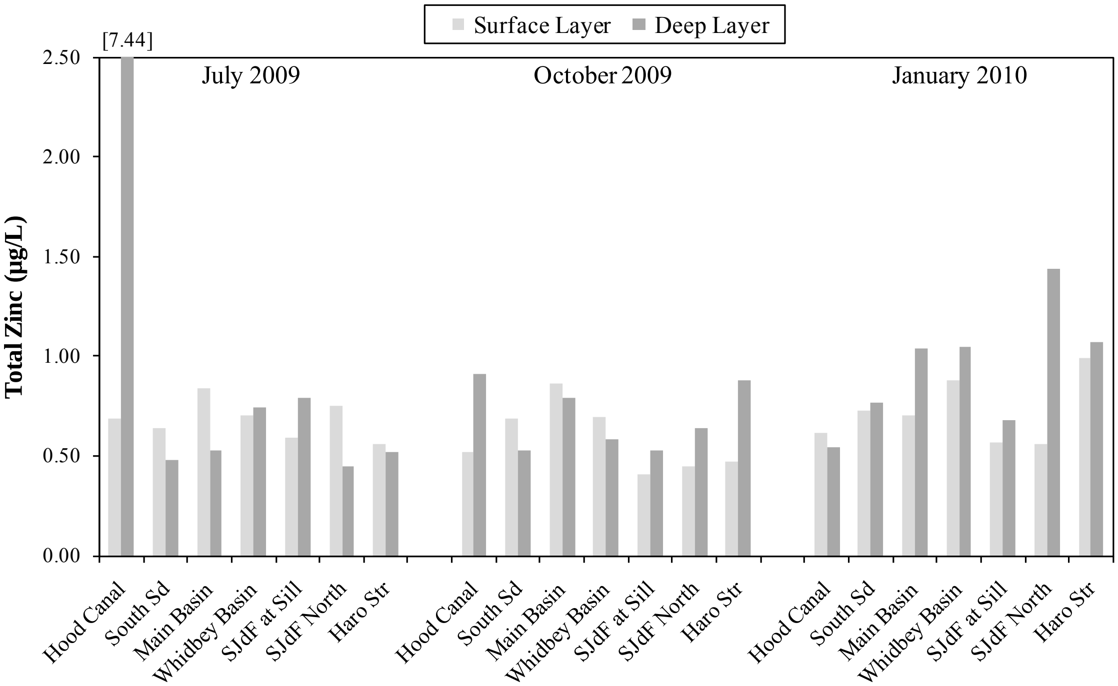

Figure 12. Concentrations of total zinc in the marine water column.

Dissolved zinc results not shown (see Data Usability).

Organics

Marine water column samples were analyzed for 33 chlorinated pesticide compounds, but only five were detected (Table 7). These compounds were found in samples collected during July and October, while no measurable concentrations were detected in January samples. Chlorinated pesticides were detected infrequently and only in the northern boundary waters.

Table 7. Summary of measurable chlorinated pesticides in the marine water column.

Date	Sampling Location	Water Column Layer	4,4'-DDE (ng/L)	Alpha-BHC (ng/L)	Beta-BHC	Delta-BHC (ng/L)	Hexachloro-benzene (ng/L)
7/8/09	SJdF North	surface	0.21 J				
		deep	0.39				
7/8/09	Haro Str	deep	0.21				
9/28/09	Whidbey	deep		0.21	0.32	0.25 J	
10/7/09	SJdF North	surface					0.21

Of the 55 BNA compounds targeted by the analyses, 11 were detected at least once (Table 8). All of these except Triclosan were detected in samples collected during July. A narrow range of cholesterol concentrations was detected in October and January samples. Triclosan was only detected in the samples collected during October. No measureable concentrations of any compounds were found in January.

PAH analyses targeted 22 compounds. PAHs were not detected in any marine water column sample at the detection limits (from 0.0005 to 0.033 µg/L).

PCBs and PBDEs

Results for marine water column PCBs and PBDEs are summarized in Table 9. All results were method blank-qualified at the congener level before calculating homolog totals.

PCBs were detected in all marine water column samples (Figure 13). Total PCBs ranged from 6.09 to 75.1 pg/L, averaging 26.3 pg/L. The sum of the congeners in the tetra- and penta-chlorinated homolog groups comprised an average of 80% of the total PCBs.

Table 8. Summary of measurable BNA compounds in the marine water column.

Date	Sampling Location	Water Column Layer	2,4-Dichlorophenol (µg/L)	2-Methylphenol (µg/L)	3B-Coprostanol (µg/L)	4-Chloro-3-Methylphenol (µg/L)	Bis(2-Ethylhexyl) Phthalate (µg/L)	Bisphenol A (µg/L)	Caffeine (µg/L)	Cholesterol (µg/L)	Ethanol, 2-Chloro-, Phosphate (3:1) (µg/L)	Phenol (µg/L)	Triclosan (µg/L)

Table 9. Summary statistics for PCB and PBDE homologs in the marine water column.

Congener summation rules are described in Appendix D. Congeners in each homolog group are listed in Appendix E (Tables E-20 to E-22, and E-24). Concentrations of tentatively-identified congeners (results qualified as N or NJ) were not included in homolog or overall totals. Note: Homolog concentrations in a single sample can be summed to equal the total concentration in that sample, but summing the homolog statistics below will not result in the total concentration statistics.

Parameter (pg/L)	Times Detected	Percent Detected	Min.	25th %ile	Median	Mean	CV	75th %ile	Max.
PCB homologs and totals (pg/L)									
Mono-chlorinated	11	26	0.40	0.96	1.73	4.28	1.45	2.84	18.7

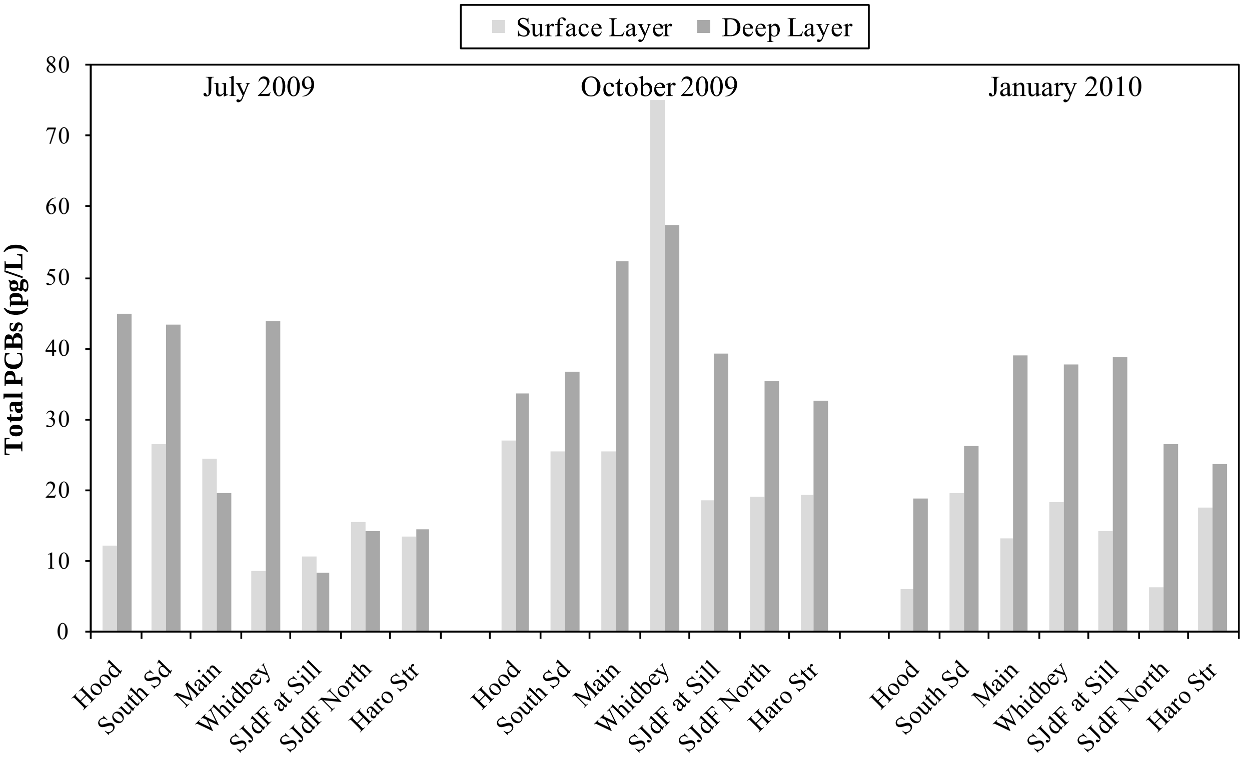

Figure 13. Summary of results for total PCBs in marine water column samples.

Tentatively-identified congeners (qualified as N or NJ) were not included in total PCB sums.

The average concentration of total PCBs in Puget Sound was greater than the average in ocean boundary water samples. October samples usually contained greater concentrations than those in samples collected at other times. Deep layer total PCB concentrations generally exceeded surface water concentrations (Figure 13). One notable exception was that July samples from all three boundary water sites had nearly identical surface and deep layer concentrations. Another exception was the October surface sample from Whidbey Basin, where the highest total PCB concentration of the study was observed (75.1 pg/L). This latter sample also had extremely elevated results for TSS, POC, dissolved lead, and dissolved zinc.

Measureable concentrations of PBDEs were detected in 10 of the 42 samples. Detected total PBDEs ranged from 51 to 18,700 pg/L and were highly variable (CV=1.98). The average total PBDE concentration was 2,860 pg/L, while the median value was much lower at 749 pg/L. Penta-brominated congeners and PBDE-209 were detected most frequently.

The maximum detected total PBDE concentration of 18,700 pg/L was measured in the January sample from the deep water layer at the Haro Strait site. The only other chemical concentration elevated in this sample was total zinc. The next highest concentration of total PBDEs was 3,190 pg/L, also from the Haro Strait site but in the October surface water sample. These and other PBDE concentrations were identified as statistical outliers (Appendix J, Table J-1), but were included in analyses because there was no evidence that the samples had been contaminated.

Marine SPM

As previously mentioned, after a deployment period of three months only one of the five sediment trap moorings was successfully recovered. The particulate sample collected from this mooring represented the deep layer of Hood Canal. Analyses included % solids, TOC, five metals, PCB congeners, and PBDE congeners. To partially compensate for the paucity of marine SPM samples, archived particulates collected from traps deployed in Case and Carr Inlets during the spring of 2008 were submitted for the same analyses of metals, PCBs, and PBDEs. Marine SPM results are presented in Table 10. The Case+Carr results were qualified as estimated values ("J") because the samples were analyzed beyond recommended holding times.

Table 10. Results for sediment trap collections of marine suspended particulates.

Parameter	Hood Canal	Case+Carr Inlets
Conventionals (%)		
TOC	2.75	n/a
Total Recoverable Metals (mg/Kg dry)		
Arsenic	7.53	5.72 J
Cadmium	0.87	1.04 J
Copper	82.0	18.5 J
Lead	9.13	8.78 J
Zinc	90.0	72.0 J
PCB Homologs (ng/Kg dry) *		
Mono-chlorinated	ND	35.3 J
Di-chlorinated	429	840 J
Tri-chlorinated	280	1,290 J
Tetra-chlorinated	343 J	1,230 J
Penta-chlorinated	948	2,290 J
Hexa-chlorinated	642	2,920 J
Hepta-chlorinated	284	909 J
Octa-chlorinated	11.6 J	249 J
Nona-chlorinated	ND	53.4 J
PCB-209	27.8	32.3 J
Total PCBs	2,970	9,850 J
PBDE Homologs (ng/Kg dry) *		
Mono-brominated	n/a	n/a
Di-brominated	14 UJ	17.4 UJ
Tri-brominated	10.2 J	68.7 J
Tetra-brominated	138 J	498 J
Penta-brominated	131 J	269 J
Hexa-brominated	43.6 J	58.4 J
Hepta-brominated	54.1 J	41.2 J
Octa-brominated	57.3 J	28.4 J
Nona-brominated	270 J	92.1 J
PBDE-209	879	174 UJ
Total PBDEs	1,580 J	1,060 J

* Homolog and total concentrations do not include tentatively-identified results (those qualified with "N" or "NJ").

Of the five metals analyzed, Hood Canal particulate concentrations exceeded those found in Case+Carr particulates for four of these metals. Differences in particulate copper concentrations between the two sites were especially large, with Hood Canal concentrations more than four times higher than those measured in Case+Carr solids. Cadmium was the only metal for which Case+Carr particulate concentrations were greater than Hood Canal values, although the difference was small (0.17 mg/Kg dry).

Sediment trap collections revealed marked differences in particulate PCB concentrations between the two sites. Solids from the Case+Carr sample had a total PCB concentration over three times that found in the Hood Canal particulates, and all 10 PCB homolog concentrations were higher in the Case+Carr sample.

In contrast, PBDE homolog concentrations varied between the two locations. Congeners with lower levels of bromination (tri-, tetra-, and penta-BDEs) were found in higher concentrations in Case+Carr SPM. Hexa- and hepta-brominated congeners had similar concentrations at the two sites. Octa-, nona-, and deca-BDEs had higher concentrations in Hood Canal SPM. Overall, the concentration of total PBDEs in Hood Canal particulates was 50% higher than that measured in Case+Carr SPM.

River Water

Ecology sampled the five largest rivers flowing into Puget Sound three times between late July 2009 and early January 2010. Sampling conditions in each river spanned a range of discharges and conditions. The upper panels of Figures 14-18 highlight the mean daily flow in each river on each sampling date atop hydrographs of mean daily flow for the calendar year. For context, hydrographs of long-term median daily flow are also shown for each river. Periods of relatively high flow appear as the darkest areas, while periods of relatively low flow appear under the white areas. In general, the rivers had lower-than-normal flows in 2009, but periods of higher flows did occur in late spring and late fall.

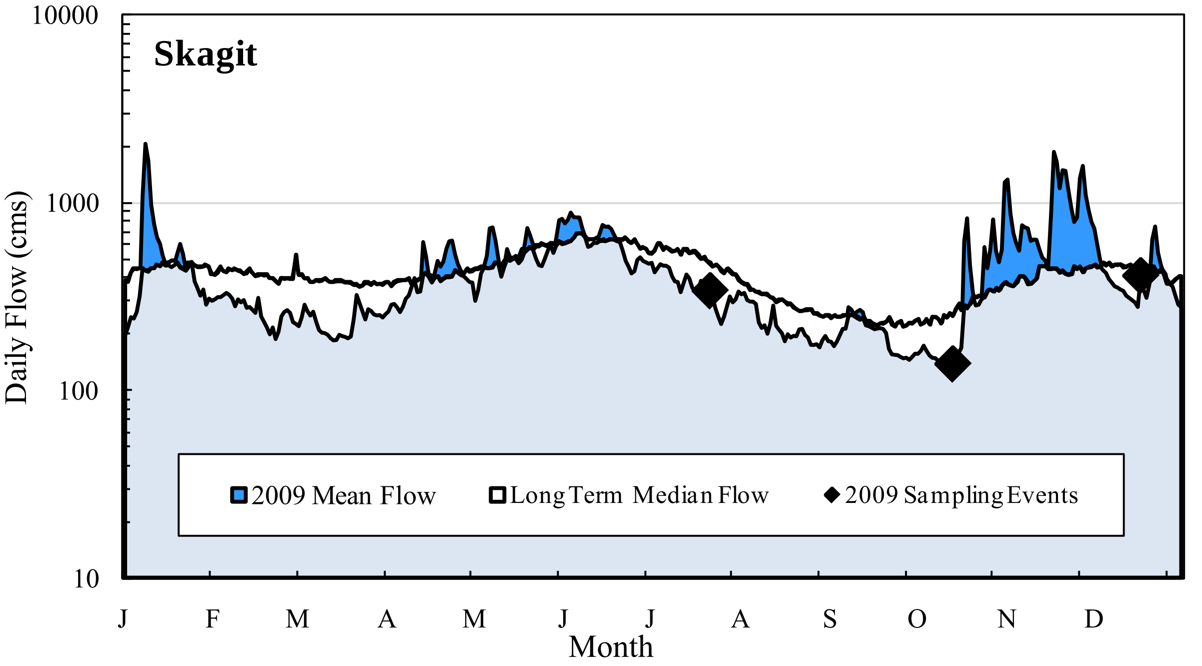
Daily flows encountered while sampling were usually below the long-term median flow for the same dates. Exceptions (higher-than-normal flows) were encountered in the Stillaguamish (October 2009), the Snohomish (December 2009), and the Nooksack (January 2010). Overall, mean daily flows ranged from 13.3 cms (470 cfs) in the Stillaguamish in July to 521 cms (18,500 cfs) in the Skagit in December (Table 11). These flows represented baseflows and runoff-related flows, with the flow regime determined after examining:

- Seasonal hydrographs.
- Mean daily flows preceding and following each sampling (lower panels of Figures 14-18).
- Recent climate records (especially for precipitation).
- Other evidence (long-term flow records, turbidity).

In July, dry-season baseflows were evident in all rivers except the Puyallup (Figure 18). The Puyallup was highly turbid, carrying a high concentration of suspended solids (233 mg/L). However, the relatively high TSS was consistent with long-term ambient monitoring data for late-summer and was probably due to silts in glacier meltwaters enhanced by recent high air temperatures.

In October, baseflows were encountered while sampling the Skagit and Nooksack (Figures 14 and 16). The Snohomish and Stillaguamish were sampled during late stages of obvious runoff events (Figures 15 and 17). It was less obvious in Figure 18 that Puyallup River flow was related to runoff. However, elevated flow and concentrations of suspended solids reflected an early stage of runoff from 1.33 inches of rain that fell upstream the day before.

Sampling during December 2009 and January 2010 found wet-season baseflows in the Stillaguamish and Puyallup. The other three rivers had flows in the rising or falling stage of runoff-related events. River water in the Skagit was running clear when sampling began but became visibly turbid soon afterward.



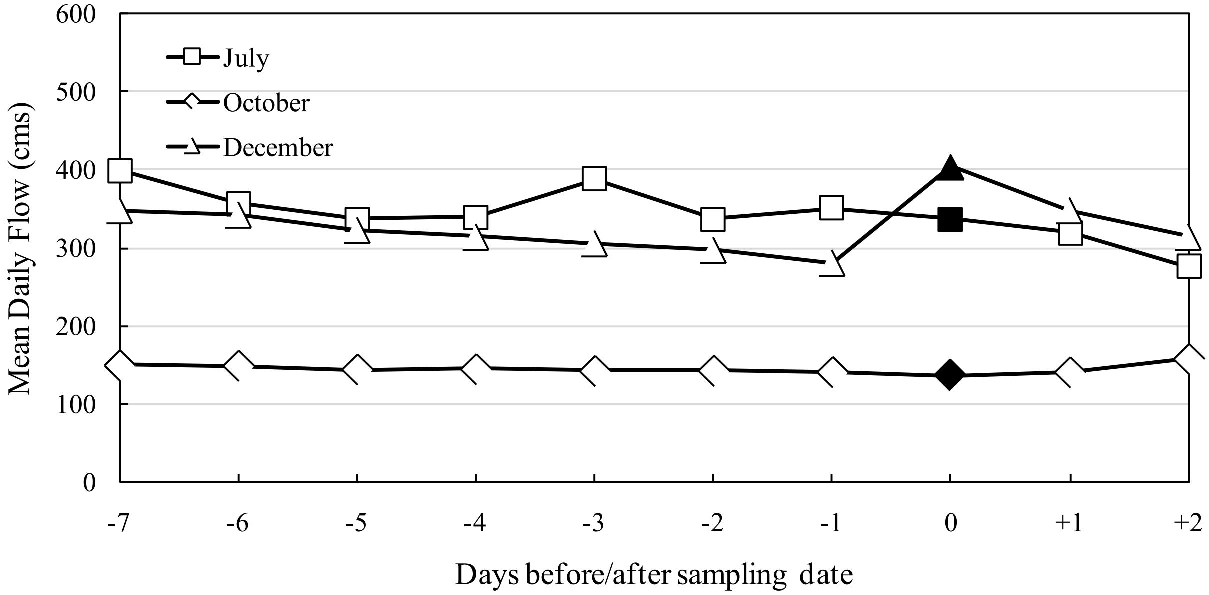


Figure 14. Skagit River daily flows.

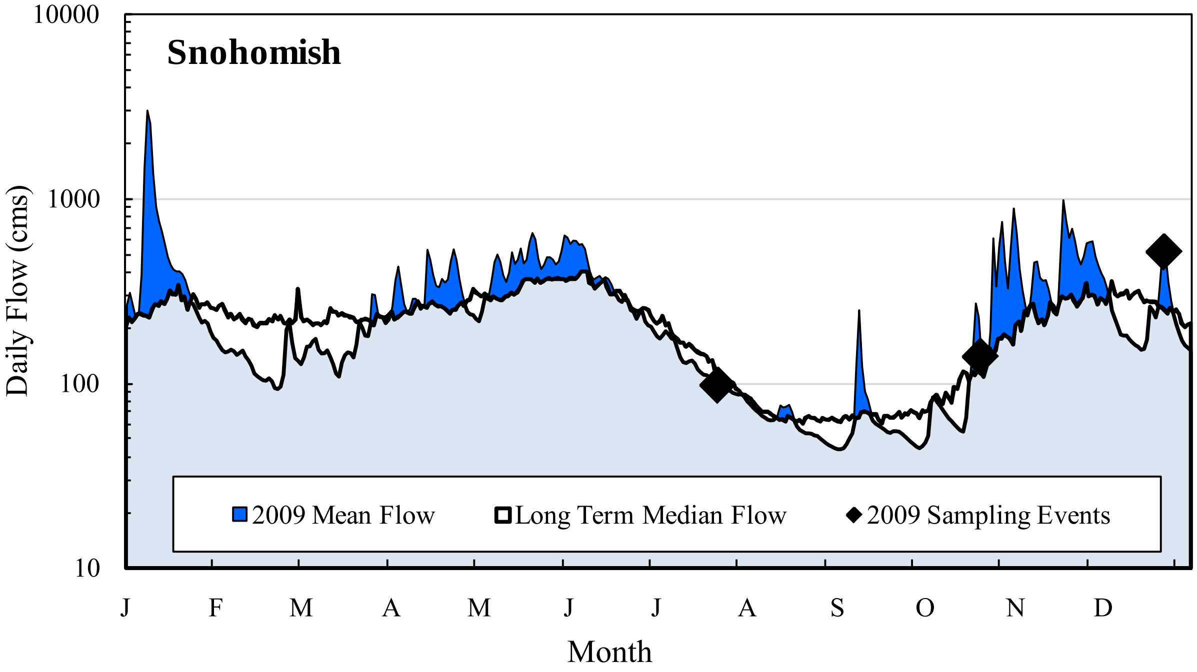
- Upper: Sampling events are shown as black diamonds on the hydrograph for mean daily flows during 2009 (shaded beneath). Relative to long-term median flows, periods of high flow appear as the darkest areas and periods of low flow appear under the white areas.
- Lower: Mean daily flows prior to, during, and immediately after each sampling event (solid black symbols).

July and October sampling occurred during baseflows, while sampling in December was during the late stages of a runoff event.



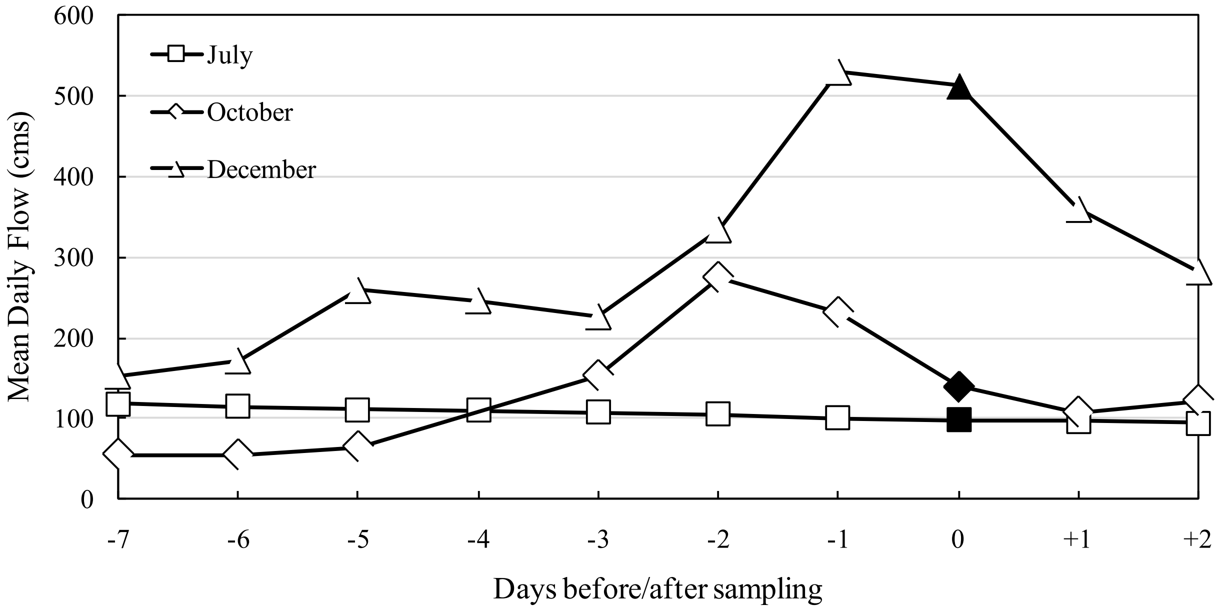


Figure 15. Snohomish River daily flows.

- Upper: Sampling events are shown as black diamonds on the hydrograph for mean daily flows during 2009 (shaded beneath). Relative to long-term median flows, periods of high flow appear as the darkest areas and periods of low flow appear under the white areas.
- Lower: Mean daily flows prior to, during, and immediately after each sampling event (shown as solid black symbols).

Sampling in July was during baseflows. October and December sampling events occurred near the end and peak of runoff events, respectively.

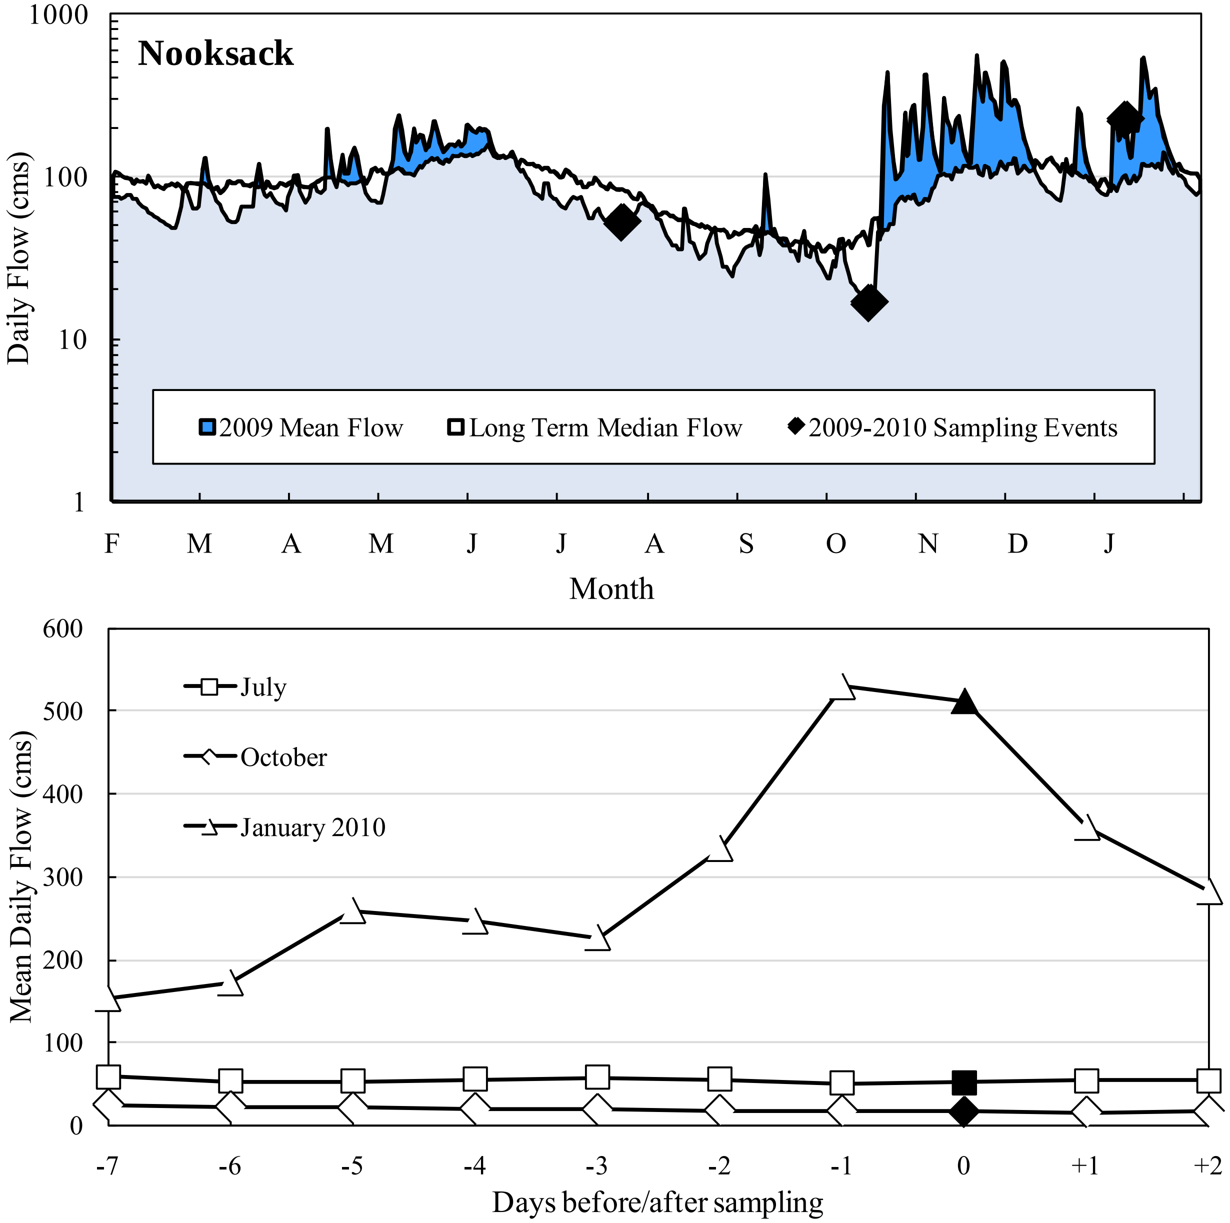

Figure 16. Nooksack River daily flows.

- Upper: Sampling events are shown as black diamonds on the hydrograph for mean daily flows during 2009 (shaded beneath). Relative to long-term median flows, periods of high flow appear as the darkest areas and periods of low flow appear under the white areas.
- Lower: Mean daily flows prior to, during, and immediately after each sampling event (solid black symbols).

  July and October sampling occurred during baseflows, while sampling in January 2010 was near the peak of a runoff event.

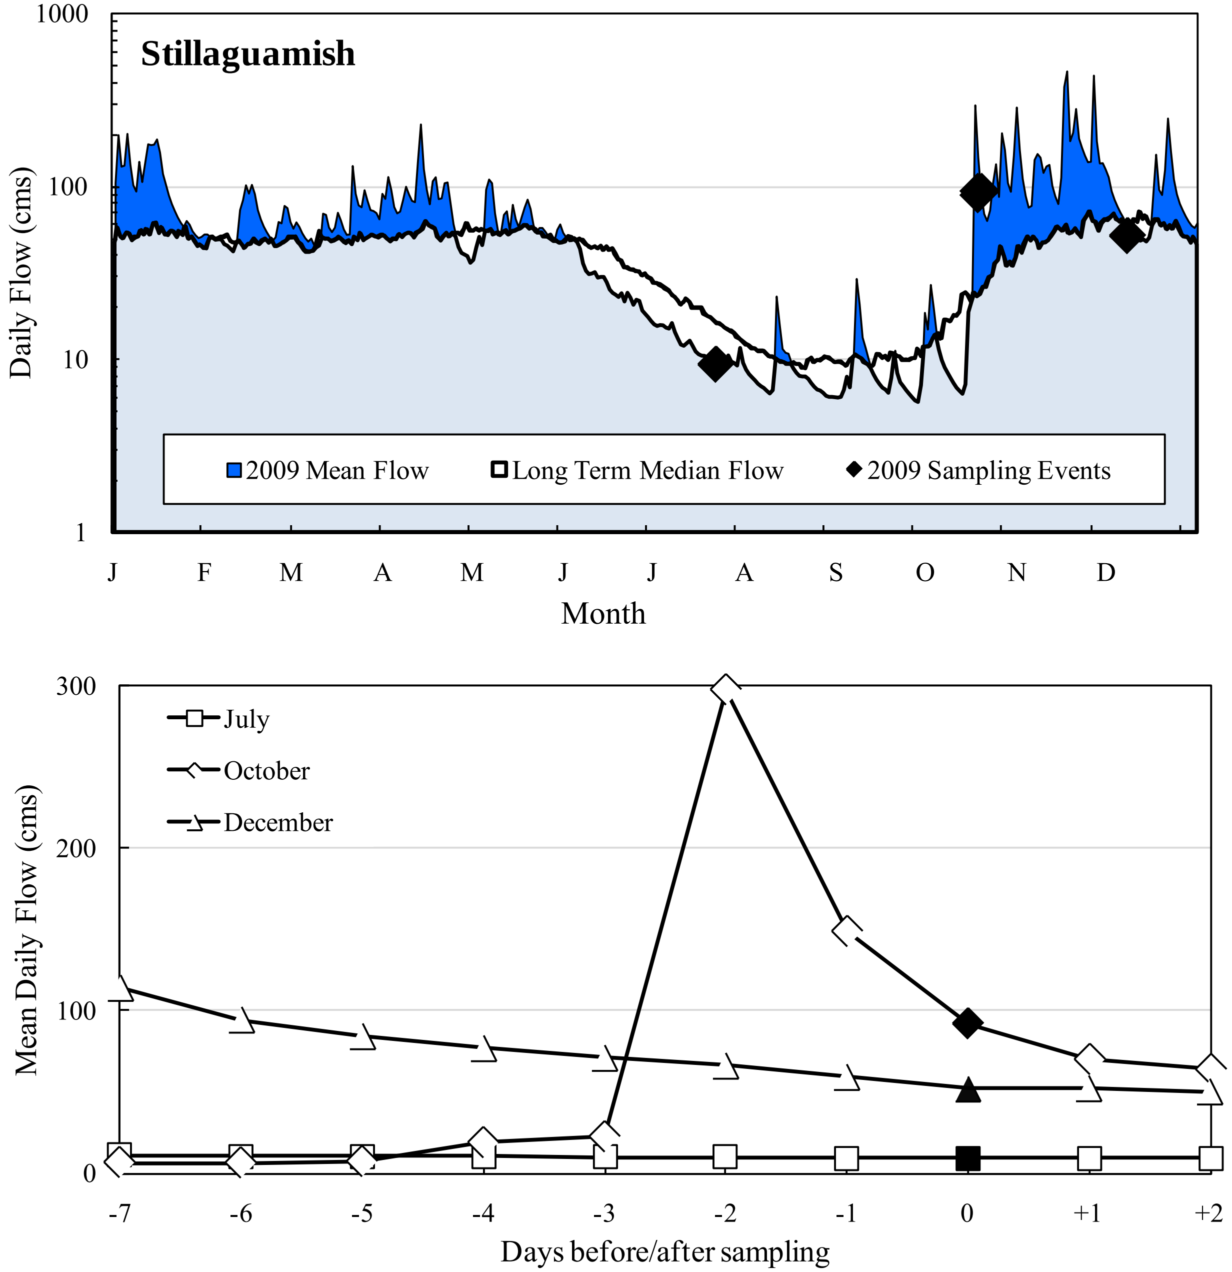

Figure 17. Stillaguamish River daily flows.

- Upper: Sampling events are shown as black diamonds on the hydrograph for mean daily flows during 2009 (shaded beneath). Relative to long-term median flows, periods of high flow appear as the darkest areas and periods of low flow appear under the white areas.
- Lower: Mean daily flows prior to, during, and immediately after each sampling event (solid black symbols).

July and December sampling occurred during baseflows, while sampling in October was during the falling stage of a runoff event.

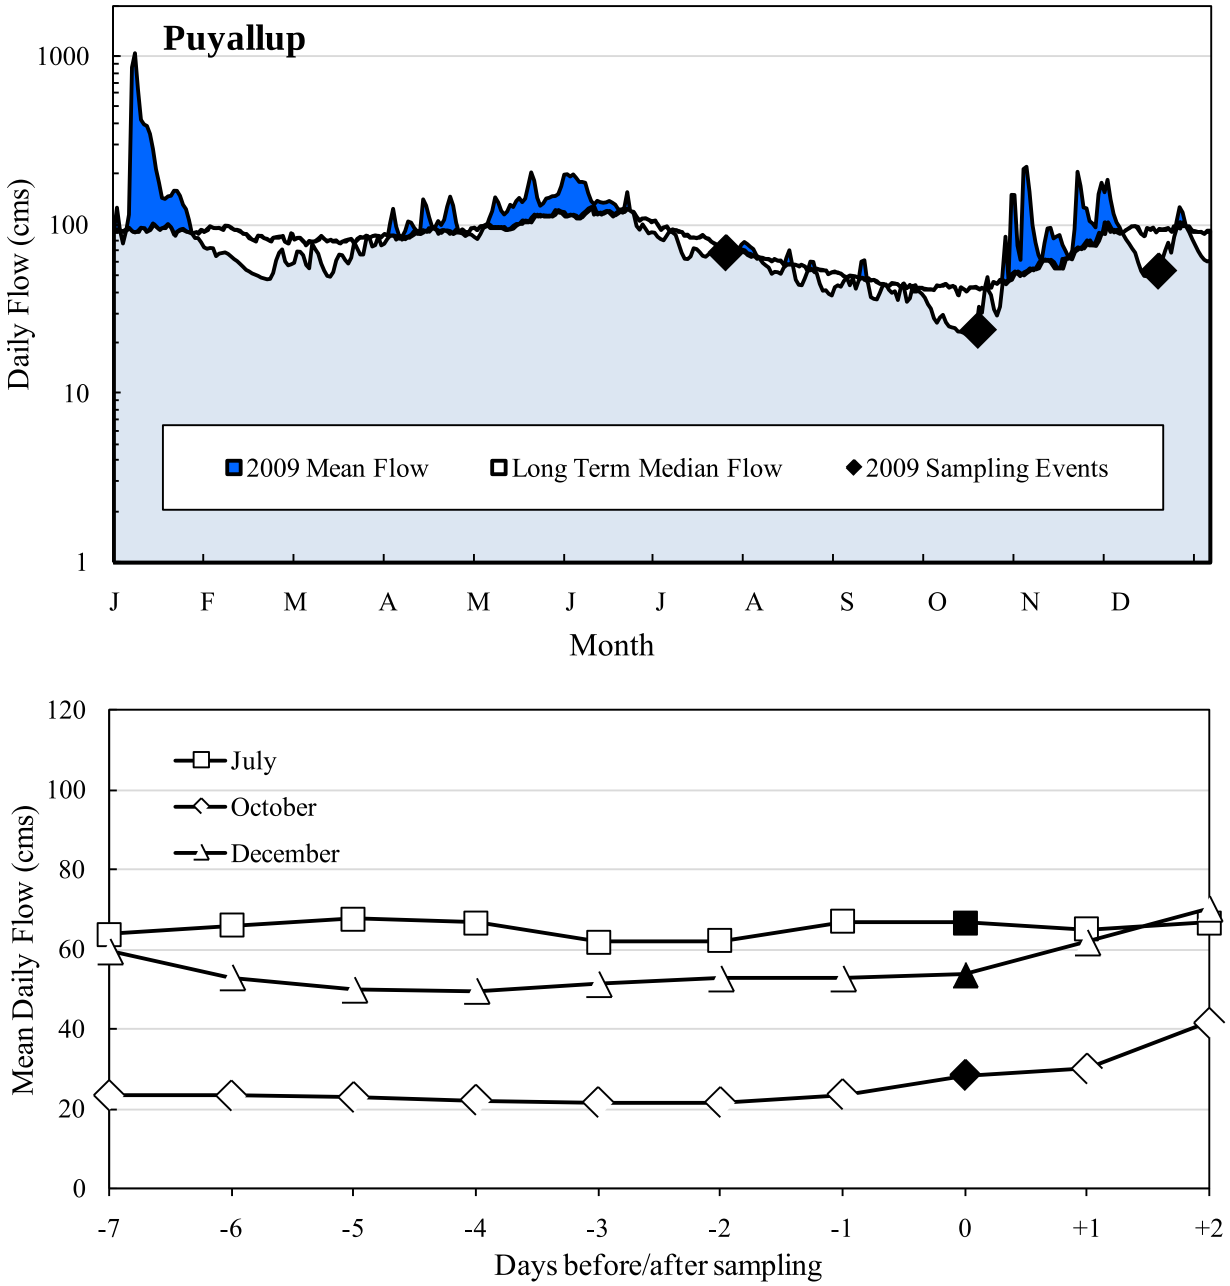

Figure 18. Puyallup River daily flows.

- Upper: Sampling events are shown as black diamonds on the hydrograph for mean daily flows during 2009 (shaded beneath). Relative to long-term median flows, periods of high flow appear as the darkest areas and periods of low flow appear under the white areas.
- Lower: Mean daily flows prior to, during, and after each sampling event (solid black symbols).

Sampling in July was during late seasonal runoff from melting Mt. Rainier glaciers. October sampling was during runoff from 1.33" of rainfall that fell upstream the previous day. The December sampling occurred under winter baseflow conditions, just prior to a runoff event.

Table 11 summarizes the mean daily flows for each river and sampling date, either measured or predicted from gaging station records. Base or runoff-related flow designations are also shown.

Flow conditions did not hinder sampling efforts except as follows. Swift currents made collecting water samples and pumping SPM from the desired depth (0.6 times the maximum mid-channel depth) more difficult. Sampling the Stillaguamish River in December was also complicated by the constant presence of disintegrating ice floes.

Table 11. Summary of field sampling activities for five major rivers discharging to Puget Sound.

River	Date	Mean Daily Flow [1]		Flow Type
		cfs	cms	
Summer – Sampling Event 1				
Skagit	7/21/09	10,500	297	Base

* *Nutrients* include total nitrogen (TN), nitrate+nitrite, ammonia, total phosphorus, and ortho-phosphate (5 analyses per sample).

** 5 analyses (arsenic, cadmium, copper, lead, and zinc) per sample.

Conventional Parameters and Nutrients

Table 13 summarizes results for conventional parameters and nutrients. TSS ranged from a minimum 2.6 mg/L to a maximum 233 mg/L, and averaged 38 mg/L. The greatest concentrations of TSS in four rivers were associated with fall or winter runoff events (Figure 19). The maximum TSS in the Puyallup River (233 mg/L), measured in July, was from seasonal melting of glaciers. The overall mean TSS decreased to 24 mg/L when this value was excluded.

TOC and DOC averaged 1.3 mg/L and 1.5 mg/L, respectively. DOC exceeded TOC in 10 of 15 samples, averaging 115% of TOC. Organic carbon was consistently lowest in the summer. Concentrations were greatest in fall or winter and were usually associated with runoff events or increased TSS (Figure 20).

The mean concentration of total nitrogen (TN), 0.285 mg/L, was 85% dissolved inorganic forms. Concentrations of nitrate+nitrite nitrogen averaged about five times those of ammonia nitrogen. TN in all of the rivers was lower in the summer than in fall and winter (Figure 21), with the Skagit River containing the lowest concentrations. Concentrations of total phosphorus (TP) were associated with TSS, indicating that elevated TP concentrations would be expected in rivers carrying a high load of solids. Ortho-phosphate averaged 41% of TP. Ortho-P concentrations were greatest in the Puyallup River and least in the Skagit River (Figure 22).

Table 13. Summary statistics for conventional parameters and nutrients in river water.

Parameter	Times Detected	Percent Detected	Min.	25th %ile	Median	Mean	CV	75th %ile	Max.
Conventional Parameters (mg/L)									
TSS	15	100	2.6	5.1	11.9	38.0*	1.56	51.2	233
TOC	15	100	0.5	0.6	1.1	1.33	0.66	2.0	3.3
DOC	15	100	0.6	0.8	1.0	1.47	0.65	2.0	4.0
Nutrients (mg/L)									
Total Nitrogen (TN)	15	100	0.057	0.140	0.321	0.285	0.62	0.386	0.656
Nitrite (NO_2^-) + Nitrate (NO_3^-) Nitrogen	15	100	0.045	0.087	0.276	0.221	0.65	0.307	0.544
Ammonia Nitrogen	10	67	0.007	0.010	0.025	0.041	1.17	0.046	0.162

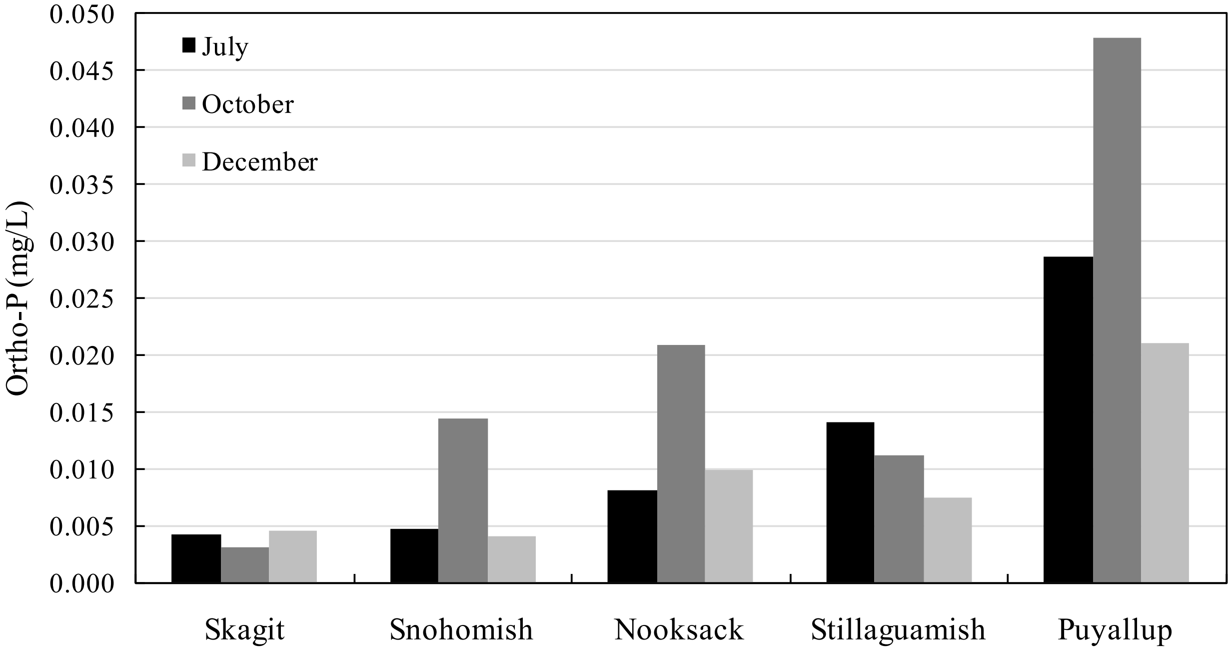

Figure 22. Ortho-phosphate near the mouths of major rivers discharging to Puget Sound in 2009.

Metals

Table 14 summarizes results for hardness, as well as for total recoverable and dissolved fractions of the five metals. The mean hardness for all water samples was 27.3 mg/L (as $CaCO_3$), and the low coefficient of variation (0.41) indicated relatively little variability between rivers. Mean values for total metal concentrations, ranked from high to low, were 6.41 µg/L zinc, 2.99 µg/L copper, 0.75 µg/L arsenic, 0.44 µg/L lead, and 0.012 µg/L cadmium. High total metal concentrations were associated with high TSS that usually accompanied runoff-related flows. This is shown for total copper and total zinc in Figures 23-24. Seasonal variability in concentrations of total arsenic, cadmium, and lead was similar.

The dissolved fraction generally made up the majority of total arsenic and cadmium concentrations. But the majority of copper, lead, and zinc was in particulate form. The relative contribution of particulate metals (total concentration minus dissolved concentration) tended to increase with TSS.

Table 14. Summary statistics for hardness and five metals measured in river water samples.

Parameter	Times Detected	Percent Detected	Min.	25th %ile	Median	Mean	CV	75th %ile	Max.

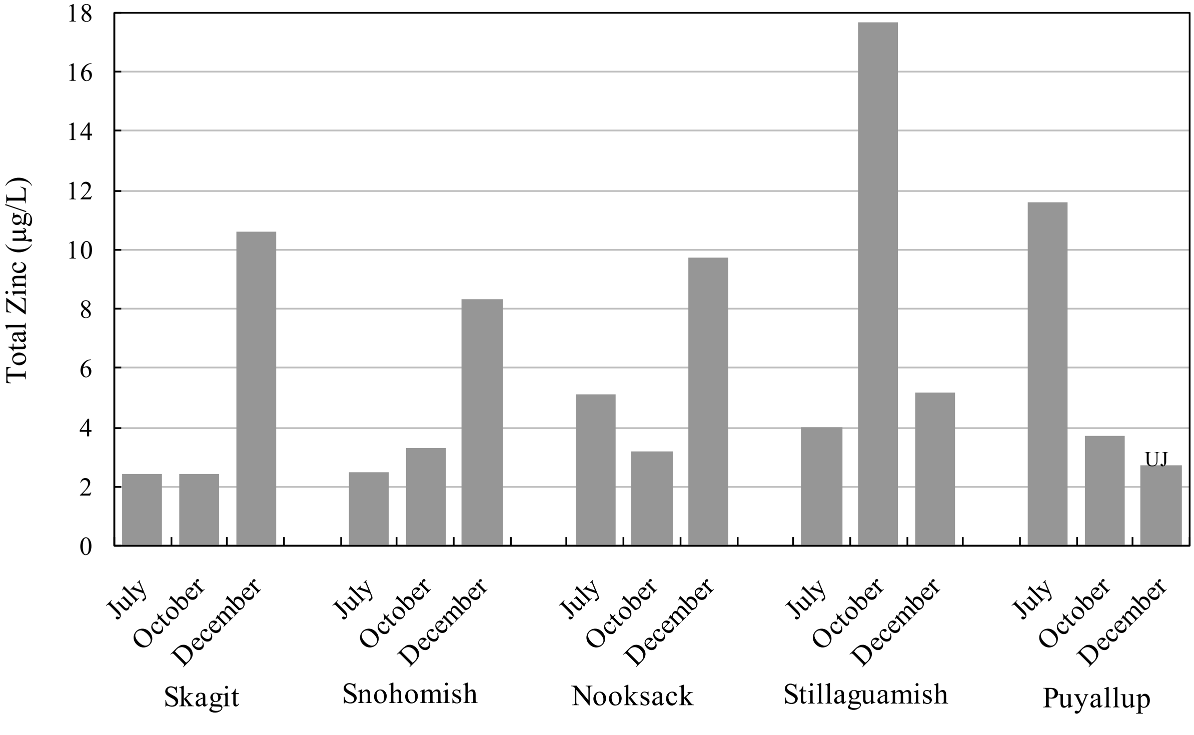

Figure 24. Total zinc near the mouths of major rivers discharging to Puget Sound in 2009.

Organics

Concentrations of 55 BNA, 22 PAH, and 32 chlorinated pesticide compounds were seldom detected. When detected, the compounds were often present in the corresponding method blank at a similar concentration. Table 15 summarizes results for these groups of organics. It shows that only five of the more than 100 compounds in these classes were detected in two or more samples:

- 4-methylphenol (various origins).
- Cholesterol (a biogenic steroid sometimes used as a marker for fecal material).
- Triethyl citrate (food additive, ingredient in cosmetics and pharmaceuticals, plasticizer).
- 1-methyl naphthalene (an occasional pesticide).
- Retene (a biomarker for higher order plants).

Measured concentrations were in the 0.0009 - 0.110 µg/L range. If one-half the RL was used to represent concentrations in nondetect samples, total PAH concentrations were in the range of 0.076 - 0.106 µg/L, and averaged 0.084 µg/L. The subset of seven carcinogenic PAH (cPAH) compounds [12] had toxic equivalent (TEQ) concentrations in the range of 0.009 - 0.014 µg/L, and a mean TEQ of 0.011 µg/L.

Table 16 summarizes results for petroleum-related compounds, total PCBs, and total PBDEs. Petroleum-related compounds were seldom detected. Oil and grease was detected in 40% of the samples (6 of 15), with MDLs ranging from 0.5 to 1.5 mg/L. Measured concentrations ranged from 0.9 - 2.8 mg/L, and averaged 1.6 mg/L. TPH-D or TPH-G were never detected despite MDLs of approximately 0.006 mg/L and 0.014 mg/L, respectively.

PCBs were present in all five rivers and 15 river water samples, with maximum concentrations recorded in three rivers during the fall (Figure 25). Total concentrations were always low: 2.6 - 59 pg/L. After assigning a "UJ" to congener concentrations less than three times (< 3X) those in corresponding method blanks, the average concentration of total PCBs was 16.3 pg/L [13]. The congeners detected most frequently were in the tri-chlorinated, tetra-chlorinated, and penta-chlorinated homolog groups. Congeners in the tri-chlorinated through hexa-chlorinated homolog groups made up an average 84% of total PCBs.

In contrast, PBDEs were detected in less than half of the river water samples. Total concentrations averaged 55.6 pg/L, but results were highly variable (CV = 1.67) within a range of 10.9 - 265 pg/L. PBDEs were detected in all five rivers during the summer, only in the Nooksack and Puyallup Rivers during the fall, and in no river during the winter. Congeners belonging to the tri-brominated and penta-brominated homolog groups were detected most frequently.

---

[12] Carcinogenic PAH compounds (cPAH) include benzo(a)pyrene, benzo(a)anthracene, benzo(b)fluoranthene, benzo(k)fluoranthene, chrysene, dibenzo(a,h)anthracene, and indeno(1,2,3-c,d)pyrene

[13] If tentatively identified congeners were included, the mean concentration increased 55% to 25.3 pg/L.

Table 16. Summary statistics for petroleum-related compounds, PCBs, and PBDEs in river waters.

Congener summation rules are described in Appendix D. Congeners in each homolog group are listed in Appendix E (Tables E-20 to E-22, and E-24). Concentrations of tentatively-identified congeners (results qualified as N or NJ) were not included in homolog or overall totals. Note: Homolog concentrations in a single sample can be summed to equal the total concentration in that sample, but summing the homolog statistics will not result in the total concentration statistics.

***** The mean concentration of total PCBs in river water would be approximately 60% higher if concentrations of tentatively-identified congeners (“N” and “NJ”) were also included.

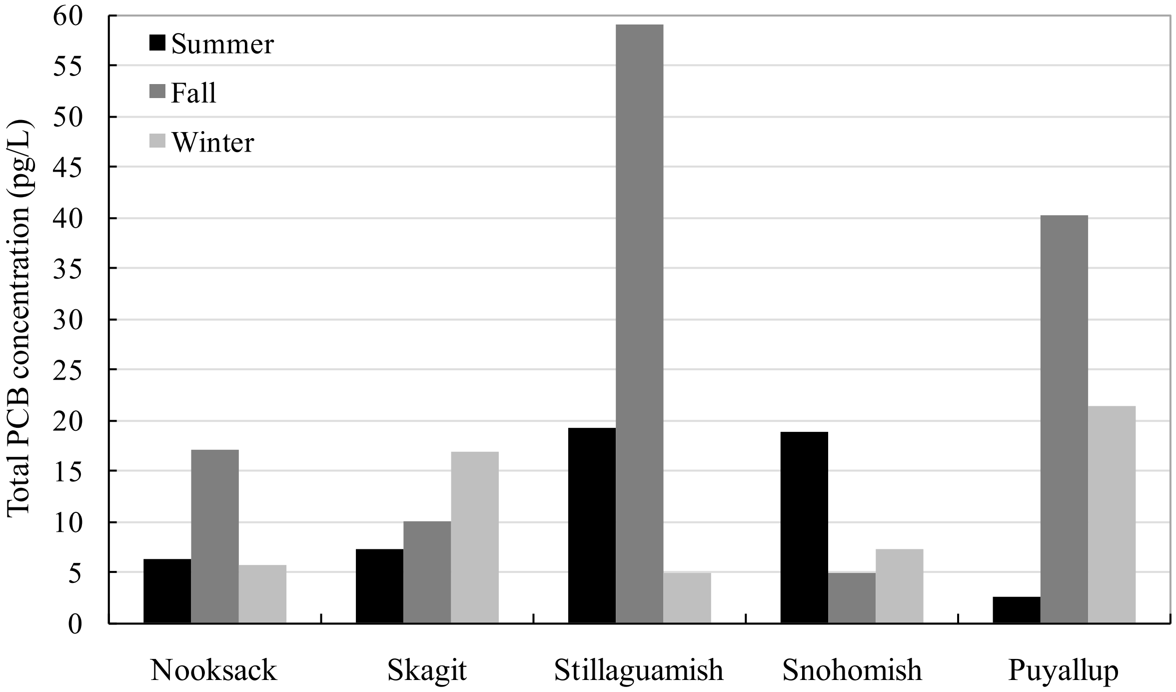

Figure 25. Total PCBs near the mouths of major rivers discharging to Puget Sound in 2009.

River SPM

Collecting suspended solids from river water using pump-and-centrifuge methods required an average of 18 hours per site (Table 17), not including setup and demobilization time. River water was usually pumped at rates of 10 - 13 liters (2.6 - 3.4 gallons) per minute. At these pump rates, SPM retention efficiencies were highly correlated with inflowing TSS concentrations ($r^2 = 0.95$), and the mean efficiency was 72%. Five samples of suspended solids were collected by the centrifuges, one from each river. Sample mass ranged from 153 to 960 wet grams, which was equivalent to approximately 67 to 660 dry grams.

Table 17. Collection of suspended solids from five rivers by continuous-flow centrifuges.

River	Start Date	End Date	Average Pump Rate		Pump Time (hrs)	Volume Pumped (liters)	Inflow TSS (mg/L)	Outflow TSS (mg/L)	Estimated Efficiency (%)
			gpm	L/hr					
Skagit	12/16/09	12/17/09	2.31	524	17.13	8,970	65.8	22.1	66

Conventional Parameters

Table 18 summarizes results for the five samples of suspended river solids. Suspended particulate matter contained 0.36 - 1.88% TOC (mean = 1.2 %).

Metals

Mean concentrations of total metals were rank ordered as were whole water samples: 68.7 mg/kg zinc, 36.5 mg/Kg copper, 7.79 mg/Kg arsenic, 5.86 mg/Kg lead, and 0.16 mg/Kg cadmium.

Organics

BNAs were rarely detected. Only cholesterol, its degradate (3-beta coprostanol), and BEHP were found in all samples. TPH-D, analyzed in BNA extracts, was not detected. Unlike whole water, 16 of 22 PAH compounds were detected in more than one-half the SPM samples. Individual PAHs averaged less than 20 µg/Kg, except for retene (mean = 230 µg/Kg). Mean concentrations of high and low molecular weight PAHs were similar. Total PAHs, excluding retene, ranged from 32 - 210 µg/Kg and averaged 119 µg/Kg. Pesticides were virtually absent from particulates collected this time of year (winter). PCBs were measured in all samples, as were PBDEs. The average concentrations of total PCBs and total PBDEs were 408 ng/Kg and 1680 ng/Kg, respectively.

Table 18. Summary statistics for parameters measured in SPM collected from five rivers.

Discussion

Marine Water Column

Comparison with Historical Data

Serdar (2008) conducted a review of readily available data collected since 1995 on selected toxic chemicals in Puget Sound and the boundary waters of the Straits of Juan de Fuca and Georgia. Little existing data were found, especially for organic compounds. Despite the paucity of existing data for the region, the information compiled provides an indication of the range of concentrations that might be expected for each target chemical. Table 19 presents a comparison of results from the present 2009-10 study to existing data.

While data collected for the present study were in good agreement with concentration ranges from historical data (with few exceptions), the 2009-10 results yielded new insights into the variability and range of ambient concentrations:

- Total and dissolved measurements of arsenic, cadmium, and copper agreed well with previously reported values, but also revealed slightly broader ranges of ambient concentrations. Arsenic and cadmium results tended to be somewhat higher than comparable data, while copper concentrations were generally lower than historical values.
- Previously reported total lead concentrations for the region were at the low end of the range of 2009-10 project results, which tended to be markedly higher and more variable. Nearly half of the project measurements were above the highest historical concentration.
- Total zinc concentrations were in good agreement with previous measurements. The exception was the maximum concentration of 7.44 mg/L measured in the deep water sample collected from Hood Canal in July 2009. This was five times greater than the concentration measured in any other sample and may represent the high end of the concentration range for total zinc in marine ambient waters [14].
- The mean concentration of total PCBs in regional marine waters (26.3 pg/L) and for boundary waters (20.4 pg/L) were lower than the mean concentrations reported by Dangerfield et al. (2007) for surface and deep Canadian waters. The diversity of sites and multiple depths sampled for the present study may provide a better indication of the variability in total PCBs concentrations that can be expected in regional waters.
- Total PBDE concentrations spanned a wide range throughout the region. Previously available data were limited and provided a low estimate of typical ambient concentrations. Current project data, however, exposed marked variability in total PBDEs. Concentrations were below detection limits in more than 75% of project samples, but detected total PBDE concentrations were often at least 10 times greater than those reported by Dangerfield et al. (2007). There was no evidence from QC data that the samples had been contaminated. One explanation for the dissimilar results may be that the discrete samples from the present study

---

[14] It was noted that concentrations of most metals in Hood Canal SPM were also greater than those measured in SPM collected from traps deployed in the more developed South Sound region.

captured heterogeneous concentrations of PBDEs that could be diluted when collecting time-integrated pump samples as was done by Dangerfield et al.

- Organic carbon concentrations throughout Puget Sound and the oceanic boundary waters were very similar to those reported by Johannessen et al. (2008).
    - Results of the present study indicate that the organic carbon concentration records taken from Ecology's EIM database and used by Pelletier and Mohamedali (2009) were above typical ambient concentrations. Past methods used to collect and handle seawater samples for analysis of organic carbon were likely susceptible to contamination. The rigorous sampling procedures used throughout the present study (see Appendix C) appeared to be more successful at preventing contamination.
    - A single high POC result (1.78 mg/L) fell outside the range of concentrations observed by Johannessen et al. (2008; maximum observed POC of 0.36 mg/L). However this result is not unrealistic and may be representative of POC concentrations associated with elevated productivity, as there was high TSS and a strong phytoplankton bloom (revealed by CTD fluorescence profile) at the time of sample collection.
    - The median concentration of TOC in deep waters entering Puget Sound (0.73 mg//L) was greater than the mean of 0.53 mg/L TOC reported for deep waters further west in the Strait of Juan de Fuca (Johannessen et al., 2008) and for typical mid-ocean concentrations (0.5 mg/L; J. Sharp, pers. comm.).

Table 19. Marine water column results compared to previously reported concentration ranges.

Patterns and Relationships

The nonparametric Kruskal Wallis Test and Test of Medians were used to determine the significance of differences in parameter concentrations. These tests were used because chemical concentrations seldom reflected a normal distribution and only some log-normal distributions became normal when transformed (Appendix J, Table J-1). Test results provided in Table J-2 showed that concentrations of some chemicals were statistically different between regions, seasons, and depth layers.

- **Regional differences**. Comparing all sample results from the three ocean boundary sites (from both depths and all seasons) to those from the four Puget Sound basin sites revealed:
    - Mean concentrations of DOC, TOC, total and dissolved copper, and total PCBs were significantly greater in Puget Sound samples than in ocean boundary waters.
    - Mean concentrations of total and dissolved cadmium in ocean boundary waters were significantly greater than in the basins of Puget Sound.

- **Seasonal differences**. Comparisons of the seasonal mean chemical concentrations (measured at all stations and depths) yielded the following:
    - TSS, total arsenic, and total and dissolved copper concentrations were significantly lower in October than in July or January.
    - Concentrations of all forms of organic carbon were significantly higher in October 2009 than in January 2010.
    - Total PCB concentrations were greatest in the fall.

- **Water column depth layer differences.** Results from all stations and seasons were pooled by collection depth for comparison of surface and deep layer concentrations. Samples were additionally separated by region to test for layer differences within the boundary waters or the Puget Sound basin waters.
    - For the entire sampling area, mean concentrations of total and dissolved arsenic and total lead were significantly lower in the surface layer than in the deep layer.
    - In the Puget Sound basins, dissolved arsenic had significantly greater mean concentrations in the deep layer compared to the surface layer.
    - In ocean boundary waters, mean concentrations of dissolved arsenic, total and dissolved cadmium, and total lead in the deep layer were significantly greater than those in the surface layer.
    - For ocean boundary waters, the mean DOC concentration in the surface layer was significantly greater than the mean DOC in the deep layer.
    - Mean concentrations of total PCBs were significantly lower in the surface layer of ocean boundary waters, Puget Sound basins, and all locations combined than in the deep layer (Figure 26).

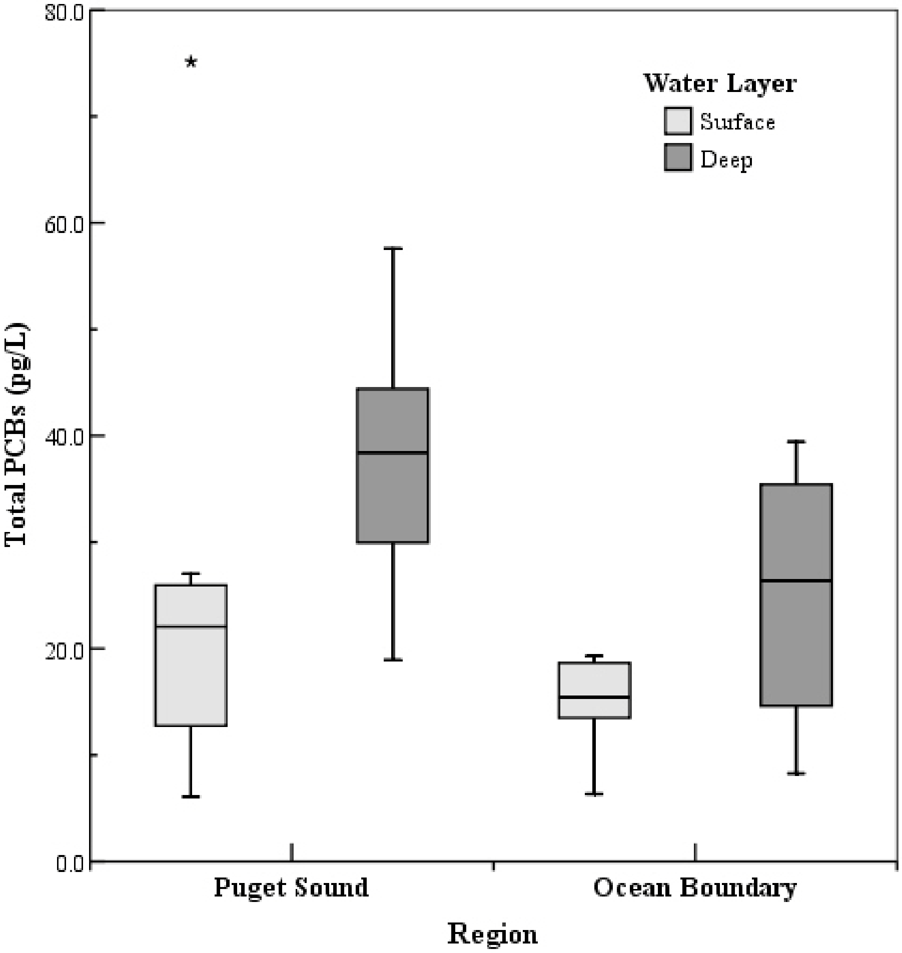

Figure 26. Total PCB concentrations in surface and deep marine water column samples.

Spearman rank correlation analysis was conducted to identify relationships between different chemicals. Results are presented in Appendix J, Table J-3. Significant relationships included:

- Suspended solids were negatively correlated with organic carbon. Both dissolved and particulate forms of organic carbon tended to decrease with increasing TSS.
- Organic carbon was negatively correlated with total and dissolved forms of arsenic and cadmium. When DOC (the main fraction of TOC) was relatively high, concentrations of these metals were low.
- Concentrations of most metals species were positively correlated.
- Total PCBs appeared linked to the presence of particles, as indicated by positive correlations with TSS.
- Total PCB concentrations were negatively correlated with TOC, and its main constituent DOC, in water column samples. (There was no correlation between PCBs and POC.)
- There was no apparent relationship between concentrations of PBDEs and other parameters.

Of the spatial patterns, temporal trends, and parameter relationships identified through statistical analyses, an interesting discovery was that total PCB concentrations in the deep waters were significantly higher than in the surface waters. This was true for all samples but also for the four Puget Sound basin sites and the three ocean boundary water sites separately (Figure 26). This finding was somewhat counterintuitive, as major sources of PCBs were expected to be surface inputs from urban-industrial centers (e.g., stormwater, surface runoff, atmospheric deposition). PCBs from land-based sources may have diminished by the time they reached the mid-basin and ocean boundary sampling sites because:

- Total PCB concentrations derived from land-based sources are diluted by Puget Sound surface waters containing lower PCB concentrations.
- Suspended, particle-bound PCBs settle through the water column into deeper waters.
- Total PCBs are transported downslope from the nearshore environment because of bathymetry- or density-driven focusing processes.

The significant positive correlation between total PCBs and TSS (Table J-3) suggests that sedimentation and sediment focusing contribute to total PCB concentrations in deep waters greater than those in surface waters.

Ocean Exchange

One objective of the present 2009-10 study was to measure concentrations of toxic chemicals in ocean boundary waters. These are generally considered to be near the west entrance to the Strait of Juan de Fuca. However, models of Puget Sound circulation and transport consider the north end of Admiralty Inlet to be the main seaward boundary (Pelletier and Mohamedali, 2009; Babson et al., 2006). This is where higher salinity and density deep waters flow *into* Puget Sound, and lower salinity and density surface waters flow *out of* the Sound. Accordingly, water column samples were collected from sites in the Strait of Juan de Fuca and Haro Strait (Figure 1) where deep water chemistry better represents that of water entering Puget Sound.

Samples were collected from central locations in four Puget Sound basins (Figure 1), but only results from the Main, Whidbey, and Hood Canal basin sites were used to represent water flowing out of Puget Sound for ocean exchange calculations [15]**.** Chemical concentrations measured in these samples were weighted in proportion to predicted flows from each basin into Admiralty Inlet and used to represent concentrations that exit Puget Sound [16]. To represent chemical concentrations in water leaving Puget Sound through Deception Pass (near Anacortes, Washington), Whidbey Basin surface water sample results were used.

The direction of net exchange with the ocean (ocean exchange) for different chemicals was evaluated using estimates of annual mass transport into and out of Puget Sound. A range of annual mass transport was calculated using 25th and 75th percentile chemical concentrations.

---

[15] Results for Strait of Juan de Fuca and Haro Strait surface samples were not used to represent water flowing out of Puget Sound because they may have been influenced by sources outside of Puget Sound (Fraser River water).

[16] The Box Model predicted that Main, Whidbey, and Hood Canal basins contribute 56.4%, 27.4%, and 16.2% of the flow into Admiralty Inlet, respectively.

These were multiplied by Box Model-predicted flows into and out of Puget Sound across the two seaward boundaries:

- The long-term median flow of deep water *into* Puget Sound through Admiralty Inlet was -18,555 cms (-5.85 x 10^{11} m^3/year).
- The long-term median flow of surface water *out of* Puget Sound was 20,300 cms (6.40 x 10^{11} m^3/year), with 18,771 cms flowing out through Admiralty Inlet and 1,529 cms flowing out through Deception Pass.

Results of ocean exchange calculations are presented in Tables 20-22. Concentration ranges for TSS, TOC, metals, and organic compounds measured in deep ocean boundary waters are shown in Table 20. The table also presents probable ranges for annual chemical mass transport into Puget Sound. Table 21 shows concentrations of the same chemicals in Puget Sound surface waters, along with ranges for chemical mass transport out of Puget Sound. Table 22 combines results from the previous tables to yield estimates of net chemical exchange between Puget Sound and the ocean boundary waters. Example calculations follow.

The procedure for calculating net exchange of total arsenic, based on median concentrations, is described here. First, the mass of arsenic imported into Puget Sound was calculated by multiplying the median deep boundary water concentration (1.49 µg/L = 1.49 mg/m^3) by the annual incoming volume of water (-5.85 x 10^{11} m^3/year). This resulted in an estimate of -8.72 x 10^{11} mg/year, equivalent to -872 mT/year (see Table 20). Second, the mass of total arsenic exported from Puget Sound through Admiralty Inlet was calculated as the flow-weighted median surface water concentration of the three most northern Puget Sound stations times the outflow volume. The mass exported through Deception Pass was calculated as the median surface water concentration measured at the Whidbey Basin site times the Deception Pass outflow volume. The total exported mass was estimated to be 895 mT/year (Table 21). Finally, the net exchange based on median concentrations, 23 mT/year, was the sum of the exported and imported masses (see Table 22).

The net ocean exchange is positive - out of Puget Sound - for most chemicals. This assumes that the chemical concentrations measured in marine water column samples for the present study adequately represent those transported into and out of the Sound.

Estimates of net exchange predicted that copper and organic carbon were exported from Puget Sound. The export resulted from concentration differentials combined with the net flow of water out of the Sound. For copper, mean and median concentrations in deep boundary waters were not significantly different from those in surface waters leaving the Sound [17]. Nevertheless, the flow-weighted median total copper concentration exiting Puget Sound (0.40 µg/L) was 43% greater than the median value for incoming boundary deep waters (0.28 µg/L). Factors contributing to the concentration differential included:

- Relatively high copper concentrations in surface runoff (the median concentration of total copper in 15 river water samples was 1.81 µg/L).
- Formation of copper complexes that remain dissolved in surface waters.

---

[17] Kruskal Wallis (means), p = 0.18; Test of Medians, p = 0.64.

TOC concentrations in surface waters of Puget Sound were significantly greater than concentrations in deep waters near the ocean boundary [18]. The flow-weighted median TOC concentration in surface waters leaving Puget Sound (1.17 mg/L) was 60% greater than the median deep water concentration near the ocean boundary (0.73 mg/L). The difference was likely due to:

- Organic carbon loading from surface runoff (rivers).
- Primary productivity in the euphotic zone (especially when the water column was stratified).
- Decomposition of organic carbon in deep waters.

Table 22 shows that TSS, arsenic, zinc, and PAHs were probably exported from Puget Sound. For these parameters, there was no more than a 13% difference between concentrations in surface waters leaving and concentrations in deep boundary waters entering Puget Sound [19]. Therefore, the net flow of water out of Puget Sound played more of a role in the export of these chemicals than did concentration differences. These chemicals could have been imported into Puget Sound if 75th percentile concentrations were used to represent inflows and 25th percentile concentrations represented outflows.

The negative net exchange values in Table 22 indicated that cadmium and lead were imported into Puget Sound. For cadmium, the median concentration in deep boundary waters (0.92 µg/L) was significantly greater than the median for surface waters leaving Puget Sound (0.80 µg/L) [20]. As in the case of copper, concentrations of lead were not significantly different for inflow and outflow waters. However, the median concentration in deep boundary waters (0.109 µg/L total lead) was sufficiently higher than and the flow-weighted median concentration in surface waters leaving Puget Sound (0.065 µg/L) to cause a net import. Only if the 75th percentile concentration of total lead was used to represent outflows and the 25th percentile concentration represented inflows was export indicated.

The direction of net exchange for total PCBs and total PBDEs between ocean boundary waters and Puget Sound was unclear based on results of the present study. Combinations of annual mass transport into or out of Puget Sound indicated these chemicals could be imported or exported (Table 22). Net ocean exchange for total PCBs could range from an export of approximately 2-12 kg/yr to an import of approximately 1-11 kg/yr. Total PBDE concentrations were detected in four deep boundary water samples and two surface water samples. Variable concentrations (CV = 2) led to a large interquartile range for PBDE concentrations and net annual ocean exchange estimates that indicated total PBDEs might be exported or imported. Total PCBs and total PBDEs were likely exported because concentrations in deep boundary waters entering and surface waters leaving Puget Sound were not significantly different [21] and net flow of water is out of Puget Sound. Any net import of total PCBs or total PBDEs into Puget Sound would need to be confirmed by means of future sampling and analysis. If

---

[18] Kruskal Wallis and Test of Medians, $p<0.01$.

[19] Test of Medians showed no significant difference between inflow and outflow concentrations for these chemicals.

[20] Test of Medians, $p<0.02$. The mean concentration of total cadmium in deep boundary waters was also significantly greater than the mean concentration in Puget Sound surface layer waters (Kruskal Wallis, $p<0.02$).

[21] Kruskal Wallis test results for chemistry of deep boundary water vs. surface Puget Sound waters: $p<0.27$ for total PCBs and $p<0.64$ for total PBDEs.

confirmed, and caused by a substantial concentration differential, then the explanation might involve:

- Adsorption of total PCBs and PBDEs to suspended particles in surface runoff (rivers) entering the Sound.
- Dilution and settling of such suspended particles into the deep waters of major basins before being transported beyond ocean boundaries.
- Ongoing sources of PCBs and PBDEs contributing to the deep boundary waters entering Admiralty Inlet.

To summarize, ranges of values for net ocean exchange of various chemicals were presented in this section (Table 22). The ranges were derived from different estimates of annual chemical mass transport into and out of Puget Sound. Each mass transport estimate was based on two variables – annual flow and chemical concentration. Annual flows across the two boundaries between the Sound and the ocean (Admiralty Inlet and Deception Pass) were long-term median values predicted by the Puget Sound Toxics Box Model [22]. Concentration ranges were calculated from the limited chemical results of the present study.

As such, this evaluation of net ocean exchange was exploratory in nature. Furthermore, this evaluation did not attempt to address transport and fate processes within Puget Sound (e.g., chemical partitioning, horizontal transport, sedimentation and resuspension, burial, volatilization, and biological degradation) that are better examined by modeling.

---

[22] Calculations did not incorporate interannual variability in flows.

Table 20. Chemical concentrations in deep ocean boundary waters and estimates of annual mass transport *into* Puget Sound.

Percentile concentrations were derived from results for Haro Strait, SJdF North, and SJdF Sill stations.
Annual mass transport estimates were based on the concentrations shown and the predicted median annual flow of deep water into Admiralty Inlet for 2000-2050 (see text). Flows and transports into the Sound are shown as negative values.

[1] Summary statistics for concentrations of dissolved lead and zinc are not presented here. Dissolved concentrations often exceeded total concentrations such that distinguishing valid results from ones that reflected field or laboratory contamination was difficult.

Abbreviations as in Table 20.

Sedimentation Rates for Toxics

Sediment traps deployed in Hood Canal from October 2009 through January 2010 collected marine particulates from that basin's deep layer. Archived mid-water solids from the Case and Carr Inlets, composited from material collected from March to June 2008 (Norton, 2009), were resurrected for comparison.

Sedimentation rates (g/cm^2/yr) were calculated for both locations by dividing the total dry mass of solids collected by the surface area of the traps, and by the duration of deployment. Since resuspended particulates could potentially be included in the trap material, these values should be considered estimates of *gross* sedimentation. Mass accumulation rates (mass/cm^2/yr; also called "downward flux") for each parameter were determined by multiplying the measured concentration by the sedimentation rate.

Sedimentation rates from the present study are summarized in relation to historical rates for other areas of Puget Sound in Table 23. The sedimentation rate in the deep waters of Hood Canal was comparable to rates measured by Norton (2009) in the Case+Carr Inlets. Both rates were markedly lower than rates typical of more urban embayments.

Table 23. Gross sedimentation rates for various areas of Puget Sound.

Source	Location	Mean Sedimentation Rate (dry g/cm^2/yr)
Present Study (2009-10)	Hood Canal	0.2
Present Study; Norton, 2009	Carr+Case Inlets	0.3
Norton, 2009	Eld Inlet	1.6
Norton, 2009	Budd Inlet	1.0
Norton and Boatman, 1998	Inner Budd Inlet	1.4
Norton, 1996	Inner Commencement Bay	1.5
Norton and Michelson, 1995	Elliott Bay Waterfront	0.7

Analyses conducted on the Hood Canal solids and on the archived Case+Carr Inlet material from Norton (2009) allowed estimation of the downward flux for various parameters. The measured concentrations and calculated mass accumulation rates are presented in Table 24.

Downward flux of organic carbon was low at both sites relative to rates found in more urban embayments. Norton (2009) measured average TOC accumulation rates of 0.048 and 0.033 g/cm^2/yr in the Eld and Budd Inlets, while the Case+Carr Inlet solids averaged 0.011 g/cm^2/yr. The Hood Canal TOC accumulation rate from the present study was even lower at 0.007 g/cm^2/yr. Likely contributing factors included distance from anthropogenic inputs, lower biological productivity during the late fall and early winter period of deployment, and depth of collection (below the surface mixed layer).

Table 24. Summary of mass accumulation rates for solids, TOC, metals, PCBs, and PBDEs.

All concentrations reported on a dry weight basis.

Parameter	Hood Canal		Case+Carr Inlets	
	Concentration	Mass Accumulation Rate ($g/m^2/yr$)	Concentration	Mass Accumulation Rate ($g/m^2/yr$)
Solids (g)	7.9	2,400	20.7*	3,440
TOC (%)	2.75	66	4.47*	154
As (mg/Kg)	7.53	0.018	5.72	0.020
Cd (mg/Kg)	0.87	0.002	1.04	0.004
Cu (mg/Kg)	82.0	0.197	18.5	0.064
Pb (mg/Kg)	9.13	0.022	8.78	0.030
Zn (mg/Kg)	90.0	0.217	72.0	0.248
PCBs (ng/Kg)	2,970	7.1E-6	9,850	33.9E-6
PBDEs (ng/Kg)	1,580	3.8E-6	1,060	3.6E-6

* Values from Norton (2009)

Metals concentrations in Hood Canal particulates were slightly higher than those from the Case+Carr Inlets for four of the five metals analyzed. With the exception of copper, however, mass accumulation rates of all metals were similar at these sites. Hood Canal copper concentrations were more than four times higher than those measured in Case+Carr Inlet SPM, and the resulting mass accumulation rate in Hood Canal was estimated to be three times greater than that of the Case+Carr Inlets.

Total PCB concentrations were markedly higher in SPM from the Case+Carr Inlets than in SPM collected from Hood Canal. This was consistent with expectations, as South Puget Sound is more highly developed and has more potential sources of PCBs than Hood Canal. Mass accumulation rates in the Case+Carr Inlets and Hood Canal were estimated to be 0.0339 and 0.0071 $mg/m^2/yr$, respectively.

Differences in total PBDE concentrations and mass accumulation rates between the two sites were minor. Rates of total PBDE accumulation were estimated to be 0.0038 and 0.0036 $Kg/m^2/yr$ in Hood Canal and Case+Carr Inlets, respectively.

Rivers

Comparison with Historical Data

Average concentrations of TSS, TOC, and nutrients in the five rivers, based on three seasonal samples, were within ranges obtained from EIM data and other studies (Table 25). The mean values were also remarkably similar to historical median or mean values (Appendix I, Table I-4). In general, the same was true for river water hardness and total metal concentrations (Table 26; Appendix I, Table I-5).

Table 27 compares the concentrations of organic compounds that were measured or estimated for the present 2009-10 study with concentrations reported by other studies. TPH concentrations were never detected. The detection frequency for oil and grease was 40% (6/15), and the measured concentrations ranged from 0.9 - 2.8 mg/L in the five rivers. The mean concentration of 1.6 mg/L changed little when nondetect values were included (1.7 mg/L when ND = ½ RL; 1.2 mg/L when ND = MDL). According to Herrera (2010a), this mean concentration would be observed with reasonable frequency in all land use categories except commercial/industrial.

Possible reasons for the low detection frequency and low mean concentrations included:

- The compounds were not present at the time of sampling (e.g., lost due to volatilization).
- Standard sampling methods failed to collect the surface-most layers most likely to contain compounds less dense than water.
- Current analytical methods could not detect the compounds after the dilution that occurred between points of discharge and sampling locations.

MEL seldom detected PAHs in whole river water samples even with low detection limits. Six of the 15 samples contained concentrations of individual PAHs in the 0.0009 - 0.11 µg/L range. Assuming nondetect concentrations are one-half the RL, total PAH concentrations ranged from 0.076 - 0.11 µg/L. Assuming nondetect concentrations are one-half the MDL, the range was 0.012 - 0.055 µg/L. Using the latter assumption, the range of cPAH concentrations was 0.009 - 0.014 µg/L. This was within the range of cPAH concentrations measured in Lower Green River near Tukwila (<0.001 - 0.040 µg/L; Willston, 2008).

The range of total PCB concentrations measured in the five rivers (2.6 - 59 pg/L) was lower than the range reported for the Green/Duwamish River system (83 - 814 pg/L). It was also lower than most probability-of-exceedance concentrations listed for different land uses in Herrera (2010a). Lower concentrations of toxic organic compounds would generally be expected in the five rivers sampled for the present study than in the Green/Duwamish River system, other areas of commercial/industrial land use, or highway runoff.

Patterns and Relationships

The same graphic and statistical methods used to explore marine water column results were used to examine the river water data obtained from this study. Few differences in mean or median concentrations of the various chemicals could be attributed to different seasons, rivers, or flow regimes. This was expected from such a limited data set. However, some statistically significant relationships were identified. As with the marine water column results, most chemicals measured in river waters were not normally distributed (Appendix J, Table J-4) and the nonparametric Kruskal Wallis Test and Test of Medians were conducted. Results are shown in Appendix J, Tables J-5 and J-6. They show the following significant differences between seasons:

- TSS was lowest during the summer (excluding Puyallup River result).
- TOC and DOC were lowest in the summer (Figure 27a).
- Total nitrogen (TN) and nitrate+nitrite N were lowest during the summer (Figure 27b).
- Ammonia nitrogen concentrations were highest during the fall (not shown).
- Concentrations of total lead and zinc were highest in winter (not shown).

The only chemicals for which the mean concentrations (across all seasons) differed between the five rivers were:

- Ortho-phosphate concentrations were highest in the Puyallup River (Figure 28a).
- Hardness was lowest in the Snohomish River and highest in the Nooksack and Puyallup Rivers (not shown).
- Dissolved arsenic concentrations were lowest in the Nooksack River (Figure 28b).

The flow regimes assigned to each seasonal sampling in each river (base or runoff-related in Table 11) were not significant determinants of mean chemical concentrations. This was no doubt due to the limited number of samplings conducted in different systems with high natural variability. Total PCB concentrations were greater during runoff-related events, but the significance level was only $p<0.16$.

Spearman rank-correlations showed significant relationships between many chemical pairings. These are summarized in Appendix J, Table J-6. Total phosphorus (TP) and total metal concentrations were correlated with TSS. The total fractions of the five metals covaried. PCB homologs that were more polar (fewer chlorine atoms) correlated with chemicals such as ortho-phosphate and dissolved metals, while non-polar homologs (more chlorines) sometimes correlated with parameters common in particulate form (TSS, TOC, TN, TP, and total metals).

Loading

Instantaneous mass loading rates for TSS, TOC, total nitrogen, total phosphorus, and total metals for the five rivers were calculated by multiplying the mean daily flows (Table 11) by the chemical concentrations measured on the same date (Appendix G, Table G-1). The results are shown as daily loads in Table 28. Total arsenic daily loads for the three smaller rivers studied here ranged from 0.96 - 19 kg/day. This was similar to the 0.13 - 7.28 kg/day arsenic load associated with SPM from the Green/Duwamish River system (Gries and Sloan, 2009) despite different mean annual flows.

Daily loading rates for petroleum-related compounds, total PCBs, and total PBDEs are presented in Table 29. Rates for oil and grease, TPH-D, and TPH-G were based on nondetect concentrations set at one-half the RL and at the MDL. The range of estimated daily loads for the sum of all petroleum-related compounds was 445 - 94,500 kg. The daily loading of total PCBs from the five rivers ranged from 0.015 - 0.57 g. This was lower than but comparable to the 0.06 - 1.2 g PCBs/ day load associated with SPM measured in the Green/Duwamish River system (Gries and Sloan, 2009). Daily loading of total PBDEs was between 0.11 - 5.6 g (using one-half the single highest RL when no PBDEs were detected). Daily loading was not calculated for BNAs, PAHs, or chlorinated pesticides because of their low frequency of detection.

Much of the variability in the daily loads was due to the wide range in mean daily flows. To reduce the influence of flows, instantaneous loads were also normalized to the area of each watershed above the gaging station where sampling occurred (see Table 2). Summary statistics for daily loading across all rivers and sampling events are presented in Table 30 (not normalized) and Table 31 (area-normalized). These rates of daily loading can be compared to results from ongoing and future studies.

Table 28. Instantaneous loads of conventional parameters, nutrients, and total metals from major rivers discharging to Puget Sound.

Instantaneous loads (kg/day) were calculated using measured concentrations and mean daily flow.

Conclusions

The primary purpose of the present 2009-10 study was to measure toxic chemical concentrations in Puget Sound marine waters, ocean boundary waters (Strait of Juan de Fuca and Haro Strait), and freshwater near the mouths of the five largest rivers discharging to Puget Sound. The concentration data obtained will help identify the largest remaining sources of uncertainty in the Puget Sound Toxics Box Model and the data gaps that still require field studies or analysis.

Marine Water and SPM

Major findings from the marine water column sampling portion of this study include:

- Low concentrations of suspended solids, organic carbon, metals, PCBs, and PBDEs were routinely detected in marine water samples. Chlorinated pesticides, BNAs, and PAHs were rarely or never detected in the same samples. Analytical detection limits were not adequate to detect these organic compounds at sampling sites far removed from sources.
- The range of total PCB concentrations measured for ambient marine waters was 6.1 - 75 pg/L. Average concentrations in the ocean boundary waters (20.4 pg/L) and Puget Sound (30.7 pg/L) were significantly different and both were lower than those previously reported for the Strait of Georgia (42 pg/l) by Canadian researchers (Dangerfield et al., 2007).
- Total PCB concentrations in the deep waters were significantly greater than those in the surface waters. This was true for the ocean boundary waters and Puget Sound. A significant positive relationship between total PCBs and TSS suggested that sedimentation may play a key role in the fate of PCBs in Puget Sound.
- The range of detected total PBDE concentrations in marine waters (51 - 18,700 pg/L) was much wider than the range of total PCB concentrations. Total PBDEs concentrations were often 10 times higher in the present study than concentrations reported by Canadian researchers (Dangerfield et al., 2007) and apparently not related to TSS. No evidence suggested the higher concentrations were due to sample contamination. Potential sources of high PBDE concentrations were not identified.
- Organic carbon concentrations in marine water samples resembled concentrations previously reported for the Strait of Georgia (Johannessen et al., 2008) but were substantially lower than marine water concentration records in Ecology's EIM database.
- Estimates of two-directional transport across Box Model boundaries (Admiralty Inlet and Deception Pass) were calculated from concentrations of toxic chemicals in Puget Sound surface waters and deep ocean boundary waters. Estimates showed that most chemicals were probably exported from Puget Sound. Notable exceptions were cadmium and possibly lead, which appeared to be imported into Puget Sound. This was due to significantly higher concentrations in incoming ocean boundary waters than in the surface waters flowing out of the Sound. The direction of net exchange for total PCBs and total PBDEs at the ocean boundaries could not be determined from data collected.

- Samples of SPM collected by sediment traps moored in Hood Canal and the Case+Carr Inlets contained similar concentrations of organic carbon, metals, and PBDEs. PCB concentrations in Case+Carr SPM were more than three times greater than those in Hood Canal SPM.

River Water and SPM

Major findings from the river water sampling portion of this study include:

- Concentrations of TSS, organic carbon, nutrients, hardness, and metals were within the concentration ranges reported from previous studies by Ecology and other monitoring programs (Inkpen and Embry, 1998; Wise et al., 2007).
- River water samples seldom contained detectable concentrations of petroleum-related compounds, BNAs, PAHs, or chlorinated pesticides. SPM centrifuged from December 2009 and January 2010 contained detectable concentrations of a number of PAHs.
- The mean concentration of total PCBs measured in surface water from the five rivers was 16.3 pg/L. The range of concentrations measured was 2.6 - 59 pg/L. This range is somewhat lower than that measured by King County in the Green/Duwamish Rivers (83 - 814 pg/L). This is likely because land use in the lower watershed of the Green/Duwamish Rivers is more urban and industrial in character than the rivers sampled for this 2009-10 study.
- PBDEs were detected in 7 of the 15 river water samples. Total PBDE concentrations were highly variable ranging from 10.9 - 265 pg/L, with an average of 55.6 pg/L.
- Total PAH concentrations in SPM (excluding retene) ranged from 32 - 210 μg/Kg, with an average of 120 μg/Kg. Concentrations of individual PAHs were <20 μg/Kg, except for retene which averaged 230 μg/Kg.
- Few other organic compounds (BNAs, TPH-D, chlorinated pesticides) were detected in SPM.
- Estimated daily loading of total PCBs for the five rivers ranged from 0.015 - 0.57 g/day.
- Estimated daily loading of total PBDEs for the five rivers ranged from 0.017 - 5.63 g/day.

Notable relationships between parameters include:

- TSS concentrations were significantly correlated with, and explained between 63% and 86% of the variability in, concentrations of total phosphorus and total metals.
- TOC, DOC, total nitrogen, and nitrate+nitrite concentrations were significantly lower during July than during the other two sampling periods.
- Congeners belonging to the more polar PCB homolog groups (those with fewer chlorine atoms) were significantly correlated with many parameters in the dissolved phase (ortho-phosphate and dissolved metals). Congeners in the more highly-chlorinated PCB homologs were significantly correlated with TSS, TOC, and parameters often found in particulate form (total nitrogen and total phosphorus).

Recommendations

The following recommendations pertain to the use of present 2009-10 study results for modeling purposes and for future monitoring programs. In particular, more monitoring is needed to better define the normal range of concentrations for various toxic chemicals in marine and river waters.

- Selected study results should be used to revise input values to the Box Model and to calibrate the model.
- Future sampling should place more emphasis on collection and analysis of suspended particulate matter (SPM) in order to improve frequency of detection for hydrophobic compounds such as PAHs.
- More intensive water column sampling should be conducted near the ocean boundaries (Admiralty Inlet sill and Deception Pass). Samples should be analyzed for a reduced suite of chemicals, with priority given to chemicals exhibiting high variability (PBDEs) in the present study. This would improve the assessment of chemical exchange between ocean boundary waters and Puget Sound.
- Depth-integrated water sampling of large rivers should be conducted with focus on increased sampling frequency, a reduced suite of chemicals, and improved detection limits for organic contaminants. More frequent sampling during all phases of runoff-related events is needed to understand seasonal and other temporal patterns. This would facilitate a better characterization of loading during baseflow conditions and runoff-related events.
- Estimates of petroleum-related compound loadings to Puget Sound should be improved by:
  - Refining sampling methods or developing new methods better suited to capturing such compounds.
  - Refining analytical methods for measuring different petroleum fractions in whole water or other collection media (adsorbent material).
- Standard operating procedures (SOPs) for the collection and analysis of seawater samples for DOC and POC should be revised. For example, all equipment used for sample collection and processing should be made exclusively of glass or lined with Teflon.

Appendix A. Glossary, Acronyms, Abbreviations, and Units of Measurement

Glossary

Ambient: Something commonly found in one's immediate surroundings. In this case, ambient concentrations of toxic chemicals are those within the normal range found in a box within the Puget Sound Toxics Box Model and not influenced by point sources of pollution.

Analyte: Water quality constituent being measured (parameter).

Baseflow: Groundwater discharge. The component of total streamflow that originates from direct groundwater discharges to a stream.

Basin: A drainage area or watershed in which all land and water areas drain or flow toward a central collector such as a stream, river, or lake at a lower elevation.

Biota: Flora (plants) and fauna (animals).

Box Model: The simplest type of model. A box model assumes the object being modeled has the shape of a box and substances inside the box are distributed uniformly. In this case, the Puget Sound Toxics Box Model assumes different basins and water layers have the shape of a box and that chemical concentrations in each box are all the same.

Congener: In chemistry, congeners are related chemicals. For example, polychlorinated biphenyls (PCBs) are a group of 209 related chemicals that are called congeners.

Conventional pollutants: Non-toxic pollutants.

Euphotic zone: The uppermost part of a waterbody that receives enough light to allow photosynthesis to occur.

Geometric mean: A mathematical expression of the central tendency (an average) of multiple sample values. A geometric mean, unlike an arithmetic mean, tends to dampen the effect of very high or low values. The calculation is performed by: (1) taking the nth root of a product of n factors, or (2) taking the antilogarithm of the arithmetic mean of the logarithms of the values.

Harmonic Mean: A second expression of central tendency (average) among multiple values. The calculation takes the reciprocal of the arithmetic mean of the reciprocals. The harmonic mean is commonly used when average rates are calculated. It tends to mitigate the impact of large outlier values but aggravate the impact of small ones.

Homolog: One of several groups of similar organic chemical compounds whose successive members have a regular difference in composition. For example, mono-chlorinated biphenyls compounds contain one chlorine atom and belong to the homolog group, and bi-phenyl compounds containing 2-9 chlorine atoms belong to the other nine homolog groups.

Load(ing): The mass substance (suspended sediment or contaminant) passing by a horizontal or vertical plane per unit time. For example, the metric tons of sediment calculated to be transported downstream of a particular location.

Marine: Of or having to do with an ocean or sea (salt water).

Marine water column: The vertical column of water representing the entire depth of a marine waterbody. For the present 2009-2010 study, water samples were collected from various subsurface depths in the marine water column, not just dipped from the surface.

Nonpoint source: Pollution entering waters of the state from dispersed land-based or water-based activities, including atmospheric deposition, surface water runoff, subsurface or underground sources, or discharges from boats or marine vessels not otherwise regulated under the NPDES program. Generally, any unconfined and diffuse source of contamination.

Nutrient: Substance such as carbon, nitrogen, and phosphorus used by organisms to live and grow. Too many nutrients in the water can promote algal blooms and rob the water of oxygen vital to aquatic organisms.

Ocean boundary waters: Strait of Juan de Fuca and Haro Strait

Ortho-phosphate: The soluble inorganic phosphate ion (PO_4^{3-}) reported as the mass of phosphorus per unit volume (µg P/liter).

Outlier: A number (or observation) that deviates markedly from other numbers in a sample population (group of observations).

Parameter: Water quality constituent being measured (analyte). A physical, chemical, or biological property whose values determine environmental characteristics or behavior.

Particulate: Solid matter, such as a grain of fine sand, small enough to be suspended in a gas or liquid.

Pesticide: Any substance or mixture of substance intended for preventing, destroying, repelling or mitigating any pest. Pests include nuisance microbes, plants, fungus, and animals.

Point source: Sources of pollution that discharge at a specific location from pipes, outfalls, and conveyance channels to a surface water. Examples of point source discharges include municipal wastewater treatment plants, municipal stormwater systems, industrial waste treatment facilities, and construction sites that clear more than 5 acres of land.

Pollution: Contamination, or alteration of the physical, chemical, or biological properties, of any waters of the state. This includes change in temperature, taste, color, turbidity, or odor of waters. It also includes discharge of any liquid, gaseous, solid, radioactive, or other substance into any waters of the state. This definition assumes changes will, or are likely to, create a nuisance or render such waters harmful, detrimental, or injurious to (1) public health, safety, or welfare, or (2) domestic, commercial, industrial, agricultural, recreational, or other legitimate beneficial uses, or (3) livestock, wild animals, birds, fish, or other aquatic life.

Pycnocline: Depth at which water density increases most rapidly with depth.

Runoff: The variety of ways by which water moves across the land, including surface (diffuse) runoff and channelized runoff.

Seawater: Water from a sea or ocean, averaging 35 grams of dissolved salts per liter (parts per thousand).

Sediment: Solid fragmented material (soil and organic matter) that is transported and deposited by water and covered with water (example, river or lake bottom).

Spatial: How concentrations differ among various parts of the river.

Stormwater: The portion of precipitation that does not naturally percolate into the ground or evaporate but instead runs off roads, pavement, and roofs during rainfall or snow melt. Stormwater can also come from hard or saturated grass surfaces such as lawns, pastures, playfields, and from gravel roads and parking lots.

Surface waters of the state: Lakes, rivers, ponds, streams, inland waters, salt waters, wetlands and all other surface waters and watercourses within the jurisdiction of Washington State.

Suspended sediment: Solid fragmented material (soil and organic matter) in the water column.

Temporal trends: Characterize trends over time.

Total suspended solids (TSS): The suspended particulate matter in a water sample as retained by a filter.

Watershed: A drainage area or basin in which all land and water areas drain or flow toward a central collector such as a stream, river, or lake at a lower elevation

X th percentile: A statistical number obtained from a distribution of a data set, above which 100-X % of the data exists and below which X % of the data exists.

Acronyms and Abbreviations

AP	Analytical Perspectives
BEHP	Bis 2-ethylhexyl phthalate
BMP	Best management practices
BNA	(Base/neutral/acid extractable) semivolatile organic compound
cPAH	Carcinogenic PAH compounds [benz(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, chrysene, dibenzo(a,h)anthracene, and indeno(1,2,3-c,d)pyrene)]
CRM	Certified reference material
CTD	Conductivity, temperature, depth measurement devices
CV	Coefficient of variation (standard deviation divided by the mean)
Ecology	Washington State Department of Ecology
DDD	Dichloro-diphenyl-dichloroethane
DDE	Dichloro-diphenyl-trichloroethylene
DDT	Dichloro-diphenyl-trichloroethane
DOC	Dissolved organic carbon
DUP	Duplicate

EIM	Environmental Information Management database
EPA	U.S. Environmental Protection Agency
EDL	Estimated detection limit
EQL	Estimated quantitation limit
Frontier	Frontier Global (formerly Frontier Geosciences)
GFF	Glass fiber filter
GIS	Geographic Information System software
GPS	Global Positioning System
HDPE	High-density polyethylene
HEM	Hexane-extractable material (synonymous with oil and grease)
HPAH	High molecular weight PAHs [benz(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(g,h,i)perylene, chrysene, dibenzo(a,h)anthracene, fluoranthene, indeno(1,2,3-c,d)pyrene, and pyrene]
KCDNR	King County Department of Natural Resources
LPAH	High molecular weight PAHs [acenaphthylene, acenaphthene, anthracene, fluorene, naphthalene, and phenanthrene]
MDL	Method detection limit
MEL	Manchester Environmental Laboratory
MQO	Method quality objective
MS/MSD	Matrix spike/matrix spike duplicate
N	Number
n/a	Not applicable
NAD	North American Datum
ND	Not detected, nondetect
NPDES	National Pollutant Discharge Elimination System
NTR	National Toxics Rule
Ortho-P	Ortho-phosphate
P	Phosphorus
p	Probability of a result as extreme as the one observed assuming the null hypothesis is true
PAH	Polycyclic aromatic hydrocarbon compounds
PBDE	Polybrominated diphenyl ethers
PBT	Persistent, bioaccumulative, and toxic substance
PCB	Polychlorinated biphenyls
POC	Particulate organic carbon
POTW	Publically-owned treatment works
PRL	Pacific Rim Laboratories
PSTLA	Puget Sound Toxics Loading Analysis
QA	Quality assurance
QC	Quality control
REP	Replicate
RL	Reporting Limit
RM	River mile
RPD	Relative percent difference
RSD	Relative standard deviation
Sd	Sound
SJdF	Strait of Juan de Fuca

SOP	Standard operating procedure
SPM	Suspended particulate matter
SRM	Standard reference materials
Stdev	Standard deviation
Str	Strait
TEQ	Toxic Equivalents (for carcinogenic PAHs, relative to toxicity of benzo(a)pyrene)
TOC	Total organic carbon
TPAH	Total PAHs (sum of HPAH and LPAH concentrations)
TPH	Total petroleum hydrocarbons
TPH-D	Total petroleum hydrocarbons - diesel fraction
TPH-G	Total petroleum hydrocarbons - gasoline fraction
TSS	(See Glossary above)
USGS	U.S. Geological Survey
WDFW	Washington Department of Fish and Wildlife
WRIA	Water Resource Inventory Area

Metals

As	Arsenic
Cd	Cadmium
Cu	Copper
Pb	Lead
Zn	Zinc

Units of Measurement

cfs	cubic feet per second
cm	centimeters
cms	cubic meters per second, a unit of flow.
dw	dry weight
ft	feet
g	gram, a unit of mass
gpm	gallons per minute
kg	kilograms, a unit of mass equal to 1,000 grams.
kg/d	kilograms per day
km	kilometer, a unit of length equal to 1,000 meters.
L	liters
m	meter
mg/Kg	milligrams per kilogram (parts per million)
mg/L	milligrams per liter (parts per million)
mL	milliliters
ng/Kg	nanograms per kilogram (parts per trillion)
pg/L	picograms per liter (parts per quadrillion)
psu	practical salinity units
rpm	revolutions per second
µg/Kg	micrograms per kilogram (parts per billion)
µg/L	micrograms per liter (parts per billion)
µM	micromolar (a chemistry unit)

River Water Sampling

Puget Sound Toxics Box Model

The Puget Sound Toxics Box Model depicted below, taken from Pelletier and Mohamedali (2009), provides context for the sampling conducted for the present 2009-2010 study. It shows the relative volume of surface and deep water layers in Puget Sound basins, the relative volume of surface runoff to each surface layer, and the relative volume exchanged between each basin and layer. To address data gaps identified by the Box Model, the present study analyzed toxic chemicals in samples collected from surface and deep layers of the four main basins and from the five rivers representing the largest sources of surface runoff. Samples were also collected from surface and deep layers in ocean boundary waters outside Admiralty Inlet.

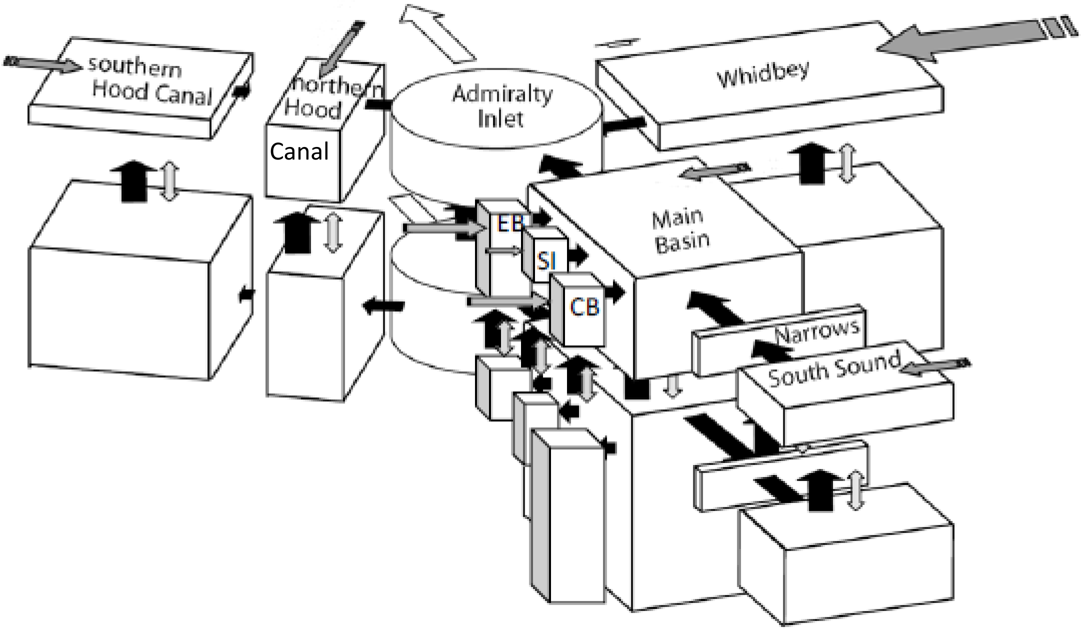

Figure B-1. Diagram of the Box Model of water circulation and transport in Puget Sound.

Grey arrows with dashed ends represent river inputs.
White arrows show exchange with the Strait of Juan de Fuca (ocean boundary waters).
Black arrows show advective transport.
Two-way grey arrows represent mixing between compartments.

Boxes are scaled to show relative volumes of water.
Arrows for rivers are log-scaled.

EB = Elliott Bay; SI = Sinclair Inlet; CB = Commencement Bay.

Sampling Marine Waters for Organic Carbon

Sample Containers, Preservation, and Holding Times

Analytical Methods

Sampling for Trace Levels of Analytes in Marine Waters using GO-FLO Samplers

Effective control of contamination during the collection and handling of marine water column samples is of paramount importance. Many of the target analytes are ubiquitous on the sampling platform and equipment, often at several orders of magnitude higher than concentrations expected in ambient waters. Introduction of contamination at this stage will negate all care taken in subsequent analytical steps.

These field protocols are intended to provide a step-by-step procedure for the collection of contamination-free water samples from depth in marine waters. Guidance was taken from the sampling literature, and to the extent possible EPA *clean hands / dirty hands* techniques are employed (EPA, 1996). Performance of these protocols should be routinely measured through the collection and analysis of field blanks and replicates.

Overview

While there is no “standard” method for obtaining at-depth samples of marine waters for trace analyses, a proven and widespread technique involves the deployment of one or more Teflon-coated GO-FLO samplers (General Oceanics, Inc.) on a non-metallic hydrowire (typically Kevlar). The sampling procedures employed in the present study are based on this “standard” foundation as follows:

> Two Teflon-coated GO-FLO samplers are mounted back-to-back (or several meters apart) on a non-metallic Vectran rope and are lowered by hand into the water with their end caps *closed* to avoid potential contamination from the microlayer at the water surface. The samplers open automatically by hydrostatic pressure release at a depth of approximately 10 meters. Site water flushes through the open samplers as they are lowered to the predetermined sampling depth. The samplers are remotely triggered by Teflon-coated messengers. A non-metallic windlass drum and Acetal sheave facilitate recovery of the GO-FLO samplers and ensure that the rope does not contact potentially contaminating materials. Once on-board, the sampler end caps are kept covered by polyethylene bags to minimize atmospheric exposure, and the samplers are secured in a purpose-built storage cabinet.
>
> Subsampling activities are conducted within a simple portable glove box. Water samples are decanted from each GO-FLO sampler via clean Teflon tubing that connects to the sampler drain valve inside the storage cabinet and to a Teflon petcock inside the glove box. In this way, sample bottles for the various analytes are filled in an environment isolated from major air- and ship-borne contamination sources. If the project lead judges the protection of a glove box to be unnecessary, the GO-FLO samplers may simply be drained through Teflon tubing and into the various analyte sample bottles (with minimal exposure to potential atmospheric contaminants).
>
> At the completion of a sampling cruise, the GO-FLO samplers undergo cleaning and storage procedures.

Principal equipment

- 10-liter GO-FLO samplers (2) – Teflon-coated with Teflon drain valves and air vent screws; spare parts kit.
- Vectran 12-strand rope (600 ft) – marked at 1- and 5-meter increments.
- Teflon-coated messengers.
- Snatch block and non-metal sheave – Ronstan single snatch block with Trunnion head and Acetal sheave.
- Non-metallic line weight – 20-lb. lead weight encased in epoxy resin.
- Cabinet for clean storage and transportation of GO-FLO samplers – constructed of UHMW polyethylene and Teflon materials.
- Large polyethylene bags capable of completely enclosing a single 10-liter GO-FLO sampler.
- Elasticized polyethylene "shower caps" (Saranwrap Quick Covers) or 2-gallon Ziplock bags.
- Talc-free Nitrile gloves.
- Clinometer or like instrument.
- Metals tubing train – 2-in. segment of MasterFlex 73 (3/8" O.D.) connects to GO-FLO drain valve, 6-ft segment of Teflon tubing (3/16" I.D.), and 2-ft segment of MasterFlex 73 tubing (3/8" O.D.) at peristaltic pump.
- Metals filter – in-line Gelman capsule filter, 0.45 µm.
- Peristaltic pump.

General rules

- Personnel must wear clean Nitrile gloves during all sampling and subsampling operations. If glove contamination is detected or suspected, work must be halted, the contaminated gloves removed, and a new pair of clean gloves put on. Wearing multiple layers of clean gloves allows the old pair to be quickly stripped with minimal disruption to the work activity.
- The upper ball valve of each GO-FLO sampler must be covered with an elasticized polyethylene "shower cap" at all times except during active deployment. The drain valve of each GO-FLO sampler must be covered with a Nitrile glove at all times except during active deployment and sample decanting.
- Samplers are transported around the vessel within polyethylene bags when possible, and are handled only by gloved personnel. The samplers should never be placed directly on deck or any hard surface where foreign particles might be lodged in the ball valves and cause contamination of subsequent samples. Improper use and handling of GO-FLO samplers can result in permanent contamination.
- Ensure at all times that the Vectran 12-strand rope does not make contact with any part of the vessel (other than the Acetal sheave and windlass drum). When not in use, remove the rope from the snatch block and coil it inside a clean polyethylene bag. Place the bagged rope within a sealed plastic container to minimize exposure to air- and ship-borne contaminants.
- Store the snatch block, line weights, and messengers in clean polyethylene bags when not in use.

- All polyethylene storage bags are considered "one-time use." That is, once a piece of equipment is removed from its storage bag, a separate clean bag must be used for subsequent storage.

Preparation

- Upon arrival at the sampling location, turn the engine off and wait 10 minutes before placing any sampling equipment in the water. Allow the vessel to drift during all sampling operations and conduct all sampling on the windward side of the vessel to minimize contamination from shipboard sources.
- Remove the snatch block from its polyethylene storage bag and secure it to the A-frame.
- Tie off the bitter end of the Vectran rope to a plastic cleat to secure it in case of mishap. Feed the working end of the rope over the sheave, being careful not to touch any metal objects that could embed foreign particles in the braid. Keep as much standing rope inside the covered plastic container as possible.
- Remove the line weights from storage bags and attach the weights to the loop eye at the working end of the Vectran rope. Lift the weights overboard and lower them into the water so that at least 10 meters of rope extend above the weights. Secure the rope to a plastic cleat to maintain this configuration, and replace any extra rope into the rope storage box.
- Arm the GO-FLO samplers and secure each to the Vectran rope – *This is a 2-person activity and personnel must wear clean gloves*. Layering of gloves is recommended to facilitate rapid discarding of dirty/contaminated gloves. Technicians should work carefully but quickly, striving to minimize the duration of atmospheric exposure for GO-FLO samplers secured to the Vectran rope. Follow the procedures listed below for the first GO-FLO sampler, and then repeat the procedure to arm and secure the second GO-FLO sampler.
  - Technician #1 (T1) removes the sampler from the storage cabinet (keeping it inside the polyethylene bag in which it was stored).
  - Technician #2 (T2) places a clean polyethylene bag flat on a stable surface away from contamination sources. T1 places the GO-FLO sampler (still inside its polyethylene storage bag) on the bag.
  - T2 puts on clean gloves and reaches inside the storage bag to arm the GO-FLO sampler; contact with the GO-FLO sampler is only made by T2. T1 assists by stabilizing the sampler and manipulating the storage bag for T2.
    - Reverse the spring over the pulley to release tension.
    - Pull the pressure release valve all the way out and position the lanyard poly-balls on either side between the valve and the stainless steel frame.
    - Attach the lanyard to the plunger mechanism by inserting the slack loop into the trip release.
    - Re-span the spring by rotating it over the pulley so that the spring and the lanyards are under tension.
    - *Optional:* Test the closing mechanism to verify that it functions properly.
      - Push the pressure release valve to cause the ball valves to move to the open position.
      - Press the plunger to release the lanyard, which results in bottle closure.
      - Re-arm the GO-FLO sampler after this check.

  - T1 carries the armed sampler (still inside the storage bag) to the Vectran rope. T2 reaches inside the storage bag and checks that the protective "shower cap" and Nitrile glove are securely covering the upper ball valve and drain valve, respectively. T2 then removes the GO-FLO sampler from the storage bag. T1 discards the storage bag and secures the GO-FLO sampler to the Vectran rope at the 10-meter marking above the line weights.
  - T1 puts on clean gloves, and the above procedure is repeated for the remaining GO-FLO sampler. Mount the second sampler above the first and note the distance between the vertical centers of the samplers. Samplers are typically spaced two to five meters apart to ensure triggering of the lower sampler by a serial messenger.
- To prepare the samplers for serial firing, attach a Teflon-coated messenger by its lanyard to the plunger mechanisms of the upper GO-FLO sampler, and then snap the messenger onto the Vectran rope between the two samplers.

Deployment

- GO-FLO samplers armed using the above procedures are set to be deployed in a *closed* position to avoid potential contamination from the surface microlayer. If the number of line weights needed to overcome the buoyancy of the air trapped in the GO-FLO samplers becomes prohibitive, consider deploying the samplers in the *open* position. The ball valves can be easily released to the *open* position by depressing the pressure release piston. Note that the poly-balls on the lanyards are under tension and will snap quite suddenly when the pressure release piston is pressed in. Keep hands well clear of the poly-balls, and use a pen wrapped in either a polyethylene bag or a clean glove to depress the pressure valve.
- By convention, at the water surface the GO-FLO samplers are at 0 meters depth. Record the depth marking at which the GO-FLO samplers are mounted on the Vectran rope. This length of rope between each sampler and the line weights is called the "Weight Segment". In calm conditions when the rope angle (deviation from vertical) is negligible, the length of rope from the depth of the GO-FLO samplers in the water column to the surface (called the Sampler Segment) is equal to the total length of rope payed out (Total Length) minus the Weight Segment.

  Sampler Segment = (Total Length) – (Weight Segment)

- Immediately before deployment, remove the protective "shower cap" from the upper ball valve and the Nitrile glove from the drain valve of each GO-FLO sampler. Wearing clean gloves, check that all drain valves and air vent screws are tightly closed.
- Lower the samplers quickly and completely through the water surface to minimize contact with the surface microlayer. Once submerged, slowly lower the GO-FLO samplers by hand to ~15-20 meters depth. The hydrostatic pressure release valve should cause the ball valves to open at approximately 10 meters.
- Verify that the ball valves have opened properly: the parcel of air trapped in each sampler will be visible as it bubbles to the surface. If bubbles are not seen and there is concern that a sampler did not open, raise the rope slowly until the status of the ball valves can be assessed visually. However, note that contamination risks increase as the samplers approach the surface and the vessel. If water conditions are turbid or rough, assume that the bottle is open

and accept that redeployment may be necessary. The weight of a retrieved sampler will be indicative of it being empty or filled with water.

- Lower the GO-FLO samplers to the desired sampling depth.
- Pay out additional rope as needed to adjust for significant rope angles (e.g., caused by strong currents or wind).
    - Read the Total Length and subtract the Weight Segment to determine the Sampler Segment.
    - Measure the angle of the rope from vertical (called Rope Angle) using a clinometer.
    - Calculate the actual depth of the GO-FLO samplers, the "Sampler Depth":

      (Sampler Depth) = (Sampler Segment) x cosine (Rope Angle)

    - Use the vessel's depth sounder for general verification (GO-FLO samplers should be detected by the sounder).
- Remove a Teflon-coated messenger from its storage bag, attach it to the Vectran rope, and release. This messenger will trigger closure of the upper GO-FLO sampler, followed by release of the serial messenger and subsequent triggering of the lower GO-FLO sampler.
- Allow adequate time for the messenger to reach the GO-FLO samplers before retrieval.

Recovery

- Use the windlass to recover the GO-FLO samplers, and feed the rope into the storage container as it is collected to minimize the potential for contact with contamination sources. It may be necessary to have the vessel's engine running to avoid complete draw-down of the battery by the windlass. In that case, engine assistance may only be used to raise the samplers to a depth of 10 meters. Above (i.e., shallower than) 10 meters depth, the engine must be off to avoid introducing excess contamination to the water column through which the GO-FLO samplers will travel. After the engine is off, allow at least one minute for ship-influenced water to dissipate before resuming sampler recovery.
- Once the GO-FLO samplers are retrieved to deck level, quickly inspect for leakage. If leakage is detected or suspected, prepare all samplers for re-deployment as follows:
    - Empty each GO-FLO sampler.
    - Rinse the sample chamber, the drain valve, and the air vent screw with de-ionized water.
    - Wearing clean gloves, and with the GO-FLO samplers still mounted on the Vectran rope, re-arm the samplers.
    - Re-deploy the GO-FLO samplers.
- If no leakage is apparent, immediately place clean polyethylene "shower caps" on the GO-FLO samplers' top ball valves. Rinse the samplers' drain valves with de-ionized water and cover each with a Nitrile glove.
- Remove the messengers and place them in a polyethylene bag for storage.
- Disengage the GO-FLO samplers individually and transport each to the storage cabinet. *This is a 2-person activity and all personnel must wear clean gloves*. Follow the steps below for the first GO-FLO sampler, and then repeat for the second sampler.

  - T1 supports the GO-FLO sampler to be removed, and T2 releases the screws that secure the sampler to the line.
  - While T1 holds the GO-FLO sampler, T2 places a clean polyethylene bag over the unit. T1 adjusts so that the sampler is completely contained in the bag.
  - T1 carries the GO-FLO sampler to the storage cabinet; T2 acts as a spotter. The sampler should not make contact with any part of the vessel.
  - T1 places the GO-FLO sampler inside the storage cabinet in an upright position (it should remain in the polyethylene bag). T1 secures the GO-FLO sampler inside the cabinet using bungee cords.
  - T2 puts on clean gloves, opens the GO-FLO sampler's air vent screw, and removes the glove from the drain valve.
  - Inside the glove box (situated under the cabinet), T1 removes a clean Teflon tubing/ petcock assembly from its storage bag. The open end of the tubing remains covered with foil, and the petcock remains protected by a Nitrile glove until subsampling activities commence. T1 feeds the tubing from inside the glove box to the GO-FLO sampler cabinet, and checks that the petcock inside the glove box is closed.
  - T2 receives the Teflon tubing at the storage cabinet, removes the foil from the end, and connects the tubing to the drain valve's compression fitting. T2 opens the drain valve, and T1 makes sure that the petcock isn't leaking in the glove box.
- Wearing clean gloves, remove the line weights and place them in polyethylene bags for storage. Release the Vectran rope from the snatch block. Coil the rope, place it in a polyethylene bag, and store it within the sealed container to protect against air- and ship-borne contaminants. Place the snatch block in a polyethylene bag for storage.

Subsampling

- Begin decanting from the GO-FLO samplers as soon as possible to prevent settling, biological activity, or adsorptive losses.
- Prior to the cruise, pre-labeled bottles for a specific sampling location and depth (henceforth called a "set") will have been assembled in two large, layered polyethylene bags. Wearing clean gloves, remove the outer polyethylene bag and transfer the set (still contained in the inner polyethylene bag) to the inside of the glove box.
- Place a wide-mouthed waste container inside the glove box.
- The flow of water from a GO-FLO sampler is controlled from inside the glove box using the Teflon petcock. Remove the protective Nitrile glove to access a petcock. Be extremely careful, and ensure that nothing in the glove box makes contact with the exposed petcock at any time.
- Drain the first 0.5 liters of water from each GO-FLO sampler into the waste container before decanting sample water for chemical analyses.
- Decant whole-water subsamples.
  - Remove the analyte bottle(s) from the set bag as they are needed, and follow analyte-specific handling procedures (e.g. bottle rinses).
  - The recommended sequence for decanting analyte samples is as follows:

        - GO-FLO sampler #1:
            1. Total Suspended Solids – 2 L
            2. DOC and POC – 1 L
            3. PCB Congeners – 2.5 L
            4. PBDE Congeners – 1 L
            5. Chlorinated Pesticides – 1 L
            6. Backup volume in case of mishap – 1 L
        - GO-FLO sampler #2:
            7. PAHs – 1 L
            8. BNAs – 3.5 L
    - Filtration for DOC and POC is carried out immediately after their 1-liter subsample is decanted from the GO-FLO sampler (i.e., while other analyte subsamples are still being drained from the samplers). Filtration protocols are detailed elsewhere in this Appendix.
    - After each analyte bottle is filled, attach a sample tag with the required identification information (e.g., sample I.D., date/time, location, analyte, etc.). Seal the individual bottle inside a polyethylene bag and then inside another polyethylene bag.
    - *Do not* allow the mouth of an analyte bottle to contact the petcock at any time.
    - *Do not* swirl or shake the GO-FLO samplers to re-suspend settled material, as this can alter partitioning between dissolved and particulate size fractions.
- Observing *clean hands / dirty hands* guidelines, set up a clean tubing train for collecting metals samples from GO-FLO #2.
    - Use the peristaltic pump to flush 250 mL of sample water through the tubing train before rinsing and filling the total metals bottle. Label and double-bag the bottle.
    - Attach the in-line metals filter to the tubing train. Remove the end of the tubing train from the drain valve of GO-FLO #2 and place it in a bottle of laboratory-provided reagent water. Use the peristaltic pump to flush the filter with 750 mL of reagent water. Re-connect the end of the tubing train to the drain valve of sampler #2, and flush the filter with 250 mL of sample water before rinsing and filling the dissolved metals bottle with filtrate. Label and double-bag the bottle.
- Remove the set of subsample bottles from the glove box and place them in a cooler on ice.

Between stations or sampling events

- To minimize the risk of contamination to the GO-FLO samplers during short-term storage, adhere to the following precautions:
    - Store the samplers in polyethylene bag(s) inside the storage cabinet, and only remove a sampler just prior to deployment.
    - All valves (i.e., ball valves, air vent screws, drain valves) should be stored in their final closed position.
    - Cover the upper ball valve with an elasticized "shower cap," even when the sampler is inside a polyethylene storage bag.
    - Protect the drain valve by storing it covered by a Nitrile glove.
- If contamination of any GO-FLO sampler is suspected, stop using the sampler and return it to the lab for a thorough cleaning.

Extended storage

- Prior to long-term storage, rinse the GO-FLO samplers with de-ionized water.
- Ensure that all valves are in their final closed position.
- Cover the upper ball valve with a clean elasticized "shower cap," and place a clean Nitrile glove over the drain valve.
- Store the GO-FLO samplers in one or more clean polyethylene bag(s) and secure them in the storage cabinet.
- If GO-FLO samplers are not to be used within 30-60 days, return the samplers to the lab and schedule a thorough cleaning and maintenance. Procedures will be guided by existing standard techniques for the cleaning of Teflon-coated sampling equipment for priority pollutant sampling.

Sampling Marine Waters for Organic Carbon

The following standard operating procedures (SOPs) represent a modified version of those used by Horn Point Marine Laboratory, University of Maryland (Lane, 2000).

Procedure for collecting particulate organic carbon (POC) samples

Equipment

- All-glass filter apparatus, pre-washed with 10% HCl (400 mL capacity filter column, scintered filter support with silicone stopper for 1000 ml side arm flask).
- Stainless steel forceps, similarly pre-cleaned.
- Certified pre-cleaned 30-50 ml amber glass DOC storage vials.
- GFF filters (25 mm diameter, 0.7 µm pore size), pre-combusted at 450°C for 90 min, handled with clean forceps only, and stored in aluminum foil packets on which the filter number is pre-recorded.

Filtration Procedure

- Assemble filtration apparatus with pre-combusted filter in place (unpatterned side up) between scintered support and funnel.
- Connect side arm flask to hand pump using pharmaceutical grade tubing.
- Apply gentle vacuum with hand pump (<10 inches Hg or <5 psi) and, ideally, filter water sample for no more than 5 minutes.
    - Volumes requiring 5 minutes filtration may be estimated by filtering incremental volumes of sample water through a discardable filter.
    - Multiple filtrations/filters may be needed to collect sufficient filtrate for DOC analysis.
- Record *total volume filtered* to 3 significant places (e.g., 1020 ml, 102 ml, 10.2 ml).
- Use clean forceps to fold used filter, still on scintered column, in half (top side of filter with POC is folded in on itself).
- Enclose individual used filters in aluminum foil packets.
- Record date/time, sample identification number, and filtrate volume legibly on exterior of aluminum foil packet with a permanent marker (CAUTION: do not puncture foil packet).
- Store aluminum foil packet in a plastic bag and refrigerate in the dark.

Drying Filters

- Within 48 hours, transfer POC filter in aluminum foil packets to laboratory environment.
- Partially open packets using cleaned forceps, place in convection oven, and dry overnight at 60°C.
- Close aluminum foil packet and place in dry plastic bag for shipment.
- Re-label aluminum foil packet if any information on label is no longer visible.

Procedure for collecting dissolved organic carbon (DOC) samples
(DOC is also referred to as NPOC or non-purgeable organic carbon)

- Collect one duplicate sample for every 10 samples to increase precision.
- Rinse side arm flask with approximately ½ sample volume expected to be filtered for POC.
- Remove filter column from flask (leaving filter in place between support and funnel), swirl filtrate thoroughly in flask and discard.
- Reassemble apparatus.
- Filter remaining volume for POC.
- Record station, date, and total volume filtered through filter for POC procedure (see above).
- Remove filter (described above).
- Rinse sample vial(s):
  - Transfer a few milliliters filtrate vial and cap.
  - Shake filtrate and discard.
- Fill vial with at least 20 mLs filtrate.
- Store vial in refrigerator in the dark (4°C).
- DO NOT FREEZE OR ADD ACID!
- Ship overnight within 2 weeks, using ice packs to keep samples cold but not frozen.

Sample Containers, Preservation, and Holding Times

Table C-1. Sample containers, requested volumes, preservation, and holding times for marine water column samples.

Parameter	Bottle Type and Volume	Sample Volume Requested	Preservation	Holding Time
TSS	1 L Poly	2 L	Cool to $\leq 6^{\circ}$ C	7 days
DOC	40 mL Amber Glass	40 mL	Filter in field w/ 0.7 µm GFF filter; Cool to $\leq 6^{\circ}$ C	28 days
POC	1 L Amber Glass	variable	Dry filter w/in 2 days; Cool to $\leq 6^{\circ}$ C	28 days
Total Metals	1000 mL HDPE	1 L	HNO_3 to pH < 2; Cool to $\leq 6^{\circ}$ C *	6 months
Dissolved Metals	1000 mL HDPE	1 L	Filter in field w/ 0.45 µm filter; HNO_3 to pH < 2; Cool to $\leq 6^{\circ}$ C *	6 months
Semivolatiles (BNA)	1 Gallon Glass	3 L	Cool to $\leq 6^{\circ}$ C	7 days
PAHs	1 L Amber Glass	1 L	Cool to $\leq 6^{\circ}$ C	7 days
Chlorinated Pesticides	1 L Amber Glass	1 L	Cool to $\leq 6^{\circ}$ C	7 days
PCB Congeners	2.5 L Amber Glass	2.5 L	Cool to $\leq 6^{\circ}$ C	1 year
PBDE Congeners	1 L Amber Glass	1 L	Cool to $\leq 6^{\circ}$ C	1 year
Total 13.54 L				

* Metals samples were acidified at the analyzing laboratory to avoid introducing contamination in the field and for safety of staff.

Table C-2. Sample containers, requested mass, preservation, and holding times for marine particulate samples.

Parameter	Bottle Type and Volume	Sample Mass Requested * (wet weight)	Preservation	Holding Time
Percent Solids	2 oz Glass	50 Grams	Cool to ≤ 6° C	7 days
TOC			Cool to ≤ 6° C; may freeze at -18°C	14 days; 6 months frozen
Total Recoverable Metals			Cool to ≤ 6° C; may freeze at -18°C	6 months
Semivolatiles (BNA)	8 oz Glass	250 Grams	Cool to ≤ 6° C	14 days; 1 year frozen
PAHs				
Chlorinated Pesticides		250 Grams	Cool to ≤ 6° C	14 days; 1 year frozen
PCB Congeners		50 Grams	Cool to ≤ 6° C; may freeze at -18°C	1 year
PBDE Congeners		50 Grams	Cool to ≤ 6° C; may freeze at -18°C	1 year
Total 650 Grams				

* The minimum mass required to obtain specified detection limits for each analysis is less than the mass requested by analytical laboratories listed here and in the QA Project Plan.

Table C-3. Sample containers, requested volumes, preservation, and holding times for river water samples.

Parameter	Bottle Type and Volume	Sample Volume Requested	Preservation	Holding Time
TSS	1 L Poly	2 L	Cool to $\leq 6^o$ C	7 days
TOC	60 mL Poly	50 mL	1:1 HCl to pH < 2; Cool to $\leq 6^o$ C	28 days
DOC	60 mL Poly	50 mL	Field filter w/ 0.45 µm; 1:1 HCl to pH < 2; Cool to $\leq 6^o$ C	28 days
Hardness	125 mL Poly	100 mL	H_2SO_4 to pH <2; Cool to $\leq 6^o$ C	6 months
Nutrients: Ortho-phosphate	125 mL Amber Poly	125 mL	Field filter w/ 0.45 µm; Cool to $\leq 6^o$ C	48 hours
Nutrients: Total phosphorus	60 mL Poly	50 mL	1:1 HCl to pH < 2; Cool to $\leq 6^o$ C	28 days
Nutrients: Ammonia, Nitrate+Nitrite, and Total Nitrogen	125 mL Clear Poly	125 mL	Pre-acidify w/ H_2SO_4; Cool to $\leq 6^o$ C	28 days
Total Metals	500 mL HDPE	350 mL	HNO_3 to pH < 2; Cool to $\leq 6^o$ C	6 months
Dissolved Metals	500 mL HDPE	350 mL	Field filter w/ 0.45 µm; HNO_3 to pH < 2; Cool to $\leq 6^o$ C	6 months
TPH-D	1 L Amber Glass	3 L	Cool to $\leq 6^o$ C	14 days

Total 450 Grams				

* The minimum mass required to obtain specified detection limits for each analysis is less than the mass requested by analytical laboratories listed here and in the QA Project Plan.

** Insufficient particle mass was collected at the Stillaguamish River to conduct these analyses.

Analytical Methods

Table C-5. Summary of marine water column sample analyses.

Number of samples analyzed includes field QA samples.

Parameter	Samples Analyzed	Final Reporting Limits	Preparation/ Extraction	Cleanup	Analytical Method	Method Description
Conventionals (mg/L)						
TSS	48	0.5 - 2.0	-	-	SM 2540 D	Gravimetric
POC	48	0.015 *	Acidification of dried samples	-	SM 5310	Combustion/oxidation Thermal conductivity
DOC	42	0.018 *	Filter 0.7 µm GFF	-		Combustion, Infrared detection
Total Recoverable and Dissolved Metals (µg/L)						
Arsenic	48 (total) and 47 (diss.)	0.05	• Reductive co-precipitation • Acid Digest • For dissolved metals, prefilter through 1.2 µm glass microfiber filters	-	FGS 054	ICP-MS
Cadmium		0.01				
Copper		0.05				
Lead		0.05				
Zinc		0.25				
Organic Compounds (µg/L unless noted otherwise)						
BNAs	48	0.08 - 3.6	Extraction	-	EPA 8270	Capillary GC/MS
PAHs	47	0.01- 0.02	Solid Phase	-	EPA 8270 SIM	GC/MS
Chlor. Pesticides (ng/L)	46	0.2 - 1.0	EPA 3510	-	EPA 8081	GC/ECD
PCB Congeners (pg/L)	53	3.9 - 0.6	Dichloromethane	Acid/base wash	EPA 1668A	GC/HRMS
PBDE Congeners (pg/L)	47	24 - 255			EPA 1614	

* These values are detection limits. The detection limit for POC is based on filtering 0.75 liters of seawater.

EPA = U.S. Environmental Protection Agency
FGS = Frontier GeoSciences
GC/HRMS = Gas Chromatography / High Resolution Mass Spectrometry
GC/MS = Gas Chromatography / Mass Spectrometry
ICP-MS = Inductively-coupled plasma detector, mass spectrometer confirmation
SIM = Selective Ion Monitoring
SM = Standard Methods (APHA, 2005)

Table C-6. Summary of river water sample analyses.

Number of samples analyzed includes field QA samples.

Parameter	Samples Analyzed	Final Reporting Limits	Preparation Method	Cleanup Method	Analytical Method	Method Description
Conventionals, Nutrients, and Hardness (mg/L)						
TSS	18	0.6 - 4.3	-	-	SM 2540 D	Gravimetric
TOC		1.0	Acidification	-	SM 5310 C	Combustion to CO_2 Infrared detection

Appendix D. Data Quality

Study-Specific Data Quality Rules

Chemical Qualifier Code Revisions

Field QA Sample Descriptions and Results

Study-Specific Data Quality Rules

Assigning chemical qualifiers

- No chemical qualifier code was assigned when:
    - a concentration was greater or equal to the estimated quantitation limit (EQL), practical quantitation limit (PQL), or reporting limit (RL) listed by the laboratory, *and*
    - all or nearly all lab QC sample results were within specified control limits, *and*
    - the analyte of interest was positively identified.
- An “N” qualifier code was assigned to an otherwise unqualified result when the analyte could not be positively identified but there was evidence it was present [third condition above not met].
- A “J” qualifier code, indicating an estimated concentration, was assigned when:
    - a result was greater than or equal to the EQL, PQL, or RL, *and*
    - some lab QC sample results were outside specified control limit, *and*
    - the analyte of interest was positively identified.
- An “NJ” was assigned to an estimated concentration of a tentatively identified analyte.
- A “J” qualifier code, indicating an estimated concentration, was assigned when a detected concentration was less than the EQL, PQL or RL, but greater than or equal to the estimated detection limit (EDL) or method detection limit (MDL) listed by the laboratory. Concentrations were reported down to the listed EDL or MDL whenever possible.
- Valid EIM result data qualifiers (e.g., “G” or “L”) that preserve evidence of low or high analytical bias were not assigned.
- An “REJ” qualifier code was assigned when the presence or absence of an analyte was not verified because of serious problems associated with the sample analysis or lab QC sample performance (results consistently or well outside of control limits). The result was unusable.
- A “U” was assigned when the analyte was not detected at or above a defined numeric value. Depending on the parameter and analytical purpose, nondetect values were set at the quantitation limit (EQL, PQL, or RL) or the detection limit (EDL or MDL). Sometimes results were presented using both methods of assigning concentrations to nondetect results.
- A “UJ” qualifier code was assigned to an individual analytical result for a variety of reasons:
    - The analyte was not detected at or above a quantification limit that is uncertain.
    - Initial or ongoing instrument calibrations were unacceptable.
    - Results for one or more lab QC samples were outside control limits.
    - The analyte was also detected in the lab method blank (see below).

Assigning chemical qualifiers and data flags due to elevated method blank concentrations

- No chemical qualifier code was assigned to a sample concentration that was ≥ a quantitation limit (EQL, PQL, or RL) and ≥ 10 times the concentration in the associated method blank.
- A "J" qualifier code was assigned to a sample concentration greater than or equal to three times (≥3 X) and less than or equal to ten times (≤ 10X) the concentration detected in the associated method blank. A "B" flag was entered into the associated EIM comment field to indicate that "J" was assigned because of the elevated blank concentration.
- A "UJ" qualifier code was assigned to a sample concentration ≥ EDL or MDL and less than three times (< 3X) the concentration detected in the associated method blank. A "B" flag was entered into the associated EIM comment field to indicate that "UJ" was assigned because of the elevated blank concentration and that the result may be used for some purposes.

Correcting for analytes detected in method blanks

Sample concentration results were not corrected for the presence of the same analyte in the batch-specific method blank. Exceptions included the following marine water column sample results:

- DOC. The mass of carbon (µg C) measured on batch-specific filter adsorption blanks was added to the µg C measured in filtered marine water column samples.
- POC. The µg C measured on batch-specific filter trip blanks was subtracted from the µg C measured on marine water column sample filters. The resulting sample concentration was then adjusted for the µg C (DOC) measured on batch-specific filter adsorption blanks.
- Metals. The contract laboratory adjusted the measured concentrations of metals in marine water column samples by subtracting the mean concentration measured in 3 batch-specific "preparation" (method) blanks. Ecology staff derived the original (uncorrected) lab result by adding the mean preparation blank concentration to the reported results. A different chemical qualifier code was then assigned if appropriate.

Correcting for analytes detected in field blanks

Sample results were not modified when field blanks (bottle, filter, transfer, and sampler blanks) showed presence of the same analyte. This decision was based on the following lines of evidence:

- Field blanks, although attempting to mimic sampling processes, were exposed to sources of contamination that the marine and river water samples were not.
  - Marine water column samples were thoroughly pre-rinsed with seawater.
  - Marine water column and river water samples were not exposed to ambient air to the same extent as were field blanks.
- The "fingerprint" of organic compounds (PCB and PBDE congeners) in field blanks was different from that found in field samples.

Summing analytes to estimate total concentrations

Summing rules were developed from Ecology internal *Guidance for Calculating Total Values of Selected Analytes for the EAP Toxics Studies Unit and EIM Parameter Names to Use (2008):*

- If some of the individual analytes were detected (greater than or equal to EDL or MDL), then only detected concentrations were summed to represent the total concentration.
- If none of the individual analytes was detected (greater than or equal to EDL or MDL), then various alternatives were taken:
    - For summed PAH values, ½ the RL was assigned to each PAH compound.
    - For summed PAH values, the MDL was assigned to each PAH compound.
    - For total PCBs and total PBDEs, the largest nondetect concentration (RL) for an individual congener was used.

Using nondetect values

Descriptive statistics and other statistical analyses, as well as estimates of annual mass exchange and loading of toxic chemicals, sometimes involved chemicals or chemical classes that were never or seldom detected in the water samples collected. Therefore, it was important to determine how to use nondetect ("U") values in statistics and calculations.

Several options were considered for using nondetect values for toxic chemicals such as petroleum-related compounds, BNAs, PAHs, chlorinated pesticides, and PBDEs. For statistical summaries and analyses, nondetect values were not used unless stated otherwise in the report. For calculations of annual mass fluxes and loadings, based on multiplying mean water concentrations by predicted water flux or river flow, nondetect values were used as follows:

- When all or most samples had detected concentrations, nondetect values were not used to calculate mean water concentrations.
- When a parameter was never or seldom detected, flux and loading calculations were based on:
    - Nondetects = 1/2 the RL.
    - Nondetects = the detection limit (EDL or MDL), if available.

Chemical Qualifier Code Revisions

Field Quality Control Sample Descriptions and Results

Field replicates

Replicate sampling involved the analysis of two samples collected in an identical manner and in close spatial and temporal proximity. Field replicates provide a measure of field precision and allow for the assessment of the environmental variability of concentrations of target parameters.

Marine water column field replicates
- Parameters analyzed: All.
- Procedure: Following water collection from a regular sampling site, the GO-FLO samplers were immediately redeployed and collection was repeated at the same location and depth.

River water field replicates
- Parameters analyzed: All.
- Procedure: First, the complete set of depth-integrated river water samples was collected (compositing from three quarter points). After these samples were processed and stored, the river was sampled a second time using a new, acid-cleaned sampler.

Results for each replicate sample are presented beside the regular station sample results in Tables D-5, D-7, and D-8 for marine water, and in Tables D-11, D-13, and D-14 for river water. Replicate results were in good agreement with their corresponding station sample results for most parameters, as indicated by low relative percent difference (RPD) values. Marine water POC, marine water dissolved lead, and river water total cadmium occasionally had elevated RPDs that were attributable to low measured concentrations (i.e., near the analytical method detection limit) that exaggerated differences.

Elevated RPDs for other parameters suggested environmental variability. Slightly elevated RPDs for total PCB replicate sample pairs in both marine and river waters showed that samples collected in close spatial and temporal proximity may yield slightly variable concentration measurements, likely as a consequence of the affinity of these chemicals for particulates. Marine total lead and freshwater dissolved copper replicate pairs also had instances of anomalously high RPDs, but the observed variability was nowhere above what might be expected for samples collected up to three hours apart in dynamic bodies of water. As such, replicate results did not warrant the re-qualification of any project data.

For the purposes of this report, field replicates were used for QA assessment only; field replicate results were not averaged with their corresponding station sample results for data analyses presented in this document.

Field Duplicates

Duplicate sampling involved the analysis of two samples obtained from a single water collection. Field duplicates allow for the evaluation of analytical variability, or lab precision.

Marine water column field duplicates

- Parameters analyzed: TSS, DOC, POC, and PCB congeners.
- Procedure: Two samples for a given parameter were decanted from a single GO-FLO water collection. Organic carbon samples were processed simultaneously on separate clean filtration apparatuses.

Results for each duplicate sample are presented beside their corresponding station samples in Tables D-6 and D-7. These pairs of results generally agreed very well, as indicated by their low RPDs. Thus, duplicates were not used to re-qualify any project data.

For the purposes of this report, the results of the field duplicate analyses were not averaged with their corresponding station sample results.

Bottle and transfer blanks

Bottle blanks involved the analysis of analyte-specific blank water that was carried unopened into the field and treated as a sample. Transfer blanks involved pouring the same lab-provided blank water into a sample bottle in the field. These types of blanks allow for the evaluation of contamination arising from the sample bottles themselves, from general bottle handling, and from the atmosphere during sample transfers. Results also allow evaluation of the cleanliness of the blank water that was used for other field QA samples, such as equipment blanks.

Marine water column bottle blanks

- Parameters analyzed: PCB congeners.
- Procedure: Lab blank water obtained from Analytical Perspectives was brought unopened into the field and treated as a sample.

River water transfer blanks

- Parameters analyzed: Total metals, chlorinated pesticides, BNAs, PAHs, PCB congeners, and PBDE congeners.
- Procedure: For total metals, blank water from MEL's metals lab was transferred (by pouring) to an acidified sample bottle. For organics, blank water from MEL's organics lab was carried in 1-gallon glass containers and transferred into individual sample bottles.

Results for the two marine PCB bottle blanks are presented in Table D-10. Both bottle blanks showed low concentrations of four PCB congeners in Analytical Perspectives reagent water. These congeners were not detected in the corresponding method blanks, suggesting that the detected contamination was associated with bottle transport and handling. From only two blanks it was unclear whether this congener-specific contamination might be pervasive throughout the marine water column samples. For the purposes of this project, results were not re-qualified at the congener level based on this potential contamination.

Results for the freshwater transfer blanks are given in Tables D-12 and D-14. A low concentration of zinc was detected in the total metals transfer blank, likely attributable to atmospheric exposure during the unprotected transfer process. No contamination was detected in the transfer blanks for chlorinated pesticides and BNAs, and only a low concentration of naphthalene was detected in the PAH transfer blank. The results for both PCB and PBDE transfer blanks were deemed unusable due to the improper creation of these samples (blank water should have come from Analytical Perspectives and Pacific Rim laboratories, not MEL). Overall, transfer blanks for river water sampling did not warrant re-qualification of project results.

Tubing and filter blanks

Tubing and filter blanks were created by mimicking transfers through tubing and contact with filtration apparatuses that occur during regular sampling. These blanks help assess metals contamination arising from the pumping and filtration systems.

Marine water column tubing and filter blanks

- Parameters analyzed: Total and dissolved metals.
- Procedure: Metals reagent water (supplied by Frontier Geosciences) was drawn directly from its bottle using a peristaltic pump and a clean tubing train. The tubing train was flushed with 250-500 mL of reagent water before rinsing and filling the tubing blank bottle. A new, clean filter was connected in-line and the filter was flushed with at least 500 mL of blank water before filling the filter blank bottle.

River water filter blanks

- Parameters analyzed: Dissolved metals.
- Procedure: Reagent water from MEL's metals lab was filtered through a clean filtration apparatus, and the filtrate was poured into a pre-acidified sample bottle.

Results for tubing and filter blanks from marine sampling are presented in Table D-9. Lead and zinc were detected in the tubing blank. It had been necessary to modify the tubing train in the field prior to conducting this tubing blank (using a Teflon-coated tubing cutter of uncertain cleanliness), and the detected lead and zinc were likely attributable to that adjustment. Project results for marine metals were not re-qualified based on tubing and filter blanks.

Results for the freshwater filter blank are shown in Table D-12. Very low concentrations of dissolved copper and zinc were detected in the blank, but these were deemed insufficient to warrant the re-qualification of project results for river water metals.

Sampler blanks

Sampler blanks involved the placement of analyte-specific laboratory reagent water into the sampling gear (GO-FLO samplers for marine water, DH-95 bottle/cap/nozzle set-up for river water) to mimic sample water contact with the collection equipment. These blanks allow assessment of contamination arising from pre-cleaning methods, the sampling equipment itself, and sample decanting procedures.

Marine water column sampler blanks

- Parameters analyzed: All.
- Procedure: GO-FLO samplers were rinsed thoroughly with analyte-specific blank water and emptied, re-filled with blank water, and then a subsample was decanted through clean Teflon tubing following standard procedures. Sampler blanks were conducted using GO-FLO

samplers immediately after acid-cleaning, as well as samplers that had been used (or "conditioned") by previous deployments to collect site water.

River water sampler blanks

- Parameters analyzed: Total and dissolved metals, chlorinated pesticides, BNAs, PAHs, PCB congeners, and PBDE congeners.
- Procedure: The DH-95 bottle/cap/nozzle was rinsed with analyte-specific blank water and emptied, re-filled, assembled, and left for two minutes to approximate the duration that a typical water collection would be in contact with the sampling gear. In September 2009 the sampler was left exposed to the bridge atmosphere for the two minutes, while in December 2009 the opening of the bottle/cap/nozzle was covered with a nitrile glove to minimize exposure to airborne contaminants.

Results for marine sampler blanks are presented in Tables D-9 and D-10. All parameter results for the July 2009 "used" sampler blank were discarded, for these blanks were improperly created using blank water that was not obtained from the appropriate analytical laboratories. Blanks created immediately after acid-cleaning the sampling equipment detected low concentrations of total and dissolved lead and zinc, as well as several BNA and PAH compounds and a number of PCB congeners. However, "used" sampler blanks revealed that nearly all of these contaminants were absent after normal use of the equipment during sampling. During deployment the GO-FLO samplers were flushed with site water as they were lowered to the collection depth, and this appeared to be sufficient to remove residual contamination from pre-cleaning procedures.

Potential PCB contamination from marine sampling gear was investigated in January 2010. A blank was first created using an acid-cleaned sampler. Next the sampler was deployed to a depth of 60 meters (flushing to depth) where site water was collected. Finally a "used" (or "conditioned") sampler blank was created. A bottle blank was also conducted to determine the presence of congener-specific contamination from the laboratory reagent water used in the creation of the sampler blanks. After accounting for congener-specific, low-level contamination from the lab water and from cleaning procedures (i.e., contamination that was noted to "wash away" during deployment), only three to six PCB congeners appeared to persist in the "conditioned" sampler blank. These lines of evidence suggested that much of the residual contamination from pre-cleaning procedures was removed by the thorough flushing of the sampler during deployment.

Results for river sampler blanks are shown in Tables D-12 and D-14. September 2009 sampler blanks appeared to have been influenced by exposure to the bridge atmosphere during creation. This exposure was well in excess of that experienced by regular samples during standard collection procedures, and so the results of these sampler blanks were deemed unrepresentative. Despite precautions in December 2009, those sampler blanks also appear to have been exposed to contamination sources not experienced during normal sampling activities.

This contention is supported by PCB congener *fingerprints*, which showed that field blanks tended to contain greater abundance of mono- to tri-chlorinated congeners and relatively lower concentrations of tetra- to hepta-chlorinated congeners. This was not the pattern for river water or marine water column samples. If PCBs in water samples were derived from the same sources as field blanks, then similar total concentrations and similar congener compositions would be expected. Therefore, the sources of elevated PCB congener concentrations in field blanks were different from the sources of PCBs in marine water column or river water samples.

One explanation is that the high-quality de-ionized water used to create most field blanks (<15 pg/L) effectively scavenged PCBs from the ambient air (to which field blanks were exposed longer than actual water samples).

Overall, it was concluded that sampler blanks did not exactly reproduce conditions encountered during normal sampling procedures. Sampler blanks reflected opportunities for contamination not shared with actual marine and river water samples, and so sampler blank results were not used to further interpret or qualify sample results.

Organic Carbon Blanks

A variety of field blanks were created to evaluate the newly developed protocols for marine organic carbon sampling. These included the following:

Laboratory filter blanks

- Purpose: Quantification of the mass of "background" carbon inherent in a typical filter.
- Procedure: The analytical lab (Horn Point) retained and analyzed several clean, unused filters from the batch that was sent for field sampling.

Filter trip blanks

- Purpose: Quantification of the mass of carbon that accumulated on a filter during typical transport and handling activities.
- Procedure: A filter from the batch provided by the analytical lab was carried unopened into the field and treated as a POC sample. During October 2009 and January 2010 sampling, a total of eight filter trip blanks were conducted.

Adsorption blanks

- Purpose: Determination of the concentration of carbon that was adsorbed to a typical filter during filtration.
- Procedure: Standard marine carbon filtration procedures were followed, but using two "stacked" filters. After subtracting the background carbon mass inherent in a typical filter, the mass of carbon measured on the lower filter and the volume of sample water filtered were used to calculate the concentration of adsorbed carbon. The mass of carbon adsorbed was assumed to increase linearly with the volume of sample filtered.

Results for the various organic carbon blanks were used to blank-correct marine sample results. The average mass of background carbon inherent in a filter was 8.40 µg C, and the average mass accumulated during transport and handling was 4.84 µg C. That combined mass of carbon (13.24 µg C) accounted for an average of 25% of each regular project sample's total measured (i.e., uncorrected) POC. After these "filter effects" were subtracted from POC measurements, the average carbon concentration contributed by adsorption of DOC to the filter (mg C per liter filtered) was 0.0045 mg/L C, accounting for approximately 7% of the remaining total measured POC. This adsorbed carbon was also subtracted from the total measured POC to arrive at a final result. For DOC, the only blank correction needed was to add the carbon that was lost due to adsorption during filtration (proportional to the volume filtered).

Example series of measurements and calculations for blank-correction of POC results

a) The POC sample was obtained by filtering 600 mL of sample water.
b) The instrument-measured carbon signal of the sample filter = 1445 µVolts.
c) The average carbon signal measured in three lab filter blanks = 168 µVolts.
d) Sample filter carbon signal, corrected for average lab filter blank carbon signal, equals:
    1445 – 168 = 1277 µVolts.
e) Average carbon signal measured in three filter trip blanks = 74.7 µVolts.
f) Sample filter carbon signal, corrected for average filter trip blank carbon signal, equals:
    1277 – 74.7 = 1202.3 µVolts.
g) "K-factor" (provided by the lab) allows conversion of a carbon signal to mass:
    "K-factor" = 23.0 µVolts / µg carbon.
h) Mass of carbon on filter, corrected for lab and field filter blanks, equals:
    1202.3 / 23.0 = 53.6 µg carbon.
i) Calculate the carbon concentration of the three individual adsorption blanks. For example, the creation of one adsorption blank had involved "stacked" filtration of 435 mL of sample water. After correcting the measured carbon signal for lab and field filter blanks and then applying the K-factor, the mass of adsorbed carbon was 2.51 µg carbon. Thus, the carbon adsorbed to the filter was:
    2.51 / 435 = 0.006 mg/L carbon.
    That is, 0.006 mg carbon was adsorbed to the filter for every liter filtered.
j) The average carbon concentration of the three adsorption blanks = 0.0045 mg/L carbon.
k) The mass of carbon adsorbed for the sample of interest equals:
    600 mL filtered X 0.0045 mg/L carbon = 2.70 µg carbon.
l) The mass of carbon on the filter, corrected for the adsorbed mass, equals:
    53.6 – 2.7 = 50.9 µg carbon.
m) Finally, the concentration of POC in the sample water equals:
    50.9 µg carbon / 600 mL filtered = 0.085 mg/L POC.

Table D-5. Summary of field replicate results for marine water samplings.

Non-detect values for the listed BNA compounds are given at the reporting limit (RL). Total PCB values are sums of detected congeners (unqualified and J-qualified results). PCB homolog and congener results for field replicates are detailed in Tables D-7 and D-8, respectively.

Table E-19. January 2010 BNA Results for Marine Water Samples from Boundary Water Sites.

Non-detect values are given at the reporting limit (RL). The method detection limit (MDL) is presented for comparison.

[1] The following 36 congeners were measured (listed by homolog group):
Di-brominated congeners = PBDEs 007, 010, and 015; tri-brominated congeners = PBDEs 017, 028, and 030; tetra-brominated congeners = PBDEs 047, 049, 066, 071, and 077; penta-brominated congeners = PBDEs 085, 099, 100, 119, and 126; hexa-brominated congeners are PBDEs 138-140, 153, 154, and 156/169; hepta-brominated congeners are PBDEs 171, 180, 183, 184, and 191; octa-brominated congeners are PBDEs 196, 197/204, 201, 203, and 205; nona-brominated congeners are PBDEs 206-208; the deca-brominated congener is PBDE 209.

Appendix F. Analytical Results - Marine SPM

Table F-1. Summary of Results for Marine Particulate Samples.

All results for the Case+Carr Inlet sample were J-qualified due to analysis beyond holding time. PBDE results show only detected congeners.

Appendix I. 2009-2010 Results Compared to Historical Data

Table I-1. Marine water column results for conventional parameters compared to historical data.

Parameter (mg/L)	Number	Median	Mean	Stdev	Low	High	Data Source*
TSS	42	1.6	1.75	1.05	0.8	6.0	Present Study
	18	4.5	4.9	1.6	2	9	Johnson (2009)
	19185	~2.5	~3.0	~2.47	0.0	64.1	Pelletier and Mohamedali (2009)
POC	28	0.059	0.133	0.326	0.028	1.780	Present Study
	~472	~0.08	~0.11	~0.03	~0.01	~0.36	Johannessen et al. (2008)
	(calc'd)	~2.84	~5.12	-	-	-	Pelletier and Mohamedali (2009)
DOC	28	0.754	0.757	0.089	0.611	0.969	Present Study
	~472	~0.64	~0.66	~0.02	~0.44	~0.91	Johannessen et al. (2008)
	24	1.06	1.23	-	0.70	2.16	Pelletier and Mohamedali (2009)
TOC	28	0.807	0.891	0.379	0.660	2.749	Present Study
	~472	~0.71	~0.77	~0.03	~0.48	~1.2	Johannessen et al. (2008)
	348	4.00	~6.35	-	0.85	79.0	Pelletier and Mohamedali (2009)

* Data sources:
Johannessen et al. (2008) data from Straits of Juan de Fuca and Georgia, 2003.
Johnson (2009) data from Strait of Juan de Fuca, Guemes Channel, and Commencement Bay, 2008-2009.
Pelletier and Mohamedali (2009) summary of EIM data for various Box Model regions; POC calculated as the difference of TOC and DOC.

Table I-2. Marine water column results for PCBs and PBDEs compared to historical data.

Parameter (pg/L)	Number	Median	Mean	Stdev	Low	High	Data Source*
Total PCBs	42	24.0	26.3	14.9	6.09	75.1	Present Study
	~14	-	~42	-	40.3	43.5	Dangerfield (2007)
Total PBDEs	10	749	2865	5678	51	18691	Present Study
	~14	-	~19	-	14.8	23.4	Dangerfield (2007)

* Data source:
Dangerfield et al. (2007) data from Boundary Pass and Rosario Strait, Strait of Georgia.

Table I-3 (presented on the following page). Marine water column metals results compared to historical data.

* Data sources:
Crecelius (1998) data from Cherry Point, Strait of Georgia and from March Point, Strait of Juan de Fuca, 1997.
Johnson (2009) data from Strait of Juan de Fuca, Guemes Channel, and Commencement Bay, 2008-2009.
Johnson (2009) summary of KCDNR data from Strait of Juan de Fuca, 1997-2000 (King County, 2001).
Johnson (2009) summary of Johnson and Summers (1999) data from Commencement Bay, 1997-1998.
Serdar (2008) summary of KCDNR data from Puget Sound region, 1996-2002; summary of EIM data from Puget Sound, 1995-2007.

THE ADMINISTRATOR OF THE ENVIRONMENTAL PROTECTION AGENCY

WASHINGTON, D.C. 20460

DEC - 1 2014

MEMORANDUM

SUBJECT: Commemorating the 30th Anniversary of the EPA's Indian Policy

FROM: Gina McCarthy

TO: All EPA Employees

I am proud to recognize the U.S. Environmental Protection Agency's 30th anniversary of its Indian policy, and I want to thank everyone who has worked diligently to establish and sustain the agency's Indian program. As we mark this milestone, I also want to convey gratitude to our tribal-government partners for all their time, expertise and effort in building this important partnership with the EPA.

On November 8, 1984, the EPA issued its *Policy for the Administration of Environmental Programs on Indian Reservations*. In doing so, the EPA became the first federal agency to adopt a formal Indian policy to guide its relations with tribal governments in the administration of its programs. The 1984 Indian Policy represented – and continues to represent – a bold statement on the EPA's commitment to our partnership with federally recognized Indian tribes and to tribal self-governance in implementing environmental-protection programs.

The underlying principles of the 1984 Indian policy continue to guide our unique relationship with, and the federal trust responsibility to, federally recognized Indian tribes as expressed in treaties, statutes, executive orders and court decisions. The agency remains fully committed to engaging tribes as sovereign governments with a right to self-governance, which is a commitment the EPA made and has kept since our agency's founding.

Tribal Treaty Rights

Under the U.S. Constitution, treaties have the same legal force as federal statutes. And the United States' government-to-government relationship with and trust responsibility to federally recognized Indian tribes reinforces the importance of honoring these treaty rights. As such, the EPA has an obligation to honor and respect tribal rights and resources protected by treaties. While treaties do not expand the EPA's authority, the EPA must ensure its actions do not conflict with tribal treaty rights. In addition, EPA programs should be implemented to enhance protection of tribal treaty rights and treaty-covered resources when we have discretion to do so. To help guide the agency's decisions when treaty rights should be considered, the Office of General Counsel and the American Indian Environmental Office will develop an analytical framework, with input and consultation from other EPA offices and tribal governments.

05396

Intergovernmental Cooperation

Good governance demands that the EPA increase our efforts to work in concert with other federal agencies, tribes, states and local governments to protect human health and the environment. Coming together to set priorities and define mutual roles and responsibilities regarding the administration of environmental-protection programs will build stronger, more efficient and effective partnerships. The EPA remains committed to continue building on the following notable Indian program efforts:

- engaging tribal-elected officials on key environmental and public-health issues through an annual tribal leaders' listening session;
- coordinating with the Environmental Council of the States to include tribal governments in key discussions as co-regulators;
- using the Council for the Commission for Environmental Cooperation to ensure that the U.S., Canada and Mexico continue to work with indigenous communities across North America and recognize the importance of the traditional ecological knowledge and practices of indigenous communities; and
- working with the Department of the Interior to build tribal resiliency regarding the impacts of climate change.

The EPA this year also celebrates the 20th anniversary of the Indian Environmental General Assistance Program. Through this program, the EPA has provided more than $1 billion in direct funding to federally recognized tribes and intertribal consortia to build strong, sustainable tribal environmental-protection program capacity.

Thank you all once more for your hard work and your commitment. I look forward to working with you to achieve much more in the months ahead.

Acknowledgments

The Washington State Department of Ecology wishes to thank the many people who have participated in the ongoing dialogue on fish consumption rates. There have been many conversations through the years, with a great many people providing insight and input, answering questions, reviewing draft documents, and clarifying various issues. In particular, Ecology wishes to acknowledge the following people. Persons listed here provided constructive input and feedback; they were not, however, asked to endorse the final product, and did not see the final report before its release.

University of Washington

- Dr. William (Bill) Daniell, Associate Professor, Environmental and Occupational Health Sciences
- Dr. Elaine Faustman, Professor, Environmental Health
- Dr. William (Bill) Griffith, Principal Research Scientist and Director of the Risk Assessment Core of the Institute for Risk Analysis and Risk Communication
- Alison Scherer, Research Scientist, Environmental and Occupational Health Sciences
- Anna Schmidt, Graduate Student, Environmental and Occupational Health Sciences
- Dr. Thomas M. Burbacher, Professor, Environmental Health
- Dr. Vincent F. Gallucci, Professor, Aquatic and Fishery Sciences

Preface to Version 2.0

Washington's marine and fresh waters are home to rich stocks of finfish and shellfish, and these resources are vital to the well-being of the peoples of our state.[1] Several years ago the Washington State Department of Ecology (Ecology) began work reviewing fish consumption rates as part of updating environmental cleanup regulations, and subsequently produced a draft Technical Support Document. The evaluations presented in that document followed similar evaluations done in Oregon. Ecology received several hundred comments on the draft document and has made revisions based on input received. Additional analyses were performed and supplemental information was gathered to support preparation of this revised version.

Regulatory context plays a role in this topic, and Ecology will be addressing both the scientific and policy questions associated with fish consumption rates. This Technical Support Document, however, does not address the policy questions. It focuses quite specifically on the issue of how much and what types of fish are consumed by the people of Washington, and what data are available about fish consumption rates.

It is appropriate and necessary to review and, if needed, update exposure parameters used in various regulatory contexts, and this document is offered as one part of the effort to consider fish consumption rates. Readers may notice that this document has evolved. Ecology produced the *Fish Consumption Rates Technical Support Document: A Review of Data and Information about Fish Consumption in Washington, Version 1.0* to support dialogue related to updating the default fish consumption rates used in Washington environmental regulations. At that time, Ecology was focused on updating the Sediment Management Standards, with updates to water quality standards to follow at a later time. It was a draft document that posed several questions and was distributed for public review and input in October 2011. Although scheduled to end December 31, 2011, the comment period was extended until January 18, 2012.[2]

In Version 1.0 of the Technical Support Document, Ecology collected data about fish consumers in Washington and looked at national data about fish consumption in the United States. We reviewed this information as a first step in addressing how to establish a fish consumption rate for use in Washington. Ecology then considered how to systematically and scientifically determine a default rate appropriate for use in a regulatory context. Multiple questions arose, including: How should the data be combined in a statistically correct manner? Is it appropriate to establish a single default rate for use in multiple settings? How should salmon be included in the default fish consumption rate?

---

[1] In most places in this document, unless noted otherwise, fish refers to both finfish and shellfish.

[2] Due to a winter storm that caused statewide power outages during that week, Ecology accepted all late comments.

Ecology received over 300 comments on Version 1.0 of the Technical Support Document. Comments were posted on the Ecology website in the order in which they were received. Ecology announced that a response to comments would be prepared.

In order to respond to comments and to update the document based on public input, Ecology performed a number of additional analyses. The additional work in response to comments falls generally into the following categories:

- Technical analyses to more accurately characterize fish-consuming populations, including statistical review of data and methodologies.
- Research of relevant supporting information (for example, regarding recreational fish consumption, health benefits and risks from eating finfish and shellfish, and life strategies for different fish species).

Purpose

The purpose of this Technical Support Document (Version 2.0) is to compile and evaluate available information on fish consumption in Washington State. It is a technical document, and is not designed to resolve policy issues associated with using that information to make regulatory decisions. Those issues will be dealt with in separate rulemaking documents and processes. However, in order to assist readers, this document does provide a certain amount of context and identifies some of the policy questions that are relevant to the topic of fish consumption rates.

This document is narrower in scope than Version 1.0 of the Technical Support Document (distributed in October 2011). At that time, Ecology planned to adopt a default fish consumption rate in the Sediment Management Standards (SMS) rule. One purpose of the Technical Support Document (Version 1.0) was to identify a recommended range of fish consumption rates for consideration in the SMS rule revision process. Since that time, Ecology has decided not to propose a default fish consumption rate in the SMS rule. Instead Ecology is proposing to use a *reasonable maximum exposure* as the sediment cleanup standard for protecting fish consumers. Ecology is also beginning the process to revise the Water Quality Standards for Surface Waters and adopt human health criteria.

Instead of identifying a fish consumption rate appropriate for use in a particular regulatory context, this document compiles relevant data and information. Ecology acknowledges the complexity of this topic and offers this Technical Support Document to provide a thorough, rigorous, and comprehensive review of the available technical information about fish and fish consumers in Washington.

Executive Summary

Problem statement

Washington's aquatic resources provide tremendous benefit to the people of the state. Large quantities of finfish and shellfish are caught each year, both recreationally and commercially, and many residents eat seafood harvested from our waters. In addition, tribal populations enjoy treaty fishing rights, and harvesting and eating seafood plays a significant role in their cultures. Finfish and shellfish are important parts of a healthy diet.

Polychlorinated biphenyls (PCBs), dioxins, mercury, and other persistent chemicals can accumulate in fish tissue and harm the health of people who consume fish. Those who may be particularly vulnerable include adults who eat large amounts of finfish or shellfish, as well as children and other sensitive populations. Current fish consumption rates used by Ecology to make regulatory decisions are not consistent with data about fish consumption by Washington populations for which fish consumption survey information is available.[3]

Ecology currently identifies two separate default fish consumption rates that have been used to establish regulatory requirements:

- Washington's Model Toxics Control Act (MTCA) Cleanup Regulation includes a default fish consumption rate of 54 grams (1.9 ounces) per day. This value was established in 1991. It is based on information from a survey of Washington recreational anglers in Commencement Bay (Pierce et al., 1981).
- Washington is covered under a federal regulation – the National Toxics Rule. Washington's Water Quality Standards for Surface Waters currently rely on the 1992 National Toxics Rule (57 Fed. Reg. 60848-60923 codified at 40 CFR 131.36), which includes Water Quality Standards for human health protection based on a fish consumption rate of 6.5 grams (0.22 ounce) per day.

There have been many scientific and regulatory developments related to fish consumption rates over the past 20 years. The review of Washington fish consumption in this Technical Support Document is offered to provide data and information pertinent to ongoing public dialogue concerning regulatory issues. This report reviews recent scientific data, noting the uncertainty and variability associated with those data.

---

[3] Ecology has the ability to make site-specific decisions and use site-specific information, including fish consumption rates protective of tribal populations.

The aquatic environment challenge

Many different species of finfish and shellfish are harvested from Washington waters. Each species has a unique life history and preferred habitat. Some finfish and shellfish are exposed to contaminants, but determining how much or where that exposure occurs is difficult. In an aquatic environment, contaminants move between water and sediment and from one location to another. In addition, the various salmon species, like other anadromous fish, migrate between river and open ocean environments, spending only a portion of their life cycle near shore.

The issues surrounding salmon life history are particularly complex. Most salmon leave freshwater streams when they are juveniles, only a couple of inches long, and spend varying amounts of time in coastal waters. Salmon spend most of their life cycle in the open ocean, and return to Washington waters at the end of their life cycle. Salmon are the most frequently consumed fish in Washington, but how to account for the complexity they present when considering questions related to water and sediment quality is a challenge. This document does not resolve these questions. Instead it offers information that will be useful as readers think through various options.

Washington fish resources

A large variety of fish and shellfish are available for harvesting in Washington, including more than 50 species of edible freshwater fish and almost as many in marine waters (WDFW, 2010).

Commercial fish landings from Washington non-treaty fisheries totaled over 109 million pounds of finfish and shellfish in 2006, including over 25 million pounds of shellfish and over 11 million pounds of salmon.

Recreationally caught finfish in Washington include albacore, bottomfish, Pacific halibut, salmon, steelhead, and sturgeon, with the 2006 catch totaling over 840,000 fish. Over 113,000 pounds of shellfish were collected from Washington waters in 2006, primarily Dungeness crab and razor clams.

Washington fish consumers

Ecology estimates that between 1.4 and 3.8 million Washington adults and 290,000 children consume some amount of fish as part of their diet.[4]

---

[4] The term *fish* in this document may refer to finfish or to both finfish and shellfish. The term *fish consumption* usually refers to consumption of both finfish and shellfish. The intent should be clear from the context; where appropriate the distinction is noted.

Recreational fishers may consume more fish than the general Washington population. Some population groups consume especially large amounts of finfish and shellfish as part of traditionally influenced diets. These include Native Americans and Asian and Pacific Islanders.

Fish consumption surveys

Information about fish consumption can be collected in a variety of ways. This document describes the different methodologies used to collect information about fish consumption. To identify robust and defensible surveys relevant to Washington, Ecology reviewed survey methodologies and survey results by considering measures of technical defensibility.

Ecology reviewed general population data from national surveys. Statistical methodology used by the National Cancer Institute (NCI) was applied to the national survey data to better estimate long-term consumption rates using short-term dietary records.

Ecology reviewed available information on fish consumption in Washington. Certain dietary recall surveys are identified as well-designed and well-conducted. The following studies meet measures of technical defensibility and contain data directly applicable to Washington population groups:

- *A Fish Consumption Survey of the Umatilla, Nez Perce, Yakama, and Warm Springs Tribes of the Columbia River Basin* (CRITFC, 1994).
- *A Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region* (Toy et al., 1996).
- *Fish Consumption Survey of the Suquamish Indian Tribe of the Port Madison Indian Reservations, Puget Sound Region* (The Suquamish Tribe, 2000).

The *Asian and Pacific Islander Seafood Consumption Study* (Sechena et al., 1999, including EPA’s 2005 re-evaluation) is a well-designed and conducted study, but it represents a very small sample of each of the Asian and Pacific Islander populations surveyed, and statewide populations may differ.

Data on recreational fishing provide another piece of information about fish consumers in Washington. However, this information is collected from creel surveys and is therefore less useful than dietary recall surveys for estimating consumption rates for a population. (The data are included with the table below for convenience only.)

Survey information for the general population, Pacific Northwest populations, and recreational fishers is summarized in Table 1.

Table 1. Summary of Fish Consumption Data, All Finfish and Shellfish (g/day)

Population	Source of Fish	Number of Adults Surveyed	Mean	Percentiles		
				50th	90th	95th
General population (consumers only)	All sources: EPA method	2,853	56	38	128	168
	All sources: NCI method	6,465	19	13	43	57
Columbia River Tribes	All sources	464	63	41	130	194
	Columbia River	–	56	36	114	171
Tulalip Tribes	All sources	73	82	45	193	268
	Puget Sound	71	60	30	139	237
Squaxin Island Tribe	All sources	117	84	45	206	280
	Puget Sound	–	56	30	139	189
Suquamish Tribe	All sources	92	214	132	489	797
	Puget Sound	91	165	58	397	767
Recreational Fishers (compilation of multiple studies)	Marine waters, WA State	–	11–53	1.0–21	13–246	
	Freshwater, WA State	–	6.0–22	–	42–67	

Sources: Adapted from Polissar et al., 2012, Table E-1. Data for recreational fishers is from Table 3, Technical Issue Paper: *Recreational Fish Consumption Rates* (Ecology, 2012). General population data are for consumers only, as opposed to per capita. See Chapters 4 and 6.

Key technical findings

Key findings of this Technical Support Document include the following:

- Significant numbers of people in Washington consume finfish and shellfish. Ecology estimates that between 1.4 and 3.8 million adults in Washington eat finfish or shellfish at least occasionally.
- No survey data currently exist about fish consumption rates specific to the general population in Washington. Statistical evaluation of national fish consumption data may provide useful information about fish consumption among the general population. For estimates based on national data, the methodology developed by the National Cancer Institute provides improved accuracy for episodically consumed foods.
- Regional-specific fish dietary surveys provide technically defensible information about high fish-consuming populations in the Pacific Northwest.

In response to public review comments received by Ecology on Version 1.0 of this Technical Support Document, supplementary information (provided as separate Technical Issue Papers) has been prepared to provide additional detail on topics of specific relevance to the evaluation of fish consumption rates. These topics include:

- Estimating annual fish consumption rates using data from short-term surveys.
- Recreational fish consumption rates.
- Health benefits and risks of consuming finfish and shellfish.
- Chemical contaminants in dietary protein sources.
- Salmon life history and body burdens.

These Technical Issue Papers are provided in Ecology, 2012 (*Supplemental Information to Support the Fish Consumption Rates Technical Support Document*).

Supporting information

In addition to the key findings, this document includes information that allows a more comprehensive understanding of fish consumption patterns in Washington. This information, taken collectively, provides multiple lines of evidence about fish consumption in Washington. For example, water body-specific evaluations, predominantly creel surveys, do provide additional information about fish consumption.

In addition, this document looks at identifying species that are locally harvested[5] and consumed.

- About 68 percent of total fish consumed by the Squaxin Island tribal population is locally harvested. The percentage of total fish consumed that is locally harvested is somewhat higher for the other tribal populations surveyed: approximately 88 percent for the Columbia River Tribes, 72 to 88 percent for the Tulalip Tribes, and 81 to 96 percent for the Suquamish tribe.
- Where possible, data on types of fish consumed and where the fish were obtained are provided, allowing a regional look at fish consumption patterns.
- About 62 percent of shellfish consumed by Squaxin Island tribal populations are locally harvested. The percentage of shellfish that is locally harvested is somewhat higher for the Suquamish Tribe (81 percent), and highest for the Tulalip Tribes (98 percent or higher).

---

[5] The term *locally harvested* is used to identify the source of fish. It is used to distinguish fish harvested locally from fish purchased and coming from unknown and potentially non-local (out of state) sources.

This page purposely left blank for duplicate printing.

Chapter 1: Introduction and Purpose

1.1 Introduction

This report addresses fish consumption among Washington fish consumers, including the general population, tribal populations, and other groups, such as Asian and Pacific Islanders and recreational anglers, who are known to eat large amounts of fish.[6]

The Washington State Department of Ecology (Ecology) currently recognizes two separate default fish consumption rates used to establish regulatory requirements:

- Washington's Model Toxics Control Act (MTCA) Cleanup Regulation includes a default fish consumption rate of 54 grams (1.9 ounces) per day. This value was established in 1991. It is based on information from a survey of Washington recreational anglers in Commencement Bay (Pierce et al., 1981).
- Washington is covered under a federal regulation – the National Toxics Rule. Washington's Water Quality Standards for Surface Waters currently rely on the 1992 National Toxics Rule (57 Fed. Reg. 60848-60923 codified at 40 CFR 131.36), which includes Water Quality Standards for human health protection based on a fish consumption rate of 6.5 grams (0.22 ounce) per day.[7] This value is based on technical evaluations completed by the U.S. Environmental Protection Agency (EPA) in the mid-1980s. It represents the low estimate of national average per capita consumption of fish and shellfish from estuarine and fresh waters (45 Fed. Reg. 79348; U.S. EPA, 1980).[8]

The methods used to develop these two rates included a number of differing assumptions about exposures. The MTCA fish consumption rate of 54 grams per day (g/day) is a recreational rate based on a creel survey from Commencement Bay. The Water Quality Standards default fish consumption rate of 6.5 g/day is the average per capita consumption rate of all (contaminated and non-contaminated) freshwater and estuarine fish for the U.S. population (57 Fed. Reg. 60848-60923 codified at 40 CFR 131.36). This average includes people who never eat fish.

To estimate the average per capita intake of a pollutant due to consumption of contaminated fish and shellfish, the results of an early 1980s seafood dietary survey (U.S. EPA, 1980) were analyzed to calculate the average consumption of freshwater and estuarine fish and shellfish (45

---

[6] For the purposes of this report, *fish consumers* include all people in Washington who eat finfish or shellfish. While there is variability among how much fish is consumed by—both within and among—various population groups, some people never include fish in their diets. These people are considered non-consumers.

[7] The 6.5 grams per day contaminated fish consumption value is equivalent to the average per-capita consumption rate of all (contaminated and non-contaminated) freshwater and estuarine fish for the U.S. population (57 Fed. Reg. 60863).

[8] Moderate and high average fish consumption estimates for the U.S. national population were based on the consumption of fish and shellfish from fresh, estuarine, and marine waters (U.S. EPA, 1989a).

Fed. Reg. 79348). In the absence of estimates of fish dietary information from local fish-consuming populations, an EPA companion guidance document to the National Toxics Rule proposed the following average consumption rates:

- 6.5 g/day to represent a low estimate of average consumption of fish and shellfish from estuarine and fresh waters by the U.S. population.
- 20 g/day to represent a moderate estimate of the average consumption of fish and shellfish from marine, estuarine, and fresh waters by the U.S. population.
- 165 g/day to represent a high estimate of the average consumption of fish and shellfish from marine, estuarine, and fresh waters by the 99.9th percentile of the U.S. population.

In contrast to the low average estimate, the moderate and high average fish consumption estimates for the U.S. population is based on the consumption of fish and shellfish not only from fresh and estuarine waters but also from marine waters (U.S. EPA, 1989a, page 58 and Table 7, page 71).

There have been many scientific and regulatory developments related to fish consumption rates over the past 20 years. These include:

- Acquisition of recent scientific data on finfish and shellfish consumption rates for different population groups.
- Updated approaches used by other state and federal agencies.
- Analysis of uncertainty and variability in finfish and shellfish consumption rates for different population groups and individuals within those groups.
- Analysis of current and potential future exposures resulting from finfish and shellfish consumption.
- Revision of state laws and policies, including MTCA and the Water Pollution Control Act.
- Assertion of tribal fishing rights by tribes.

1.2 Intended audience

Ecology will use this document to engage multiple audiences in discussions on issues related to fish consumption rates.[9] This report is meant to facilitate discussions with interested parties and persons throughout Washington.

To facilitate these discussions, it is important to understand the different ways we express fish consumption rates in this Technical Support Document. In general, a fish consumption rate is presented as grams of fish consumed per day (g/day). For many readers, it is easier to understand a fish consumption rate expressed in ounces per day, or number of 8-ounce meals per week. (An

---

[9] The term *fish* includes all types of finfish and shellfish. When discussing the species that are consumed, fish are categorized by species groupings.

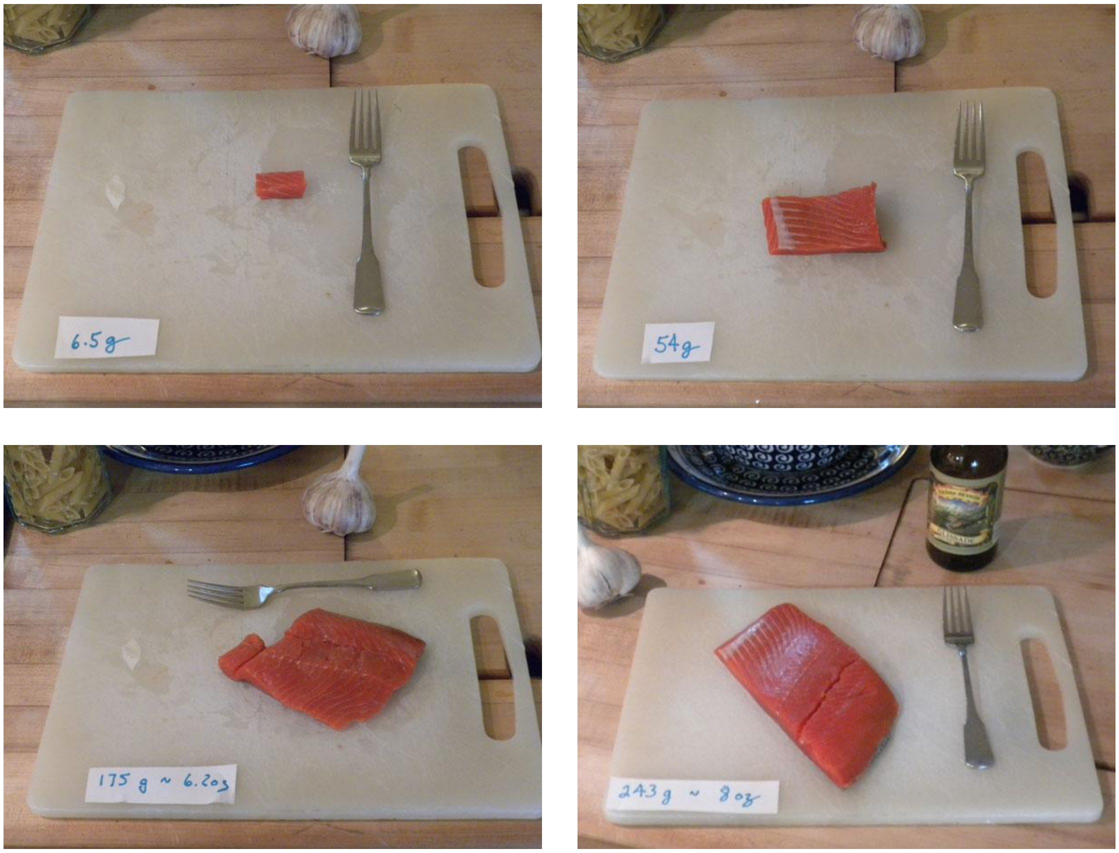
8-ounce meal corresponds to approximately 227 grams.) Another way to express fish consumption is in terms of the frequency of an 8-ounce meal (e.g., once per month, three times per week), or as total pounds of fish per year. Table 2 summarizes the different metrics that are used to describe fish consumption rates.

Table 2. Different Metrics Used to Describe Fish Consumption Rates

Consumption Rate Metric	Examples of Consumption Rates For Each Metric						
Grams per day	6.5	17.5	50	100	260	500	620
Ounces per day	0.23	0.62	1.8	3.5	10	18	22
Number of 8-ounce meals per week	0.2	0.5	1.5	3	8	15	17
Frequency of 8-ounce meals	< one 8-ounce meal per month	Two 8-ounce meals per month	One to two 8-ounce meals per week	Three 8-ounce meals per week	Every day or ½ pound per day	Twice per day or 1 pound per day	1 pound per day plus other forms and uses
Pounds per year	5	15	40	80	200	400	500

Source: Adapted from Swinomish Tribe, 2006, Table 30.

In the absence of population-specific fish dietary information, the U.S. EPA suggest using a default value of 8 ounces (227 grams) as an average meal size for the general adult population (72-kilogram person) for exposure assessments and fish advisories (U.S. EPA, 2000d).



Fish portion sizes (6.5, 54, 175, and 243 grams)

1.3 Purpose of this document

The purpose of this Technical Support Document (Version 2.0) is to compile and evaluate existing data on fish consumption in Washington State. It is a technical document, and is not designed to resolve policy issues associated with using that information to make regulatory decisions. Those issues will be dealt with in separate rulemaking documents and processes.

This Technical Support Document provides useful background information for discussions related to finfish and shellfish consumption rates. The primary question addressed in this document is:

- What is currently known about fish consumption habits and rates for people in Washington?

Specifically, what types of data are available, how much fish do people in various population groups eat, what kinds of fish do they eat, and where do they obtain the fish?

Ecology recognizes that many other considerations factor into calculating protective standards, including acceptable risk levels and exposure parameters (such as exposure duration). These considerations may be relevant to various regulatory discussions. This particular document, however, focuses primarily on technical information related to fish consumption rates.

1.4 Document history

Ecology distributed the *Fish Consumption Rates Technical Support Document, Version 1.0*, for public review in September 2011. The document was prepared to support discussion on whether and how to revise the fish consumption rates in the Sediment Management Standards (SMS) rule. Ecology held several public workshops to discuss the draft report and regulatory implications.

Ecology received several hundred written comments on the draft report. Ecology has reviewed those comments and prepared written responses that are compiled in a separate document. As part of that review, Ecology also performed additional technical analyses to address several issues raised during the public comment period.

Ecology has considered the comments and analyses when revising this Technical Support Document. Significant revisions include the following:

- *General population studies.* Several people recommended that Ecology provide information on fish consumption rates for the general population. Ecology has worked with the University of Washington to review national dietary surveys that provide information on fish consumption rates for the general population, and has included the results of that review in the revised document.
- *Recreational fisher studies.* Several people recommended that Ecology provide information on fish consumption rates for recreational fishers. Ecology reviewed available studies on recreational fishers. Based on that review, Ecology has conducted an

independent assessment, provided in a separate Technical Issue Paper (Ecology, 2012), that details recreational fish consumption studies conducted in Washington. Ecology has incorporated the results of that review into this revised Technical Support Document.

- *Asian Pacific Islander (API) studies.* Several people recommended that Ecology consider additional information on the fish dietary habits of API populations. Ecology has incorporated additional information on API populations into this revised Technical Support Document.
- *Estimating long-term consumption rates.* Several people expressed concerns about using the results from short-term episodic dietary studies to estimate long-term upper percentile fish consumption rates. Ecology has reviewed and evaluated methods for adjusting short-term episodic dietary information to provide fish consumption estimates and percentiles. These statistical corrections were used to estimate annual fish consumption rates for the general population from 2-day national survey data.
- *Salmon.* Ecology received a wide range of comments on salmon, their life cycles and survival strategies, and salmon contaminant body burdens. This document provides fish consumption estimates with and without salmon from several fish dietary surveys of Pacific Northwest populations. Where available, fish consumption estimates are tabulated for anadromous and non-anadromous species. Additional information on salmon contaminant body burdens is provided in Appendix C and in the Technical Issue Paper, *Salmon Life History and Contaminant Body Burdens* (Ecology, 2012).
- *Analysis of regional fish dietary information.* In Version 1.0 of this Technical Support Document, Ecology provided the results of a statistical evaluation from fish dietary surveys of Pacific Northwest populations. Ecology's evaluation provided fish consumption estimates between the 80th and 95th percentiles of the fish consumption distribution. Several people provided comments regarding policy choices embedded in this evaluation. Ecology has reviewed these comments, and in order to facilitate broad consideration in the process of revising the Water Quality Standards for Surface Waters, this version of the Technical Support Document does not provide a recommended range for fish consumption rates. Discussion is provided in Chapter 4.
- *Policy statements and recommendations.* This Technical Support Document is focused on finfish and shellfish resources in the Pacific Northwest, and Washington State fish-consuming populations. It includes information from fish dietary surveys of Pacific Northwest populations and national general population data. Ecology acknowledges that there are many policy decisions associated with estimating fish consumption rates for Washington State fish-consuming populations. Some of these policy issues are noted in Chapter 6. This document, however, does not provide a thorough discussion of policy choices. The issues are identified only to assist readers in a broader understanding of the context in which fish consumption rates are considered.

1.5 Organization of this document

The remainder of this document is organized as follows.

Chapter 2: Washington Fish Resources and Fish-Consuming Populations

Available information indicates that some Washington residents consume locally harvested finfish and/or shellfish. In addition, several population subgroups (including Native Americans and Asian and Pacific Islanders) consume large amounts of finfish and shellfish. This chapter summarizes available information on state water resources that support fishing practices. Regional differences are acknowledged and the size and demographic characteristics of Washington finfish and shellfish consumers and consuming populations are identified.

Chapter 3: Methodology for Assessing Fish Consumption Rate Information

Several approaches are available for developing estimates of finfish and shellfish consumption. Although surveys are generally considered to be the best approach for developing these estimates, a number of design features determine whether a particular survey provides a technically defensible basis for agency decision making. This chapter reviews those design features and outlines the factors considered when evaluating studies.

Chapter 4: Fish Consumption Survey Data that Apply to Washington Fish Consumers

This chapter reviews and analyzes available fish consumption survey data for the general population, Pacific Northwest Native American tribes, Asian and Pacific Islanders, and recreational fishers. It includes a discussion of variability and uncertainty in the survey data, and summarizes key findings.

Chapter 5: Sources of Uncertainty and Variability

When making regulatory decisions, it is important to consider the uncertainties associated with available data and the variability across individuals, fish species, and geographic areas. This chapter provides a high-level summary of important sources of uncertainty and variability in fish consumption surveys used to estimate finfish and shellfish consumption rates.

Chapter 6: Using Scientific Data to Support Regulatory Decisions

This chapter highlights some of the policy choices that will be needed when using fish consumption rates to support regulatory decisions. The discussion includes brief descriptions of particular regulatory issues and a range of examples to illustrate how agencies have resolved each issue.

Appendices

Included here is other fish consumption information used for regulatory decision making including fish species found in Washington, information on additional tribal studies, correspondence from the Columbia River Inter-Tribal Fish Commission and University of Washington, further discussion on the challenges of risk assessment and salmon consumption, a glossary of terms, and a complete list of reference citations presented alphabetically by author.

Chapter 2: Washington Fish Resources and Fish-Consuming Populations

2.1 Introduction

Washington is home to a wide range of water resources that support commercial, recreational, and subsistence fishing and harvesting. Many Washington residents consume some local finfish or shellfish. Several population groups consume larger amounts of finfish and shellfish than the general population. These include members of Native American tribal nations, Asian and Pacific Islanders, and people who fish recreationally (recreational fishers).

Ecology's review of available data on fish harvests identified the commercial, tribal, and recreational harvesting of multiple species, including groundfish, Pacific halibut, coastal pelagic species, highly migratory species, salmon, other anadromous species and eggs, and shellfish. Similarly, recreational sport fishing is structured around a multispecies fishery, and hundreds of thousands of sport anglers harvest fish throughout Washington.

Salmon are of particular importance in Washington, and questions about salmon are discussed at several points in this report. Salmon are harvested from both fresh and marine waters. The Puget Sound basin and the Columbia River basin dominate the areas of harvest. Steelhead and salmon (from both fresh and marine waters) accounted for about half of the recreational sport harvest (close to 400,000 fish) in 2006.

This chapter is organized into the following sections:

- *Fish resources*. A summary of finfish and shellfish resources in Washington.
- *Estimated number of Washington fish consumers.* This section provides rough estimates on the number of adults and children in Washington who regularly eat finfish and/or shellfish.
- *High fish-consuming populations.* This section defines *high fish consumers* and identifies and describes subpopulations in Washington generally known to be high fish consumers.

Washington waters support large finfish and shellfish populations and commercial, tribal, and recreational harvests.

2.2 Washington fish resources

Washington has more than 500 miles of Pacific coast shoreline and over 2,000 combined miles of Puget Sound, San Juan Islands, Strait of Juan de Fuca, and Hood Canal shoreline. This shoreline provides habitat for marine finfish and shellfish. In addition, the state has 4,000 rivers and streams, stretching over 50,000 miles. Many streams and rivers have seasonal salmon and steelhead runs. State waters also include more than 7,000 lakes, with over 2,500 lakes at alpine elevations, and more than 200 reservoirs that provide additional fishing opportunities. Many freshwater areas are open for fishing year-round (WDFW, 2010).

A large variety of finfish and shellfish are available for harvesting in Washington (WDFW, 2010, p. 17–30). The Washington Department of Fish and Wildlife (WDFW) has identified more than 50 species of edible freshwater fish and almost as many in marine waters (WDFW, 2010, p. 17–30). (See Appendix C for information on finfish and shellfish species harvested in Washington.)

A study to summarize the economic benefits of Washington's non-treaty commercial and recreational fisheries provides information on the valuation and numbers of commercial and recreational finfish and shellfish harvested throughout Washington. In 2006, commercial fish landings from non-treaty fisheries totaled more than 109 million pounds. The Washington coastal area is the largest contributor to commercial fish harvesting, accounting for 85 percent of total pounds landed (WDFW, 2008a).

The fish consumption rate tabulations in this technical support document are derived from national fish dietary data and from fish dietary surveys from the Pacific Northwest. The tribal fish dietary surveys from the Pacific Northwest document fish locally harvested and consumed. Independent and separate documentation from three different Washington State agencies (WDFW, Washington State Department of Health [DOH], and Ecology) document the harvest and consumption of local aquatic resources, including finfish and shellfish. However, data gaps remain regarding the exact locations of where fish and shellfish are harvested in Washington and how the fish are then made commercially available for consumption.

2.2.1 Washington's commercial fisheries

Washington's commercial fisheries include harvest of groundfish, Pacific halibut, coastal pelagic species, highly migratory species, salmon (including eggs), other anadromous species, and shellfish. In 2006, nontribal commercial fish landings from Washington fisheries totaled approximately 109.4 million pounds.

In 2006, groundfish (bottom-dwelling fish or bottomfish) composed the state's largest commercial fishery. Groundfish accounted for 54 percent of the commercial catch from Washington waters, with approximately 59.2 million pounds landed. Shellfish landings represented the state's second-largest commercial fishery, accounting for almost 25 percent of the commercial catch, with approximately 25.8 million pounds landed in 2006.

Salmon is a major contributor to Washington’s commercial fishing industry. Salmon landings from Washington waters totaled about 11 million pounds, accounting for about 10 percent of the commercial catch in 2006.

Table 3 illustrates the extent of Washington’s commercial fisheries, showing pounds of fish harvested from Washington non-treaty fisheries in 2006.

Table 3. Commercial Fish Landings from Washington Non-treaty Fisheries in 2006

Species	Pounds Landed
Groundfish (excluding halibut)	59,217,924
Total shellfish	25,789,641
Salmon	11,020,228
Coastal pelagic species	8,233,078
Highly migratory species	4,802,666
Other anadromous fish and eggs	158,621
Pacific halibut	135,868
Total commercial pounds landed of finfish/shellfish	109,358,026

Source: Adapted from WDFW, 2008a, Table 1, p. 6.

2.2.2 Washington’s recreational fisheries

Traditionally, Washington’s most intense freshwater fishing activity begins during the last weekend in April. Based on estimates from WDFW, over 300,000 anglers fish during opening weekend of the lowland lakes season. To meet this demand, WDFW stocks about 19 million trout and kokanee fry annually. Another 3 million catchable trout are planted in lakes and streams. In addition, many lakes receive additional sterile rainbow trout. Most rivers and streams throughout Washington are managed to produce wild trout, coastal and west slope cutthroat, salmon, and steelhead (WDFW, 2010).

An estimated total of 824,000 people fished in Washington in 2006, including both finfishing and shellfishing. Of these, an estimated 725,000 anglers (88 percent of the total) were state residents who fished a combined total of about 8.5 million days that year. This equals 93 percent of all fishing days available for licensed recreational sport fishing (WDFW, 2008a).

Marine recreational fishing and shellfishing occurs along more than 500 miles of the Pacific Coast shoreline and more than 2,000 combined miles of shoreline throughout Puget Sound, the San Juan Islands, the Strait of Juan de Fuca, and Hood Canal (WDFW, 2008a). As previously noted, freshwater recreational fish inhabit more than 4,000 rivers and streams extending over 50,000 miles, 7,000 lakes, and 200 reservoirs (WDFW, 2010, 2012). The following are selected highlights of recreational sport fishing and shellfishing that identify the species available for recreational anglers across Washington:

- Recreational fishing for shad on the Columbia River with several million shad passing through Bonneville Dam annually.
- WDFW lists state record catches for more than 50 freshwater species of fish (e.g., rainbow trout, Beardslee rainbow trout, brown trout, and numerous other trout species).
- Recreational sturgeon fishing on the Columbia River.
- Marine recreational seasonal fishing for lingcod, halibut, and rockfish as well as other marine bottomfish.
- Recreational shellfishing for oysters, clams, shrimp, and crab throughout Puget Sound, Hood Canal, the San Juan Islands, and the Strait of Juan de Fuca.

Recreational sport fishers harvest finfish in fresh and marine waters and shellfish along marine shorelines. Approximately 22 million trout and kokanee are stocked annually in lakes and inland streams and are available to recreational anglers. Tables 4 and 5 list information on the 2006 sport finfish and shellfish harvests, respectively. These numbers demonstrate the extent of recreational fishing in Washington.

Approximately two-thirds of the 2006 catch for bottomfish was harvested in coastal waters, with the remaining one-third harvested from the marine waters of Puget Sound.[10] Approximately 74 percent of the steelhead and 95 percent of the sturgeon harvested from Washington waters in 2006 were from the Columbia River and its tributaries.

Table 4. Number of Recreational Finfish Caught in Washington Waters in 2006 by Species and Region

Species/Group	Number of Finfish Harvested from each Catch Region				
	Puget Sound	Coast	Columbia River*	Unknown	Total
Bottomfish	112,457	295,151	---	---	407,608
Salmon – freshwater	98,576	7,186	65,817	1,227	172,806
Steelhead	12,709	15,415	80,294	477	108,895
Salmon – marine	65,423	43,027	---	---	108,450
Albacore	---	18,941	---	---	18,941
Sturgeon	203	456	15,695	182	16,536
Pacific halibut	2,727	6,977	692	---	10,400
Total	292,095	387,153	162,498	1,886	843,636

Source: Adapted from WDFW, 2008a, Table 6, p. 17.

* Columbia River region includes the Columbia River and all tributaries and the Snake River.

---

[10] The term *coastal waters* refers to waters having a coastline that forms the boundary between land and freshwaters and marine and/or estuarine waters. This term encompasses all freshwaters of statewide significance (lakes, rivers, streams, etc.) and those marine and/or estuarine waters extending from the landward edge of a barrier beach or shoreline of coastal bay to the outer extent of the continental shelf.

Table 5. Pounds of Shellfish Taken Recreationally From Washington Waters in 2006, by Species and Region

Species/Group	Pounds of Shellfish Harvested from each Catch Region					
	North Puget Sound	South Puget Sound	Strait	Coast	Columbia River	Totals
Dungeness crab	3,330,004	271,167	261,540	---	---	3,862,711
Razor clams	---	---	---	3,601,000		3,601,000
Oysters	19,129	632,966	---	---	---	652,095
Other clams	93,038	252,628	---	---	---	345,666
Shrimp	23,520	87,996	1,950	---	---	113,466

Source: Adapted from WDFW, 2008a, Table 7, p. 17.

All values are in pounds except oysters, which are in number of oysters harvested.

Salmon were harvested in both fresh and marine waters, with approximately 60 percent of the salmon harvest occurring in marine waters. Puget Sound salmon accounted for approximately 60 percent of all salmon harvested in marine waters. In fresh water, approximately 57 percent of salmon are harvested in Puget Sound streams and 38 percent are from the Columbia River and its tributaries.

Dungeness crab taken from north Puget Sound waters accounted for more than 85 percent of the 2006 statewide harvest. Razor clams are only harvested from coastal beaches. Tens of thousands of recreational sport clammers harvest razor clams on weekends during clamming season (WDFW, 2008a).

2.3 Washington fish-consuming population

Washington is home to a culturally and ethnically diverse population that is projected to become more diversified over the next 20 years. The Washington Office of Financial Management (OFM) provides the following demographic information (U.S. Census Bureau, 2000, 2010)[11]:

• Total Washington Population as of April 1, 2010	6.72 million
Adults (74 percent of the population is estimated at over 18)	5.14 million
Children (between 0 and 18 years of age)	1.71 million

OFM projects that the Washington population will increase by 1.8 million people in the next 20 years: [12]

---

[11] Population estimates are based on census data, and may vary depending on the census accounting procedures used to generate estimates for specific subpopulations. Therefore, subpopulation estimates and totals may not align perfectly.

[12] Population projections are provided for illustrative purposes; they are not intended as precise estimates. Population projections presented in this document do not reflect 2012 redistricting updates.

- Projected Total Washington Population, 2030	8.54 million
Projected children (between 0 and 18 years of age) 2030	2.06 million

2.3.1 Estimated number of fish consumers in Washington

The general population is made up of people with a variety of dietary preferences. Some consume fish frequently, some infrequently, and some potentially never. (However, even people who report they don't eat fish may consume some fish in processed foods like salad dressing, Worcestershire sauce, and cheese spread.) Per capita rates that take into account the entire population will differ from rates derived from consideration of so-called *consumer only* data. For protection of people who eat fish, the population of interest is generally considered to be fish consumers (CalEPA 2001, page 13; Oregon DEQ 2008; U.S.EPA 2002b).

People consume finfish and shellfish obtained from a variety of sources. Information about fish consumed by the general Washington population is available only through estimates.[13] While there are uncertainties associated with these estimates, they are useful in providing context to the discussion about fish consumption rates.

First, the total number of fish consumers was estimated. A *fish consumer* is someone who eats finfish or shellfish at least occasionally. Then a definition of *high fish consumer* was used to suggest the number of people in the general population at the high end of the exposure distribution. These estimates provide only a rough number of fish consumers and no information about the source of the fish. Ecology also reviewed available information on certain ethnic groups that consume fish from local waters.

To estimate the number of fish consumers in Washington, and how much fish they consume, Ecology considered multiple estimation methods. This is consistent with the approach taken by the Oregon Department of Environmental Quality (Oregon DEQ) Human Health Focus Group.

Using 2010 demographic information provided by the Washington OFM, Ecology estimates that between 1.4 and 3.8 million Washington adults (and approximately 290,000 Washington children 0 to 18 years old) are fish consumers. These upper and lower estimates were developed using two different methods, as described below:

- *Low Estimate: Based on national survey data.* The first approach resulted in the lower of the two estimates. It was developed using Washington population data and information on the percentage of fish consumers reported in *Estimated Per Capita Fish Consumption*

---

[13] These estimates use the EPA 2002 data and are consistent with the methodology used by the Oregon Human Health Focus Group. They do not use the National Health and Nutrition Examination Survey (NHANES) results because these estimates were developed before that work was complete.

in the United States (U.S. EPA, 2002a).[14] For this estimate of fish consumers in Washington, Ecology assumed that Washington dietary habits are similar to those for the United States as a whole. The Oregon DEQ Human Health Focus Group used this approach to prepare estimates of fish consumers in Oregon.[15] (See Chapter 4 for additional information on estimated United States per capita fish consumption.)

  - *Adults.* EPA found that 28 percent of adults interviewed in the national survey were fish consumers (U.S. EPA, 2002a, Section 5.1.1.1, Table 4). Assuming that a similar percentage of Washington's 5.1 million adults also consume fish, Ecology estimates that approximately 1.4 million adults in Washington currently eat some amount of fish.
  - *Children.* EPA found that 16 to 19 percent of children (ages 0 to 18) included in the national survey were fish consumers (Moya, 2011, personal communication).[16] Assuming that 17 percent of Washington's 1.7 million children also consume fish, Ecology estimates that there are approximately 290,000 children in Washington who currently eat some amount of fish.

- *High Estimate: Based on Washington State Department of Health survey.* The second approach resulted in the higher estimate. It was developed using Washington population data and information compiled by the DOH. DOH used the Behavioral Risk Factor Surveillance System (BRFSS) to compile information on fish consumption habits of randomly selected Washington residents.[17] This work was done over a 4-year period; it was designed to improve DOH's understanding of the percent of the Washington population that consumes fish.

Washington State Behavioral Risk Factor Surveillance System

The BRFSS telephone survey is a valuable health management tool used by DOH to collect health-based information and monitor the public's behavioral risk factors that may contribute to a person's health. The BRFSS primarily collects data on chronic diseases, injuries, infectious illnesses, and the behavioral factors underlying these conditions.

---

[14] This percent value may underestimate the fraction of fish consumers in Washington State because other parts of the United States do not have the fisheries resources available in Washington State.

[15] Ecology acknowledges the limitations of the national fish dietary data; this approach employed a 2-day dietary recall survey methodology where respondents who did not report eating fish on one of the two survey days were counted as non-consumers and averaged with consumers as a zero. As noted by the EPA 2011 *Exposure Factors Handbook*, p. 10-16, "… short-term consumption data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given fish species. This is particularly true for the tails (extremes) of the distribution of food intake. Because these are 2-day averages, consumption estimates at the upper end of the intake distribution may be underestimated are used to assess acute (i.e., short-term) exposures."

[16] Approximately 18 percent of the U.S. general population ages 16 – 21 are fish consumers; approximately 31 percent of the U.S. general population ages 20 – 50 are fish consumers. Information is based on EPA's reexamination of the National Health and Nutrition Examination Survey (NHANES) and the 2002 per capita fish consumption report.

[17] The BRFSS is sponsored by the U.S. Centers for Disease Control and Prevention (CDC) and is a probability-based telephone survey of non-institutionalized adults, ages 18 years and over.

- DOH found that in 2002 and 2004, 78 percent and 74 percent, respectively, of adults in Washington consumed store-bought fish. In 2005, 57 percent of the adults surveyed reported eating fresh fish purchased at a local grocery store or fish market (frozen fish excluded). Among Washington fish consumers, 44 percent consumed salmon, 20 percent consumed halibut, 13 percent consumed cod, and 6 percent consumed tuna.
- Although these data were intended for use by DOH in developing fish consumption advisory programs, Ecology, after consultation with DOH, determined that the information is appropriate for estimating the total number of fish consumers in Washington as needed for this report.
- Working with DOH, Ecology estimated that between 2.9 and 3.8 million Washington adults currently consume some amount of finfish and/or shellfish. Table 6 provides estimates of Washington fish consumers calculated by Ecology using the DOH data.

Table 6. Estimated Washington Fish Consumers Based on Washington DOH Survey Data

Years for Projected Population Estimates	Estimated number of Washington adults who consume:		
	Store-bought fish	Fish from local stores or markets	Salmon
2010	3.80 million [a]	2.93 million [b]	1.67 million
2030	4.88 million	3.76 million	2.90 million

a. This estimate assumes 74 percent of the total adult population consuming store-bought fish, per the DOH 2004 data.

b. This estimate assumes 57 percent of the total adult population consuming fresh fish from local stores or markets, per the DOH 2005 data.

Population projections are included to illustrate that estimates of total fish consumers in Washington are expected to increase as the population grows.

2.3.2 Estimated number of high fish-consuming adults

Pacific Northwest fish dietary information shows that certain populations—Native American tribes, Asian Pacific Islanders, and recreational fishers—consume fish at much higher rates than the average U.S. consumer and at higher rates than those used to establish surface water cleanup standards. Because these populations consume fish at higher rates than the national rates used in Ecology's regulations, their exposure to contaminants in fish may be underestimated and these populations may therefore be at a higher risk. For this reason, Ecology has estimated the number of high fish consumers in the general population. The estimate is intended only to provide

Fish consumption-related BRFSS telephone survey questions

BRFSS telephone survey questions related to fish dietary habits provide DOH with information on:

- Types and frequency of finfish consumption.
- Perceptions about the benefits of eating fish (are fish healthy to eat).
- How, where, or in what form the public receives information about fish health advisories that limit fish consumption based on mercury contamination.
- Whether people are following the fish advisories.
- Regional differences regarding frequency and types of fish consumed.

context; it does not provide information on where these consumers obtain their fish and shellfish. Specifically, it does not address the question of whether this is locally harvested.[18]

Information elsewhere in this report notes that many people in Washington consume fish from local waters—for example, recreational anglers.

For purposes of this estimate, *high fish consumers* are persons who consume fish at or above the 90th percentile of the national per capita fish consumption rate. The fish consumption rate that corresponds to the 90th percentile national per capita consumption depends on the dataset and statistical method used. The choice for defining high fish consumers this way was made for illustrative purposes. It is consistent with EPA regulatory policy and procedures and is the definition used by the Oregon Human Health Focus Group.

Selected results from BRFSS telephone survey

- In 2005, about 44 percent of all adults surveyed consumed salmon in the past 30 days.
- In 2005, about 20 percent of all adults surveyed consumed halibut in the past 30 days.
- In 2005, about 13 percent of all adults surveyed consumed cod in the past 30 days. All other species were consumed by <10 percent of survey participants.
- In 2004, about 74 percent of all adults surveyed followed fish advisories when they thought the fish advice applied to them. However, only about 44 percent of all adults surveyed thought the fish advisory applied to them.
- In 2004, about 98 percent of the pregnant women surveyed followed fish advisories when they thought the fish advice applied to them. However, only about 48 percent of the pregnant women surveyed thought the fish advisory applied to them.
- In 2004, about 35 percent of all adults surveyed reported eating sport fish in the past year harvested from Washington State waters. Among different races, about 47 percent of adult American Indians, 38 percent of Pacific Islanders, 23 percent of Asians, and 19 percent of Blacks reported eating sport fish in the past year.
- In 2004, about 35 percent of adults living in Western Washington counties (Clallam, Clark, Cowlitz, Grays Harbor, Jefferson, King, Kitsap, Lewis, Mason, Pacific, Pierce, San Juan, Skagit, Skamania, Snohomish, Thurston, Wahkiakum, and Whatcom) reported eating any sport fish in the past year. About 40 percent of adults living in counties along the Columbia River reported eating any sport fish in the past year, while 34 percent of adults living in Puget Sound counties and 57 percent of adults living in outer coastal counties reported eating sport fish in the past year.

---

[18] The term *locally harvested* is used to identify the source of fish. It is used to distinguish fish harvested locally from fish purchased and coming from unknown and potentially non-local (out of state) sources.

Based on EPA's *Estimated Per Capita Fish Consumption in the United States*, the 90th percentile of the estimated national fish consumption rate for adult fish consumers only corresponds to 250 g/day (U.S. EPA, 2002a).[19] (250 grams is approximately 0.55 pound or 8.8 ounces.) This value is used to define high fish-consuming adults in this Technical Support Document. (See Chapter 6 for a discussion of per capita vs. consumer-only fish consumption rates.)

Ecology has also evaluated national fish dietary information using data from the U.S. Department of Agriculture's National Health and Nutrition Examination Survey (NHANES), 2003–2006. This analysis is discussed in Chapter 4. Based on this evaluation, the 90th percentile of the estimated national per capita fish consumption for adult consumers is in the range of 42.5 g/day to 128 g/day, depending on the statistical method used.

Ecology estimates that between approximately 140,000 and 380,000 Washington adults are high fish consumers (Table 7). Based on OFM population projections, this number could increase by 27 percent over the next 20 years.

2.3.3 Assumptions

This estimate is based on a number of assumptions that Ecology believes to be reasonable:

- Between approximately 1.4 million and 3.8 million Washington adults consume some amount of fish on a regular basis. As described in the previous sections, this range is based on current population data and estimates indicating that between 28 and 74 percent of Washington adults regularly consume fish.[20]
- *High fish consumers* are defined as people who consume more than the 90th percentile estimate of finfish and/or shellfish per day.[21] The 90th percentile of the fish consumption distribution may be based on national data as evaluated by EPA in 2002 or by Ecology in 2012 using the 2003–2006 NHANES data. Estimates of adult fish consumption rates vary depending on the statistical methodology used to evaluate the data.
- The dietary habits and patterns for Washington fish consumers are similar to those reported for the United States fish consumers.[22]

---

[19] Corresponds to the 90th percentile intake of finfish and shellfish for adult consumers only, based on uncooked fish weight. See U.S. EPA, 2002a, Section 5.2.1.1, Table 4.

[20] The 2003 – 2006 NHANES dietary information provides reasonably comparable low end percent estimates of fish consumers as evaluated in EPA, 2002, and Polissar et al., 2012.

[21] Unless otherwise noted, in this document the term *fish consumption rate* refers to consumption of both finfish and shellfish.

[22] This assumption is discussed further in the conclusions to this chapter.

Table 7. Estimated Number of Fish Consumers among the General Washington Adult Population

Year	Total Population of Washington Adults	Estimated Number of Washington Adult Fish Consumers		Estimated Number of Washington Adults who are High Fish Consumers (90th percentile or above)	
		Low Estimate	High Estimate	Low Estimate	High Estimate
2010	5.14 million	1.44 million	3.81 million	144,000	381,000
2030	6.59 million	1.85 million	4.88 million	185,000	488,000

As noted, estimates of fish consumption that correspond to the 90th percentile of the distribution may vary depending on the statistical methods used to evaluate the national data. Regardless of the national dataset used and the statistical methodology used to evaluate the national data, population estimates for Washington State fish-consuming adults based on the 90th percentile of the fish consumption distribution indicate that there are a large number of adults in Washington who consume fish (for adult low and high estimates approximating 30 to 75 percent of the total Washington State population). Note that the information used for estimates of fish consumption among the general adult population is for total fish consumed from all sources.

2.3.4 Estimated number of high fish-consuming children

For purposes of this report, Ecology defines children as high fish consumers if they consume fish at or above the 90th percentile of the estimated national per capita fish consumption rate for children. As discussed above, the fish consumption rate that corresponds to the 90th percentile depends on the dataset and statistical method used to evaluate the data. Based on EPA's *Estimated Per Capita Fish Consumption in the United States*, the 90th percentile of the estimated national per capita fish consumption rate for children who eat fish corresponds to 190 g/day (U.S. EPA, 2002a).[23] (190 grams is approximately 0.42 pound or 6.7 ounces.) Ecology's evaluation of the NHANES 2003–2006 data, as described in Section 4.2.2, did not include estimation of fish consumption rates for children.

Ecology estimates that there are approximately 29,000 Washington children who are high fish consumers (Table 8). Based on OFM population projections, this number could increase by 83 percent over the next 20 years.

This estimate is based on the following assumptions that Ecology believes to be reasonable:

- Approximately 290,000 Washington children eat some amount of fish on a regular basis. As discussed in an earlier section, this estimate is based on current population estimates and national survey results that indicate that 16 to 19 percent of children reported eating some amount of finfish or shellfish.

---

[23] Corresponds to the 90th percentile intake of finfish and shellfish for consumers only, age 14 and under. Based on uncooked fish weight.

- Children are defined as high fish consumers when they consume more than the 90th percentile estimate of finfish and/or shellfish per day. The 90th percentile of the fish consumption distribution to define a high fish consumer may be applied to the national data as evaluated by the EPA (U.S. EPA, 2002a, Section 5.2.1.1, Table 4) or to the 2003–2006 NHANES data. Estimates of children's fish consumption will vary depending on the statistical methodology used to evaluate the data. The information in Table 8 suggests that about 20 percent of the total children in Washington State are fish consumers.
- The dietary habits and patterns for Washington fish consumers are similar to those reported for the United States fish consumers.

Table 8. Estimated Number of Child Fish Consumers among the General Washington Population

(Children Younger Than 18 Years Consuming Large Amounts of Finfish or Shellfish)

Year	Total Population of Children (18 and younger)	Estimated Number of Washington Child Fish Consumers	Estimated Number of Washington Children who are High Fish Consumers (90th percentile or above)
2010	1.71 million	290,000	29,000
2030	2.06 million	350,000	35,000

2.4 High fish-consuming populations

Some population groups consume especially large amounts of finfish and shellfish as part of traditionally influenced diets. These include Native Americans and Asian, Pacific Islanders, and subsistence and recreational fishers.

2.4.1 Washington Native American Tribes

Washington is home to 29 federally recognized and seven non-federally recognized Native American tribes (Governor's Office of Indian Affairs, 2010). Traditional fishing areas for tribes cover essentially all of Washington.

The Washington OFM estimates there are approximately 104,000 American Indian and Alaska natives in Washington. Approximately 70 percent of the American Indian and Alaska native population is 18 years of age or older (73,500 adults) (U.S. Census Bureau, 2000, Table 2). OFM estimates there are 33,600 American Indian and Alaska natives between the ages of 0 and 18 years.

OFM projects that the total number of Native Americans in Washington will increase from 104,000 in 2010 to approximately 146,000 by the year 2030:[24]

---

[24] 2010 population numbers are based on the 2010 Census redistricting data. 2030 estimates are as of the OFM 2006 Population Projections by Age, Sex, and Race.

• Population of American Indian and Alaska natives in Washington	104,000
Adults (70 percent of population is estimated at over 18)	73,500
Children (between 0 and 18 years of age)	33,600
• 2030 Population Projection	146,000

2.4.2 Asian and Pacific Islanders

Asian and Pacific Islander (API) populations include Native Hawaiians and peoples from other Pacific islands. The Washington OFM estimates there are approximately 522,000 Asian and Pacific Islanders currently residing in Washington (U.S. Census Bureau, 2000, Table 2). Finfish and shellfish consumption among this population in Washington has been documented. Approximately 75 percent of the current API population is 18 years of age or older (405,000 adults) (Sechena et al., 1999). There are 138,000 Asian and Pacific Islanders between the ages of 0 and 18 years.

OFM projects that the total number of Asian and Pacific Islanders in Washington will increase from 522,000 in 2010 to approximately 825,000 by the year 2030:[25]

• Population of Asian and Pacific Islanders in Washington	522,000
Adults (75 percent of the population is estimated at over 18)	405,000
Children (between 0 and 18 years of age)	138,000
• 2030 API Population Projection	825,000

2.4.3 Subsistence and recreational fishers

Approximately 824,000 people fished in Washington State during 2006; of these, 725,000 were Washington residents and 99,000 were nonresidents. Washington residents fished a total of 8.5 million days in 2006, an average of 12 days per angler (U.S. Department of the Interior and U.S. Department of Commerce, 2008).

Washington is home to some number of persons engaged in a subsistence lifestyle. Considerations related to subsistence fishing for Native American tribes in the Pacific Northwest have been identified (Donatuto and Harper, 2008; Harper and Harris, 2008). However, due to a lack of data, at this time Ecology is unable to estimate the number of subsistence fishers in Washington.

---

[25] 2010 population numbers are based on the 2010 Census redistricting data. 2030 estimates are as of the OFM 2006 Population Projections by Age, Sex, and Race.

2.5 Sources of Fish Consumed

Fish consumption rate tabulations in this technical support document are derived from national fish dietary data and fish dietary surveys from the Pacific Northwest. The tribal fish dietary surveys from the Pacific Northwest provide information about the types of fish that are locally harvested and consumed. These tribal fish dietary surveys document locally harvested fish from usual and accustomed tribal treaty areas throughout the Columbia River basin and throughout Puget Sound.

For example, the 1994 Columbia River Inter-Tribal Fish Consumption Survey reflects fish harvest rates throughout the Columbia River basin for over 80% of the respondents.

Independent and separate documentation from three different Washington State agencies (WDFW, DOH, and Ecology) document the harvest and consumption of local abundant aquatic resources, including finfish and shellfish. For example, WDFW has documented the amounts of different shellfish harvested from various regions in Washington State (see Table 5).

Data gaps remain regarding exact locations where fish and shellfish are harvested in Washington State, and information about their commercial availability in state-wide grocery stores and local food markets.

2.6 Summary

From current demographic information, Ecology has estimated the total number of Washington fish consumers. Ecology reached its estimate after working with OFM to use census data and applying national and Washington fish consumption rate estimates to the general Washington population. There may be some variation in the adult and child fish-consuming population estimates for Washington State depending on the dataset and statistical methods used to evaluate national fish dietary information. Adult and child fish-consuming population estimates presented in this report are based on a similar analysis conducted by the 2008 Oregon DEQ Human Health Focus Group Report (Oregon DEQ, 2008).

Ecology believes that the population estimates for Washington State adult and child fish consumers provided in this report are reasonable estimates that help gauge and approximate the number of fish consumers. There are a large number of adults and children in Washington State who routinely consume finfish and shellfish.

According to Ecology's analysis, there are between 1.4 and 3.8 million Washington adults (18 years of age or older) who are fish consumers.[26] The number of adult fish consumers is

---

[26] This includes a large number of recreational anglers. For example, the Washington Department of Fish and Wildlife estimates there were 824,000 recreational anglers (both finfishing and shellfishing) in Washington in 2006.

projected to increase by up to 27 percent as Washington's population grows over the next 20 years.

Ecology estimates that approximately 290,000 Washington children (0 to 18 years of age) consume fish. It should be noted that this estimate was developed using national survey data for the general population. Studies have shown that people living in coastal states tend to consume finfish and shellfish at a higher frequency and higher rates than inland states (Moya, 2004).[27] Ecology is not aware of Washington surveys that have examined child fish consumption frequency for the general population. The number of Washington children who eat some type of fish is also projected to increase as Washington's population grows over the next 20 years.

For this report, Ecology defined *high fish consumers* as all Washington adults and children who consume finfish and/or shellfish at or above the 90th percentile estimates from surveys of national per capita consumption. Based on data presented by the EPA (U.S. EPA, 2002a), these estimates correspond to 250 g/day and 190 g/day for adults and children, respectively.

- Ecology estimates that there are between 140,000 and 380,000 Washington adults who are high fish consumers. Ecology believes that the high end of this range provides a reasonable estimate of the number of high fish consumers in Washington. The high end of the range is based on information collected by the Department of Health on fish consumption habits of Washington residents.
- Ecology estimates that there are approximately 29,000 Washington children who are high fish consumers.

Certain population groups, including Native Americans and Asian and Pacific Islanders, consume large amounts of finfish and shellfish.[28]

- According to OFM estimates, there are approximately 104,000 Native American and Alaska natives in Washington.
- According to OFM estimates, approximately 522,000 Asian and Pacific Islanders live in Washington.

In summary, considerable quantities of finfish and shellfish are harvested for consumption in Washington, both recreationally and commercially. Many Washington residents harvest and presumably consume finfish and shellfish from local waters (WDFW, 2008a, 2012). High fish consumers include several population groups known to consume larger amounts of finfish and shellfish than the general population.

---

[27] National fish consumption studies are typically carried out over a broad geographical area, including multiple states. Consequently, national studies may underestimate the rates and frequencies for states like Washington.

[28] Chapter 4 discusses further the consumption rates, patterns, and species consumed by Native Americans and Asian and Pacific Islanders.

This page purposely left blank for duplicate printing.

Chapter 3: Methodology for Assessing Fish Consumption Rate Information

3.1 Introduction

Researchers use a variety of methods for estimating the amount of finfish and shellfish consumed. Surveys are generally considered to be the best approach for collecting data; however, a number of design features determine whether a particular survey will provide a technically defensible basis for agency decision making. *Technical defensibility* means that the survey stands up to technical and scientific scrutiny and provides a solid technical basis for regulatory decisions. Among other factors, a survey that is technically defensible: (1) uses sound scientific methods and survey methods that have been peer reviewed and tested; (2) employs interviewers who are trained and/or questionnaires that follow accepted guidance; (3) presents clear reporting and conclusions that are supported by the data; (4) studies sample populations that represent the population of concern and consider temporal, geographic, and cultural aspects of fish consumption; (5) uses current information; and (6) provides results that can be used to support regulatory decision making. The measures of technical defensibility are described in more detail at the end of this chapter.

Different surveys are designed for different purposes. This chapter reviews the design features of various methods for collecting information about finfish and shellfish consumption. The purpose of this review is to identify the specific factors that Ecology considered when evaluating fish consumption surveys.

Regional-specific dietary information about people who eat finfish and shellfish is useful in providing a weight of evidence for evaluating the fish-consuming habits and patterns of fish consumers in Washington. Fish dietary information from the Pacific Northwest indicates that Washington State's fish-consuming populations eat more fish than what is reflected in the rates used to establish regulatory standards.

To provide more information when making risk management decisions, Ecology understands that it would be desirable to have *statewide* fish dietary data and information regarding the fish consumption habits and patterns of *all* Washington State fish consumers. However, in the absence of a statewide fish dietary survey, Ecology believes that the fish dietary information from Pacific Northwest fish-consuming populations such as tribal populations is useful and relevant for making sound risk management decisions that protect Washington State's residents. Ecology believes that there is sufficient credible fish dietary information to provide fish consumption estimates for fish-consuming populations in Washington State. If the assumption is made that the fish consumption habits and patterns among the Washington State general fish-consuming population are similar to those of the U.S. general population of fish consumers, then the fish dietary estimates for the U.S. general population may be used to provide estimates for the Washington general population. Ecology notes that differences between the Washington population and the U.S. general population do exist: for example, status as a coastal state has the possibility of affecting fish consumption patterns.

The Pacific Northwest surveys have all followed a similar design: dietary recall complemented by food frequency questionnaires; they have been scientifically peer-reviewed (CRITFC, 2012; University of Washington, 2012), and have included reviews of study design and analysis of the results of the dietary surveys. The surveys have been considered and utilized by EPA on both a regional and national basis for environmental regulation as well as by the State of Oregon. These fish dietary surveys, together with other dietary information, provide a reasonable and technically sound basis to estimate the fish consumption habits and patterns for Washington State fish consumers.

This chapter is organized into three sections:

- *Surveys and other approaches used to estimate fish consumption.* This section reviews the various methods that have been used or are available for collecting data about dietary habits and patterns surrounding fish consumption.
- *Factors to consider when evaluating survey results.* This section identifies key design or implementation features that impact the quality of individual surveys.
- *Establishing technical defensibility*. This section describes the methodology Ecology used in assessing the technical defensibility of fish consumption survey information and results. The methodology explained here is then applied in the next chapter to surveys pertinent to Washington.

3.2 Surveys and other approaches used to estimate fish consumption

The various approaches to collecting information on finfish/shellfish dietary habits and patterns include telephone surveys, mail surveys, food diaries, personal interviews, and creel surveys (U.S. EPA, 1992). Each method has certain limitations, including bias, error, and variability (U.S. EPA, 1992; Moya et al., 2008). Ecology thoroughly examined the methodology used in fish consumption surveys. To determine quality and ensure utility for each survey examined, Ecology evaluated experimental design, target population, sample size, location, and potential bias (Ecology, 1999). This analysis aids general understanding and identifies the limitations and utility of the available data.

Fish dietary survey methodologies and limitations, as described in this report, are consistent with EPA guidance for conducting fish consumption surveys (U.S. EPA, 1992, 1998). Another approach, a dietary *market basket* survey, is used by EPA's Office of Pesticide Programs to evaluate aggregate exposure to pesticide residues in food to which consumers may be exposed. This is a different approach that analyzes exposure to a single chemical by multiple pathways and routes of exposure. Market basket surveys conducted by EPA's Office of Pesticide Programs are statistically designed and executed on a single-serving basis at the point of sale to the consumer (U.S. EPA, 2000a).

Five fish consumption survey methods, and the strengths and weaknesses of each approach, are briefly described below.

3.2.1 Creel surveys

Creel surveys estimate fish consumption by interviewing anglers[29] on site. Using the number of fish caught at a given location divided by the number of people who will consume the catch, creel surveys can determine a fish consumption rate (Moya, 2004). The Technical Issue Paper entitled *Recreational Fish Consumption Rates* (Ecology, 2012) provides a more detailed review and analysis of fish consumption rates for recreational fishers.

A number of creel surveys have been conducted in Washington. Examples are:

- Landolt, M.L., Hafer, F.R., Nevissi, A., Van Belle, G., Van Ness, K., and Rockwell, C. 1985. Potential toxicant exposure among consumers of recreationally caught fish from urban embayments of Puget Sound. NOAA Technical Memorandum NOS OMA 23. November 1985.
- Landolt, M.L., Kalman, D.L., Nevissi, A., Van Belle, G., Van Ness, K., and Hafer, F.R. 1987. Potential toxicant exposure among consumers of recreationally caught fish from urban embayments of Puget Sound. NOAA Technical Memorandum NOS OMA 33. As cited in Tetra Tech 1988.
- Mayfield, D.B., Robinson, S., and Simmonds, J. 2007. Survey of fish consumption patterns of King County (Washington) recreational anglers. *Journal of Exposure Analysis and Environmental Epidemiology*, 17:604-612.
- McCallum, M. 1985. Recreational and subsistence catch and consumption of seafood from three urban industrial bays of Puget Sound: Port Gardner, Elliott Bay and Sinclair Inlet. Washington State Division of Health, Epidemiology Section. January 1985.
- Parametrix. 2003. Results of a human use survey for shoreline areas of Lake Union, Lake Washington, and Lake Sammamish. Sammamish-Washington Analysis and Modeling Program (SWAMP). Prepared for King County Department of Natural Resources. September 2003.

---

[29] The term *fisher* denotes a person who fishes for any type of seafood by any method, including finfish and shellfish. The term *angler* refers to a person who fishes with hook and line.

- Pierce, D., Noviello, D.T., and Rogers, S.H. 1981. Commencement Bay seafood consumption study. Preliminary Report. Tacoma-Pierce County Health Department, Tacoma, Washington. December 1981.
- Price, P., Su, S., and Gray, M. 1994. The effects of sampling bias on estimates of angler consumption rates in creel surveys. *Journal of Exposure Analysis and Environmental Epidemiology* 4:355-371. As cited in U.S. EPA, 2011.

As with any type of survey, creel surveys have both strengths and weaknesses (see Table 9) (U.S. EPA, 1992).

Table 9. Strengths and Weaknesses of Creel Surveys

Strengths	Weaknesses
∗ Can assess site-specific consumption rates. ∗ Can target specific at-risk populations who fish at contaminated sites. ∗ The interviewer can observe the participant's fishing behaviors and catch as well as the condition of the interview site. ∗ Recall bias is minimized by using visual aids and by having the interviewer refer to the fish caught around the time of the interview as a reference. ∗ Results can be verified by looking at the daily catch of the participant. ∗ Response rate is high. ∗ More information can be gained by using visual aids and probing questions. ∗ Creel surveys are routinely done for fishery management purposes; adding fish consumption questions to the surveys can be done with little added cost.	∗ Only a limited number and types of questions are used to minimize survey time. ∗ Language barriers may exist between participants and interviewers. ∗ Surveys require well-trained staff that must be monitored for quality control. ∗ If interviews are occurring at fishing sites, answers about consumption are hypothetical because the fish have not yet been consumed. ∗ Participants who fish more frequently are more likely to be interviewed than those who fish less frequently. [a] ∗ Survey results cannot be generalized to the entire population. ∗ May miss anglers if not all fishing locations and times are surveyed. ∗ May under- or overestimate yearly consumption if survey is not conducted throughout the year. ∗ Pilot testing for a target population is not as effective as is the case with personal interview surveys. ∗ Anglers may not be as receptive to engaging in interviews as preselected personal interview survey interviewees. ∗ Fears of contact with government officials may inhibit responses of minority groups. ∗ Anglers in the field may not be as inclined or ready to respond as individuals that have been contacted and readied to participate in a personal interview survey. ∗ Visual aids for unique seafood preparations are difficult to develop without knowledge of the target population. ∗ If the water body is known to have chemical contamination, rates may be impacted by a suppression effect (i.e., the suppression of the harvest and consumption of fish), and hence may not result in protective risk estimates or cleanup levels. ∗ It may difficult to know who actually consumes the fish.

a. Moya et al., 2008.

3.2.2 Personal interviews

Personal interviews can be used to estimate fish consumption rates by asking participants questions about their dietary patterns, particularly about how much fish they consume over a given amount of time (Table 10). A useful type of personal interview survey considers 24-hour dietary recall. In this type of interview, participants are asked by a trained interviewer to report what they ate during the previous 24 hours. Although the 24-hour dietary recall format avoids recall bias, the short time period of recall is unable to show consumption variation over the course of a year (U.S. EPA, 1992). Some survey designs have addressed this by interviewing the same individual multiple times or by staggering interviews of the survey population over the course of a year. Other personal interviews may ask a participant to provide information about their consumption of finfish and shellfish over longer time periods, such as 2 weeks, a month, a season, or a year. Examples of personal interview surveys include the Native American fish consumption surveys conducted for tribes residing along the Columbia River basin and throughout Puget Sound (see Chapter 4).

Table 10. Strengths and Weaknesses of Personal Interviews

Strengths	Weaknesses
∗ Can assess site-specific consumption rates. ∗ Can identify and get information from vulnerable subpopulations (those populations at a disproportionate risk) by collecting data from participants who are close to contaminated sites and by asking community agencies who should be interviewed. ∗ Responses can be validated and supported with information gathered by the interviewer. ∗ Literacy and language barriers are minimized by face-to-face interaction. ∗ Visual aids can be used to estimate meal size or fish species, reducing recall bias. ∗ High response rate. ∗ Interviewer can clarify questions for respondents. ∗ Possible to select a random sample that is representative of the population. ∗ Pilot testing of interview with target population is possible. ∗ Possible to incorporate culturally unique seafood preparations and considerations into the dietary survey. ∗ Possible to tailor survey to specific groups. ∗ Avoids issues associated with missing fishing locations or times that are encountered in creel surveys.	∗ Only a limited number and types of questions are used to minimize survey time. ∗ Requires coordinated and supervised interviewers. ∗ If interviews are occurring at fishing sites, answers about consumption are hypothetical because the fish have not yet been consumed. ∗ Responses may be biased by fishing practices at the time the interview is being administered. ∗ Uncertainty introduced when individuals are asked to recall consumption throughout the year.

3.2.3 Diary surveys

Diary surveys use questionnaires, in the form of logbooks, diaries, or catch cards, to record fish consumption over time. Information is filled out by the participant ideally at the end of a fishing day or at the time of consumption, to minimize possible recall bias (Table 11).

The Connecticut Department of Environmental Protection used diary surveys to find out about fish meals and portion sizes eaten by Connecticut families. The families received the surveys in the mail (U.S. EPA, 1992; Moya et al., 2008).

Table 11. Strengths and Weaknesses of the Diary Method

Strengths	Weaknesses
∗ Can assess site-specific consumption rates. ∗ Information collected over long periods of time. ∗ Less expensive than personal interviews. ∗ Large numbers of participants possible. ∗ Recall bias is reduced. ∗ Visual aids can be used to improve accuracy of answers.	∗ Respondents must be taught how to complete the survey by a trained interviewer. ∗ Participants must be literate. ∗ Participants must be monitored during the study to maintain consistency. ∗ Keeping a dietary record may change a participant's dietary practices. ∗ Participants may not maintain daily record keeping. ∗ Language barriers may affect how participants are recruited and how their diary responses are interpreted. ∗ Questionnaire design is more complicated than other types of surveys.

3.2.4 Telephone surveys

Telephone interview surveys estimate recent fish consumption or information about recent fishing trips. Answers are recorded on preprinted questionnaires (Table 12) (U.S. EPA, 1992).

Table 12. Strengths and Weaknesses of Telephone Surveys

Strengths	Weaknesses
∗ Can assess region-specific consumption rates. ∗ Can target and identify specific subpopulations of concern. ∗ Less expensive and time-consuming than personal interviews. ∗ High rate of success for completion of interviews. ∗ Sensitive information may be obtained more easily. ∗ Provides immediate response to questions.	∗ Interviewers cannot reach people who do not have phones. ∗ Interviews are limited in scope and length. ∗ Difficult to verify information. ∗ Cannot use visual aids. ∗ Inability to reach people by phone may be of concern for low-income individuals who harvest more fish than more affluent people. ∗ Language barriers may pose limitations.

3.2.5 Recall mail surveys

Recall mail surveys are self-administered questionnaires used to estimate fish consumption. Most commonly they are used to obtain information from recreational anglers (Table 13) (U.S. EPA, 1992).

Table 13. Strengths and Weaknesses of Recall Mail Surveys

Strengths	Weaknesses
∗ Can assess region-specific consumption rates. ∗ Can target and identify specific subpopulations of concern. ∗ Least expensive since no interviewers are required. ∗ Large numbers of respondents may be contacted over a large area. ∗ Most likely to provide honest answers. ∗ Complex technical data may be obtained if respondent takes the time to consider the questions and/or consult other sources. ∗ Survey can cover broad areas of inquiry.	∗ Cannot reach people without mailing addresses. ∗ Questions must be carefully designed to compensate for lack of personal interaction. ∗ Questions should be limited in scope and complexity. ∗ Requires substantial follow-up efforts or incentives to achieve reasonable response rate. ∗ Higher number of inaccurate and incomplete responses. ∗ May miss respondents who are illiterate, or have difficulty in understanding questions, or who cannot read the language.

3.3 Survey selection criteria

Both dietary recall interviews and creel surveys have been used in Washington in various contexts to estimate fish consumption rates (see Chapter 4, Table 14).

Certain criteria are useful for comparing survey methodologies, and key factors influence the selection of a particular survey type (U.S. EPA, 1998). These selection criteria assist in discriminating between different survey approaches. In addition, how different survey methodologies compare based on these criteria highlights the various strengths and weaknesses.

Consistent with this approach, Ecology established key considerations for selection criteria: time frame, resources, target populations, subpopulations, accuracy, and harvest characteristics. Although many of these considerations are discussed separately, Table 14 provides a useful tool for comparing different survey methodologies.

Table 14. Comparison of Five Consumption Survey Methodologies Using EPA's Selection Criteria

Survey Type Selection Criteria	Telephone	Mail	Diary	Interview	Creel
Time Frame					
Immediate data from respondent	Yes	No	No	Yes	Yes
Resources					
Interviewer burden	Moderate	Low	Low	High	High
Respondent burden	Low	Moderate	High	Low	Low
Relative cost	Moderate	Low/moderate	Low	High	High
Target Populations/Subpopulations					
Survey sample known prior to conducting survey	Yes/no [a]	Yes	Yes	Yes/no [b]	Yes/no [c]
Can be used with low literacy populations	Yes	No	No	Yes	Yes
Accuracy [d, e]					
Reliability: Potential for response reliability	Moderate/high	Low/moderate	Low/moderate	Moderate/high	Moderate/high
Validity: Validity of consumption estimates	Low	Low/high [f]	Moderate	Moderate [g]	Low/moderate [g]
Validity: Validity of species identification	Low	Moderate	Moderate	Moderate/high [h]	High
Bias: Potential to minimize recall bias	Moderate	Low/high [f]	Moderate	Moderate/high [h]	Not applicable [i]
Bias: Potential to minimize prestige bias	Moderate	Low	Low	Moderate	Moderate
Measurement error: opportunity for respondent to ask for clarification	Moderate/high	Low	Low	High	High
Measurement error: potential for respondent participation	Moderate	Moderate	Low	High	High
Harvest Characteristics					
Many access points	Yes	Yes	Yes	Yes/no [b]	Yes/no [j]
High fishing or hunting pressure	Yes/no [k]	Yes	No	Yes	Yes/no [l]
Large geographic area	Yes	Yes	Yes	Yes [m]	No
Account for seasons and times	Yes	Yes	Yes	Yes	No [n]

Source: U.S. EPA, 1998, Table 3, p. 3-3.

a. Yes if phone numbers are obtained after sample population has been preselected; no if random digit dialing.
b. No for interviews conducted at fish/hunting access points; yes for off-site interviews.
c. Depends on ability to estimate total site usage using random sampling of all access points.
d. Given sufficient resources, all five survey approaches can generate accurate data.
e. For minority and tribal populations a sense of trust and cultural identity between interviewer and interviewee is particularly important.
f. Dependent on the recall method employed.
g. On-site interviews result in valid catch estimates, but consumption estimates are hypothetical because they measure only the intent to consume. Off-site interviews result in catch and consumption estimates with potentially low validity depending on the period of recall.
h. Moderate for off-site interviews; high for on-site interviews. Administering the survey at regular intervals can reduce bias associated with the availability of different seafood resources throughout the year.
i. Creel surveys may minimize recall bias but the responses only represent the point of time the individual starts fishing to the time the individual is interviewed.
j. Yes for roving creel survey; no for access point survey.
k. Yes for random telephone numbers; no for known telephone numbers.
l. Yes for access point survey; no for roving creel survey.
m. Yes when interviewees are preselected so they can tell interviewer where they have fished.
n. A creel survey may be designed to account for seasons and times; however, creel surveys seeking to develop health protective estimates of fish consumption may only be conducted during high harvest time periods.

3.4 Evaluating survey vehicles

Large differences in survey objectives combined with the high variability in fish consumption patterns make it difficult to make generalizations about surveys. To compare and evaluate both the survey vehicle (that is, the questionnaire or interview process) and the data obtained, a number of factors should be considered. Also, to establish whether a particular survey is appropriate to use, each factor needs to be evaluated and documented. Moya, 2004, and U.S. EPA, 1992 and 1998, identify important elements of survey design.

Also of significance is whether a survey is designed to look at short-term or long-term behaviors. This is especially relevant when comparing results of different surveys.

3.4.1 General survey design

Survey design is fundamental to the accuracy and success of a survey, and identifying the target population is important both when both choosing a survey method and effectively executing the survey (Table 15). The design establishes the type of information collected and the level of detail provided (Moya, 2004). Survey accuracy improves when the following factors are considered during the design phase. Ecology considered these as essential in a well-designed survey.

Table 15. Survey Design Evaluation Criteria

Criteria	Description
1. Timing of interviews	For a survey to adequately capture fish consumption, an appropriate time frame must have been chosen that minimizes the effect of recall bias yet captures the dietary variations.[a] (Additional discussion on survey recall error and bias are provided in the Glossary, Appendix D.)
2. Training of interviewers	Interviewers should be trained for the study protocol to avoid potential interviewer bias. Interviewers must adhere to the questionnaire wording and format and be culturally sensitive when interacting with the study participants. If possible, interviews should be conducted by members of the target population to avoid adverse impacts associated with cultural differences, language barriers, and participation refusals. [a]
3. Consideration of all fish species	The types of fish consumed can be highly variable depending on seasonal and geographic availability, market prices, and cultural preferences. Surveys should identify and record each type of fish consumed and any unique preparation methods. [a]
4. Identification of the source	If known, either the water body where the fish was caught or the purchase location (for example, grocery store or fish market) should be identified. To improve exposure assessment, both locally caught fish and store bought fish should be included in fish consumption rate estimates. This distinction allows the risk assessor to better account for regional and seasonal variations in fish consumption estimates. [b]
5. Random selection of participants, sample size, and statistical analysis	During the planning phase, statistical analysis helps identify the ideal sample size and how to randomly select participants. This analysis helps minimize bias and sampling error and ensures statistical rigor. After the data have been collected, sound descriptive statistical analysis should ensure that the data are presented accurately. The range of data should be presented with confidence intervals and appropriate distribution values. Weighting schemes should be clearly described in order to apply survey results to populations of interest. Statistical treatment of perceived outliers should be discussed.

Criteria	Description
6. Appropriate quality assurance and quality control	The study design should include appropriate quality assurance and quality controls into the planning and execution of the survey. For example, types of quality control measures would include checking questionnaires for completeness and proper entry of recorded responses, verifying correct data entry, and checking the manual coding operations and comparisons of results and error rates. This reduces bias and random error, improving accuracy. [c]
7. Accuracy and precision	The study design can affect the overall accuracy of the study. Accuracy can be split into five components. Reliability (the variability or repeatability of the response), validity (the ability of the respondent to provide the correct answer), measurement errors (which are associated with the interviewer, the respondent, the questionnaire, and the mode of data collection), bias (the consistent overestimation or underestimation due to survey design and sample selection), and random errors. [c]

a. Ecology, 1999.

b. Ebert et al., 1994.

c. U.S. EPA, 1998.

3.4.2 Survey questions

The following information should be collected from study respondents and is necessary for understanding what they eat (Strauss, 2004).[30]

- Frequency and quantity (how much fish is consumed per day, week, or month).
- Parts of the fish consumed.
- Species consumed.
- Source of the fish.
- Seafood preparation and cooking methods.
- Respondent’s body weight.
- Exposure duration.
- Approximate age (child or adult).

Survey questions should be clearly worded, unambiguous, and well understood to obtain clear and correct answers from respondents.

---

[30] See this 2004 article by Strauss for details regarding complexities and variability.

3.4.3 Population surveyed

The sample population must represent the target population. This is particularly important because fish consumption rates may be affected by the socio-demographic characteristics of a population. Furthermore, the type of survey used may influence or determine a number of things, including what population will respond to the survey, the response rates, and the level of detail obtained (Moya, 2004).

3.4.4 Description of water body

The survey must identify and understand the characteristics of all relevant water bodies, including location, size, species inhabiting the water, and fish advisory status. These characteristics influence the quantity of fish available. In addition, this information is critical to producing results that can be used to compare with or extrapolate to other populations (Moya, 2004).

3.4.5 Survey results

Ecology considered it important to evaluate how the survey results are presented and what they are meant to represent. This included identifying and considering goals of the survey.

Estimating the size of a meal is subject to error, especially when a survey vehicle (questionnaire or interview) does not include visual aids. Also, quantities of seafood may be part of stews, soups, and other recipes that may or may not be accounted for in fish dietary survey design.

Sound descriptive statistical analysis is required to ensure that the data are presented accurately. The range of data should be presented with confidence intervals and appropriate distribution values (Moya, 2004). Weighting schemes should be clearly described in order to apply survey results to populations of interest. Statistical treatment of perceived outliers should be discussed.

3.4.6 Factors to consider

Ecology identified the following factors as appropriate and necessary when evaluating survey results:

- *Cultural factors.* Does the population group of interest (for example, Native Americans or Asian and Pacific Islanders) have cultural characteristics that should be considered when designing a fish consumption survey? Native American ways of life may influence fish consumption habits and patterns; salmon is of particular significance in the diet of Northwest Pacific Native American tribal peoples. Asian and Pacific Islanders may consume parts of organisms that differ from those preferred by other populations. Also, is the survey designed to identify subsistence fishing practices?

- *Fish diet fraction (the portion of fish consumed that comes from the site).* Have sources of fish tissue contamination been considered in the design and/or evaluation of the survey? Are the fish consumed harvested from local waters? Does the survey distinguish between store-bought fish or fish consumed in restaurants and fish harvested from local waters?
- *Types of seafood (finfish and shellfish) consumed from marine, freshwater, and estuarine habitats.* This information may be useful in characterizing risks for consumption of aquatic biota that have different contaminant levels as a result of their feeding behaviors (for example, bottom feeding fish or top predator species). Has the fish consumption survey considered both the range of types of finfish/shellfish consumed and where they are harvested?
- *Cooking methods.* Use of cooked weights or uncooked weights to measure fish consumed must be standardized. Generally, uncooked weights are preferred because environmental contaminants are usually analytically determined for wet weight. Cooking fish can reduce the weight of a fillet by 20 percent or more (U.S. EPA, 1998). Have the methods of food preparation and cooking been considered in the fish consumption survey design and/or evaluating the survey?
- *Are there historical and traditional fishing areas and practices that should be identified?*
- *Environmental justice.* How have historically underrepresented populations and disproportionately impacted communities been considered in the design and evaluation of fish consumption surveys?

3.5 Measures of technical defensibility

For purposes of this report, Ecology developed several *measures of technical defensibility* to help guide the evaluation of individual surveys. These measures of technical defensibility ensure that a survey can stand up to technical and scientific scrutiny and are described in Table 16. They represent an expansion of the two selection criterion used by the June 2008 Oregon Human Health Focus Group-Oregon Fish and Shellfish Consumption Rate Project

Collectively, these measures of technical defensibility provide an assessment of overall technical suitability to support regulatory decision making (for example, they provide information about whether the survey results are suitable and appropriate in a regulatory context for establishing risk-based standards).

The measures of technical defensibility are based on:

- EPA *Exposure Factors Handbook*, 2009 Update (U.S. EPA, 2009a).
- EPA *Exposure Factors Handbook*, 2011 Edition (U.S. EPA, 2011a).
- EPA *Guidance for Conducting Fish and Wildlife Consumption Surveys* (U.S. EPA, 1992, 1998).
- Consultations with the University of Washington, Environmental and Occupational Health Sciences.[31]

Ecology applied these measures of technical defensibility to selected fish dietary surveys performed in Washington State. Ecology has not applied these measures of technical defensibility to all surveys conducted in Washington; many of these surveys were conducted for specific water bodies to help support fish advisories, or were used to assess risks to specific ethnic populations.

Water body-specific fish dietary surveys are limited in scope because they evaluate very specific populations, usually recreational anglers and specific ethnic groups, which harvest and consume fish from a particular water body within a specific county or jurisdiction in Washington State. Each serves a useful purpose to help evaluate and assess potential health risks from consuming contaminated finfish and shellfish; however, their methodology does not allow for the projection of longer term estimates of fish consumption.

The additional fish dietary information provided in Table 32 and Appendix B, although not meeting the measures of technical defensibility described in this chapter, provides support, using a weight-of-evidence approach, to the idea that people in Washington State harvest and consume considerable amounts of fish.

Table 16. Measures of Technical Defensibility

Measure	Description
1. Survey Method Development	∗ Was the survey design based on sound scientific survey methods recognized either in guidance or other technical publications? ∗ For surveys dealing with unique populations (for example, tribes or ethnic minorities), was the survey vehicle reviewed by tribal staff and tribal governments? Did it include review and collaboration with state and federal agencies? ∗ Was the survey tested and modified before it was conducted? ∗ Did the survey design evaluate the essential elements provided in Table 15?
2. Survey Execution	∗ Was the execution of the survey based on sound survey methods recognized either in guidance or other technical publications? ∗ Were the personnel conducting interviews provided adequate training? ∗ Were finfish/shellfish models used as visual aids to help participants estimate approximate amounts and types of fish consumed?
3. Publication of Results	∗ Was the publication of survey results based on sound survey methods recognized either in guidance or other technical publications? ∗ Was the study methodology clearly defined and reported? ∗ Is there a discussion of the consistency of the survey's methodology with accepted practices? ∗ Was the study methodology consistent with sound survey practices? ∗ Were the survey results tabulated and reported clearly? ∗ Were statistical approaches (including weighting and treatment of outliers) clearly explained? ∗ Were the study conclusions clearly reported and supported by study findings? ∗ Were variability and uncertainty recognized? ∗ Were uncertainties identified and reported? ∗ Did the survey design take into account and/or discuss factors that might contribute to bias in the study results?
4. Applicability and Utility for Regulatory Decision Making	∗ Is the sample population representative of the population of concern, and does the survey provide sufficient information about the sample population to characterize the population being studied? ∗ Is it reasonable to apply the results of the surveyed population to populations of concern? ∗ Are the water bodies/fisheries resources upon which the surveyed population relies similar to the water bodies being regulated? ∗ Is the information current and is suppression effects on fish dietary habits recognized and accounted for? ∗ Are fish consumption rate statistics commonly used for regulatory purposes presented and supported? ∗ Are data sufficient for descriptive statistics to define statistical fish consumption rate distributions?

3.6 Custody of fish dietary survey data

Most fish dietary surveys that address the habits and patterns of ethnic groups (Asian and Pacific Islanders, Native American populations) are funded either through state or federal cooperative agreements or grants. Survey questionnaires are generally developed in close collaboration with an organization that represents the ethnic group or technical personnel associated with the tribal governments or tribal natural resource offices. Surveys are conducted by trained tribal personnel or people representative of the ethnic population being surveyed. The resulting data may be owned by the tribal government or the ethnic group that collaborated on the survey. The survey design and methodology are generally reviewed by the funding organization (federal or state) and technical personnel or representatives from the tribe or ethnic group.

The custody of survey data by tribal governments is related to their concerns with maintaining and sustaining tribal sovereignty and honoring confidentiality agreements with individual participants surveyed. The tribal governments have employed various methods to establish data quality without releasing individual response data to entities other than tribal governments. Ecology acknowledges that further evaluations would be possible using individual level response data.

Pacific Northwest Native American fish consumption surveys are designed and executed as government-to-government collaboration with state and federal governments. They are generally published under the authority of the tribal governments.

There are a number of ways to establish the defensibility of data. Scientific journals use peer review to establish scientific defensibility of reported results. A recent *Science Magazine* editorial (Hanson et al., 2011) noted the importance of making data available for scrutiny so that other researchers can verify results and test conclusions. Using independent statisticians for review and analysis may circumvent the need to release the raw data.

Many Pacific Northwest tribal organizations or tribal governments do not provide their raw seafood dietary data to researchers outside of their sovereign tribal government or organizations. They may consider survey data as confidential and not allow independent evaluations. Data evaluation typically occurs through government-to-government agreements or tribal technical personnel.

For example, the fish consumption survey of the four tribes that reside throughout the Columbia River basin was initiated through a cooperative agreement between EPA and the CRITFC. The development, design, and execution of the CRITFC fish consumption survey vehicle were conducted through the respective tribal governments that compose CRITFC. The fish consumption data were collected and evaluated by tribal members and technical staff and are retained by CRITFC. Other Pacific Northwest Indian tribes follow a similar pattern where the data are retained by tribal governments or Pacific Northwest Indian commissions.

Ecology evaluated the Native American fish consumption surveys, as well as other available surveys conducted in the Pacific Northwest, based on the measures of technical defensibility discussed above. That evaluation is described in the following chapter.

Chapter 4: Fish Consumption Survey Data that Apply to Washington Fish Consumers

4.1 Introduction

Over the last several years, Ecology has evaluated available fish consumption surveys to support site-specific regulatory decisions.

Fish consumption survey data are identified, discussed, and evaluated against the measures of technical defensibility presented in Chapter 3. The purpose of this chapter is to identify those surveys that are most appropriate for assessing fish consumption rates in Washington. A word of caution is appropriate. Many sources of data are available and provide information that may be appropriate for answering particular questions. The question being considered in this chapter is identification of data appropriate for use in a regulatory context to characterize fish-consuming populations across Washington State.

Ecology considered a range of information that describes fish consumption rates and patterns for fish consumers in Washington. In general, Ecology examined:

- General population surveys conducted at the national level.
- Dietary surveys of Washington Native American populations.
- A dietary survey of Asian and Pacific Islander populations in King County.
- Washington water body-specific evaluations, assessments, or health advisories issued by DOH.[32]
- Technical publications, assessments, and/or evaluations of fish consumption specific to the Pacific Northwest.
- Various evaluations or assessments used to make regulatory decisions. For example, the baseline human health risk assessment performed for the Lower Duwamish Waterway, which refers to the EPA Region 10 Framework and Kissinger re-evaluation (Windward Environmental, 2007; U.S. EPA, 2007b; Kissinger, 2005).[33]

---

[32] Washington State Department of Health fish consumption advisories by water body located at the following web link: http://www.doh.wa.gov/CommunityandEnvironment/Food/Fish/Advisories.aspx, and Port Angeles: http://www.ecy.wa.gov/news/2012/052.html

[33] Besides the Lower Duwamish Waterway Remedial Investigation Report, Ecology also considered the Port Angeles and Port Gamble sediment cleanup:

Port Angeles: http://www.ecy.wa.gov/programs/tcp/sites_brochure/portAngelesHarborSed/paSed_hp.htm

Port Gamble: http://www.ecy.wa.gov/programs/tcp/sites_brochure/psi/portGamble/psi_portGamble.html

These data were examined and assessed to identify technically defensible studies appropriate for use in characterizing fish-consuming populations in Washington.

To provide a more detailed look at fish consumption patterns across the state, where possible, fish consumption data and descriptive statistics have been tabulated for both locally harvested fish, and for fish consumed from all sources including stores and restaurants. Where available, additional fish consumption estimates from Pacific Northwest fish dietary surveys are included for groups of fish species, such as finfish, shellfish, anadromous finish, and non-anadromous finfish.

4.2 General population data

Currently, there are no fish dietary data available for the general fish-consuming populations in Washington State. That is, there is not a survey of fish consumption of the entire population of Washington State. Ecology examined information on fish consumption among the U.S. national general population.

Ecology notes that national data show that people who live in coastal areas consume fish at higher rates than those living in other areas (Moya, 2004) and that EPA recommends using regional-specific data, when available (U.S. EPA, 2000b, 2007b, 2011a).

4.2.1 Continuing Survey of Food Intakes by Individuals

In 2000, the EPA developed national estimates of fish consumption based on an analysis of the U.S. Department of Agriculture's (USDA) 1994–1996 *Continuing Survey of Food Intakes by Individuals* (CSFII) and its 1998 *Children's Supplement* (U.S. EPA, 2002a). (These USDA reports are collectively referred to as CSFII 1994–1996, 1998).

The USDA surveys were designed to provide estimates of food consumption across the United States and were conducted in all 50 states and Washington, D.C. They include fish consumers and non-consumers, and provide data for federal activities related to the nutritional status of the U.S. population.[34] The national fish dietary information is not representative of some Washington State fish-consuming populations, such as Asian-Pacific Islanders and Native Americans.

Over 20,000 survey participants each provided dietary information during two non-consecutive 24-hour periods. The survey was designed so that the second interview occurred 3 to 10 days after the first interview but not on the same day of the week. The dietary recall surveys were administered over a period of 4 years.

---

[34] By definition, per capita fish consumption includes consumers and non-consumers of fish. The per capita survey methodology is different than the Pacific Northwest fish dietary recall studies and is discussed below.

The CSFII was conducted by interviewing respondents according to a stratified design that accounted for geographic location, degree of urbanization, and socioeconomics. Eligibility for the survey was limited to households with gross incomes at or less than 130 percent of the federal poverty guidelines. Survey weights were assigned to this dataset to make it representative of the U.S. population.

The CSFII is the primary source of food consumption data used in dietary risk assessments. It is well suited to national-level dietary risk assessments, because it is statistically designed to sample individuals of all ages and major ethnic subgroups to reflect various demographics. The CSFII is statistically designed so that the national estimate of consumption is not biased by seasons of the year or regions of the country (U.S. EPA, 2001). The CSFII may be considered a variation of the dietary market basket survey approach but on a larger-scale with a more sophisticated design and execution.

Ecology notes, however, that the survey methodology limits its use. In particular, participants who did not eat fish on either of the two days surveyed would be considered non-consumers. The rate of fish consumption (or non-consumption) for individual consumers during the two days surveyed was assumed to represent their consumption rate for the entire year. In other words, someone who did not eat fish during the two days of the survey was assumed to consume no fish at all during the year. The resulting values may not be representative of long-term consumption rates that have been averaged over time and presented as a daily rate.

By definition, per capita fish consumption rates reflect fish dietary habits averaged over the general U.S. population, including people who never eat fish. Hence, per capita fish consumption rates do not necessarily describe actual fish consumption by consumers of finfish and shellfish.

Although fish consumption rates derived for consumers would be preferable to per capita rates in describing the consumption of finfish and shellfish in the United States, there are limitations when “consumer only” rates are derived from national per capita surveys:

- During the two non-consecutive days of the survey period, the amount of fish and shellfish that a respondent ate on a given day would not be equivalent to the gram per day value obtained when the amount of fish consumed over a longer survey period is divided by the number of survey-period days for a more comprehensive fish dietary recall survey.
- People who typically consume finfish and shellfish, but did not do so during one of the two non-consecutive days of the survey period, were not captured by the survey and therefore are not included in national fish consumption estimates for consumers.
- It is not possible to determine the percentage of the finfish- and shellfish-consuming population that was missed, or whether the respondents who did consume finfish or shellfish during the survey’s two-non-consecutive-day reporting period are adequately representative of the U.S. fish-consuming population.

Ecology acknowledges the difficulty in evaluating the data from the EPA 2002 per capita estimates. We have considered this information in helping to estimate the number of fish consumers in Washington but not in estimating a fish consumption rate. We have also used the per capita data to define high fish consumers in order to approximate the number of high fish consumers among the general population.

Table 17. General Population: Adult Respondents, Consumers Only, Based on CSFII 1994 to 1996

Population	Number of Adults Surveyed	Descriptive Statistics (g/day)					
		Mean	Median	Percentiles			
				75th	90th	95th	99th
U.S General Population (consumers only)	2585	127	99	-	248	334	519

Source: Adapted from Oregon DEQ, 2008, Table 3, based on EPA 2002 and CSFII dietary data. Persons interested in further details on the CSFII are referred to U.S. EPA, 2002.

4.2.2 National Health and Nutrition Examination Survey, 2003 to 2006

The EPA 2011 national estimates for fish consumption are based on analysis of the USDA National Health and Nutrition Examination Survey (NHANES) from 2003 to 2006. The fish consumption estimates from the NHANES 2003–2006 data are available in Chapter 10 of EPA's Exposure Factors Handbook, 2011 (U.S. EPA, 2011a).

Designed to assess the health and nutritional status of adults and children in the United States, starting in 1999, NHANES is a continuous program that interviews nationally representative samples of about 7,000 people annually. The survey is administered for two non-consecutive 24-hour periods of dietary intake. Data for the first day is collected in-person, while data for the second day is collected by telephone about 3 to 10 days later. Using the 2000 U.S. population census estimates to develop the sampling frame, the NHANES 2003–2006 surveys are probability-based and county-based population samples from across the United States.

The EPA's Office of Pesticide Programs used NHANES 2003–2006 data to update the CSFII 1994–1996, 1998 study (as presented in EPA's 2002 *Estimated Per Capita Fish Consumption in the United States*). Summary statistics were developed for fish consumers only and on a per capita basis. Dietary rates were derived for finfish, shellfish, and finfish and shellfish combined (shown for consumers only in Table 18 and Figure 1 below). Two-day average dietary fish consumption rates were calculated for all respondents who provided dietary information for two days of the survey. If a respondent reported consuming fish on one of the two days of the survey, then their 2-day average would be half the amount reported for the one day of consumption.

The EPA 2011 *Exposure Factors Handbook* (U.S. EPA, 2011a, p. 10–16) qualifies the fish dietary estimates as follows:

> *…it should be noted that the distribution of average daily intake rates generated using short-term data (e.g., 2-day) does not necessarily reflect the long-term distribution of average daily intake rates. The distributions generated from short-term and long-term data will differ to the extent that each individual's intake varies from day to day…*
>
> *…Short-term consumption data may not accurately reflect long-term eating patterns and may under-represent infrequent consumers of a given fish species. This is particularly true for the tails (extremes) of the distribution of food intake.*

Table 18. General Population: Adult Respondents, Consumers Only, Based on NHANES 2003–2006, Using Standard Statistical Survey Methodology

Population	Species Group	Descriptive Statistics (g/day)				
		50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
National Estimates from NHANES 2003–2006 (consumers only)	All Fish	37.9	56.0	78.8	128	168
	Finfish	34.6	49.9	68.9	115	150
	Shellfish	25.7	43.0	54.4	101	147

See Polissar et al., 2012. Estimates based on statistical methodology defining *fish consumers* as those who consumed fish on at least one of the two dietary recall days.

Ecology reevaluated the NHANES fish dietary data using the National Cancer Institute's (NCI) statistical methodology (Polissar et al., 2012). The NCI method estimates usual intake of episodically consumed foods by accounting for day-to-day variations (Tooze et al., 2006). The national dietary information (CSFII and NHANES) consists of two detailed 24-hour dietary recalls conducted for a large, randomly selected U.S. population. Although 24-hour dietary recall surveys capture detailed information on a person's food consumption, this dietary assessment method does not adequately measure the usual intake of foods that are not consumed nearly every day (i.e., episodically consumed foods such as fish). The NCI method uses statistical modeling to combine food frequency questionnaire data with 24-hour dietary recall data to project long-term food consumption estimates. Results are shown in Table 19 and Figure 2 below.

Table 19. General Population: Adult Respondents, Consumers Only, Based on NHANES 2003–2006, Using NCI Statistical Survey Methodology

Population	Species Group	Descriptive Statistics (g/day)				
		50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
National Estimates from NHANES 2003–2006 (consumers only)	All Fish	12.7	18.8	24.8	43.3	56.6
	Finfish	9.0	14.0	18.1	31.8	43.3
	Shellfish	2.4	5.4	6.0	13.2	20.5

See Polissar et al., 2012. Estimates based on NCI statistical methodology (Tooze et al., 2006) that models two days of fish consumption from 24-hour episodic dietary recall and fish dietary information from the food frequency questionnaire.

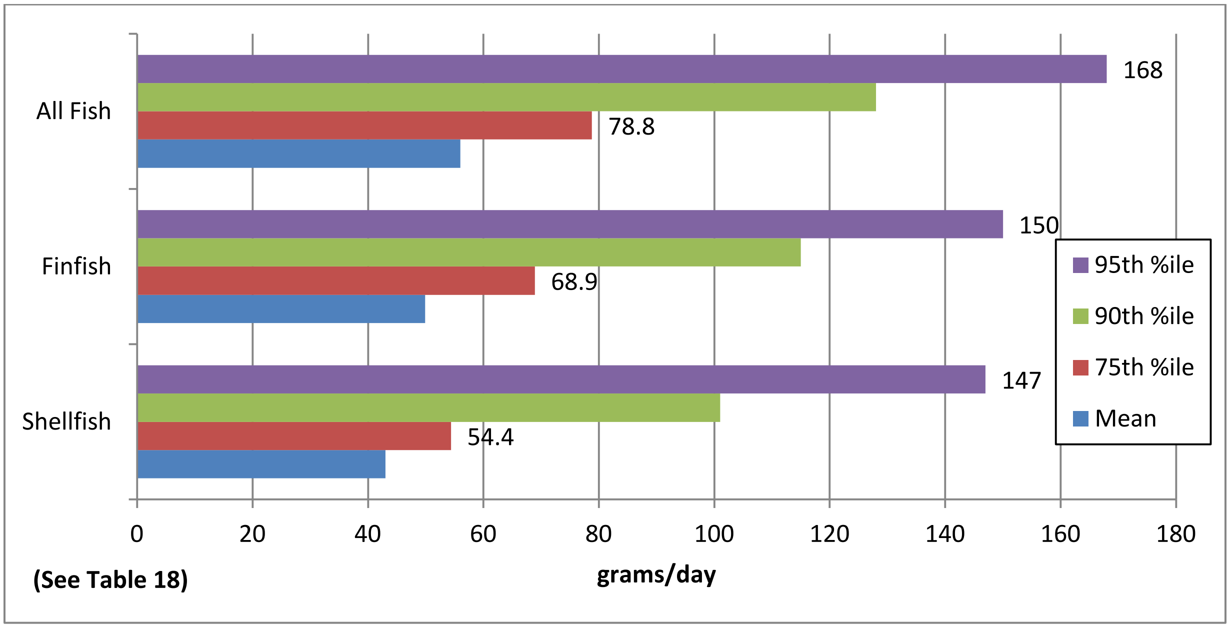

Figure 1. General Population Adult Fish Consumption Rates, Consumers Only, NHANES 2003–2006, Using Standard Statistical Survey Methodology

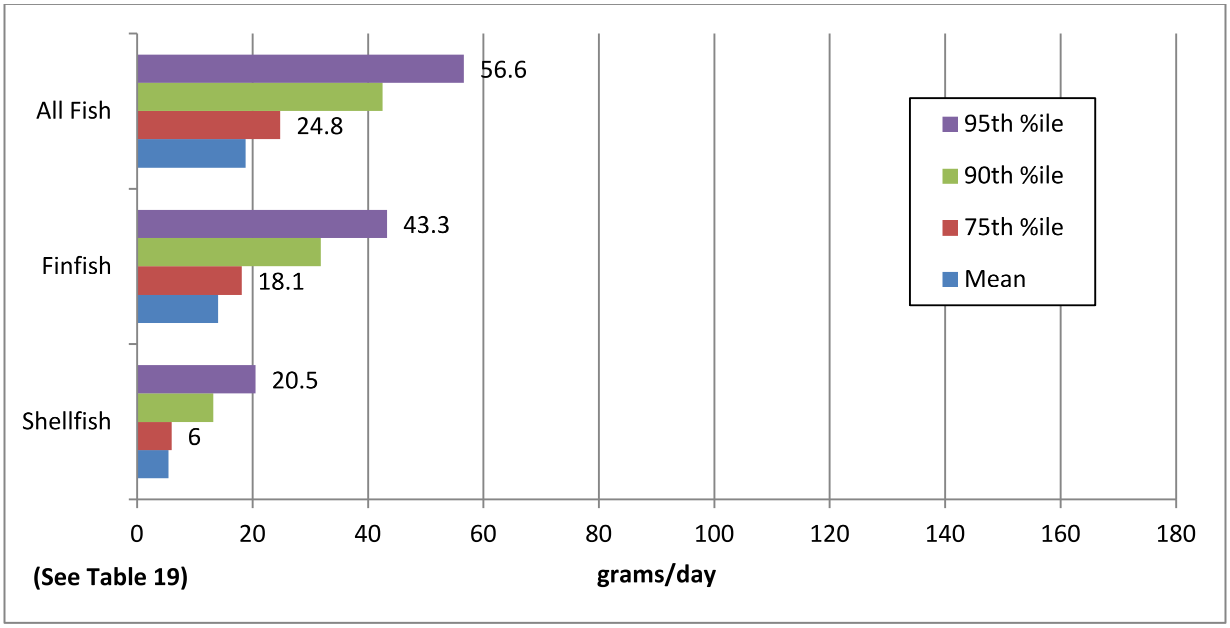

Figure 2. General Population Adult Fish Consumption Rates, Consumers Only, NHANES 2003–2006, Using NCI Statistical Survey Methodology

Technical defensibility

As summarized in Table 20 below, Ecology has determined that the national surveys of the general population are relevant to Washington and satisfy measures of technical defensibility.

Table 20. Technical Defensibility of National (General Population) Fish Dietary Information

Metric	Observations and Comments	Evaluation
1. Survey Method Development		
Description of survey vehicle	Survey methodology and analysis of survey data independently conducted by two federal agencies	Survey methodology, design and analysis described in detail; sample size very large to provide good dietary information for the general U.S. population
Description of sample population	Large sample size, randomly selected, and sample geographically representative of national general population	
2. Survey execution		
Survey method	Survey data based on recent 2-day dietary recall; data collected over short duration and independent collection periods	Nationwide survey with sample selection based on randomized selection; two non-consecutive-day recall supports development of per capita consumption estimates; high level of peer review on methodology design and execution
Bias	Good response rate (> 70%)	
Review and evaluations	Quality assurance/quality control (QA/QC) standards are high and documented	
Review and evaluations	National Center for Health Statistics	

Metric	Observations and Comments	Evaluation
3. Publication of results		
Where published and clear information	Published by USDA, EPA, and other agencies	Accessible through large number of venues and publications
Survey methodology	Two non-consecutive-day dietary recall	
Applicability for regulatory decision making		
Currency of information	CSFII 1994–1996 and 1998 2003–2006 NHANES	Suitable for average intake rates of general population; not intended to substitute for regional-specific fish dietary information [a]
Representative of target population	Representative of the general U.S. population	
4. Overall technical suitability for regulatory decision making		
Range of technical defensibility	Survey method designed to provide average intake rates for general populations	Not designed to capture long-term dietary intake
Appropriateness for use in risk-based standards	Designed to provide average dietary intake rates	Not a substitute for regional-specific dietary information

Sources: U.S. EPA, 2011a; USDA CSFII 1994–1996, 1998.

a. Study design may bias high upper percentile consumer only fish consumption estimate; however, use of national fish dietary information underestimates fish consumption estimates for areas with more fisheries and resources (i.e., Washington State).

4.3 Pacific Northwest Native American fish consumption data

As of the writing of this report, results of three tribal-specific finfish/shellfish dietary surveys of tribes along the Columbia River basin and in the Puget Sound area of Washington were available for review.

In addition, several technical publications provide information on tribal fish consumption (Harper et al., 2002, p. 513–526; Harris and Harper, 1997, 2001). These publications have been used to define a tribal reasonable maximum exposure (RME) for various regulatory decisions.[35]

Although these technical publications provide useful information for specific regulatory decisions, it is the published tribal fish consumption surveys that provide the relevant information on fish consumption. The surveys employed a well-defined, standardized, dietary survey methodology, data analysis, and reporting of results.

Tribal fish dietary surveys provide relevant fish dietary information for Washington State fish consumers because these surveys include: (1) respondents that are fish consumers from Washington State; (2) locally harvested and consumed finfish and shellfish; (3) well-defined, standardized, dietary survey methodology, data analysis, defined measures of quality assurance and quality control, and reporting of results; (4) close collaboration with and support from academia and state and federal health and resource agencies; (5) minimized recall bias in the

---

[35] In Harper et al., 2002, Table 11, p. 521 notes 885 – 1,000 g/day for those with a high fish diet (fish consumers) and 175 g/day for shellfish consumption for fish consumers and non-consumers of fish.

surveys due to dietary and culturally based dependence on fish consumption; and (6) the well-supported assumption that *locally harvested fish* includes fish from large freshwater, estuarine, and marine water areas of Washington State because tribal reserved rights include harvesting fish and consuming fish from all watersheds throughout the state.

Ecology reviewed and analyzed the data from these surveys, looking specifically at species consumed and where the fish were obtained (Polissar et al., 2012). The fish dietary surveys provide credible information on the types and amounts of fish consumed by Native American populations in Washington State. Generally, the fish dietary surveys indicate that these populations consume large amounts of finfish and shellfish harvested from marine and freshwater environments throughout Washington.

This section describes the surveys, along with an evaluation of technical defensibility.

4.3.1 Columbia River Inter-Tribal Fish Commission survey: the Umatilla, Nez Perce, Yakama, and Warm Springs Tribes of the Columbia River Basin

The Columbia River Inter-Tribal Fish Commission (CRITFC) surveyed fish consumption among four Native American tribes that reside along the Columbia River basin (CRITFC, 1994). The survey of adult tribal members who lived on or near the Yakama, Warm Springs, Umatilla, or Nez Perce Reservations was conducted during the fall and winter of 1991–1992.[36]

The survey identified individual tribal members’ consumption rates, habits, and food preparation methods for anadromous and resident fish species caught from the Columbia River basin. A random sampling was taken based on respondents selected from patient registration files of the Indian Health Service. The survey questionnaire included a 24-hour dietary recall and questions regarding seasonal and annual fish consumption. Food models were used to help respondents estimate the amounts of fish consumed.

Information obtained included age-specific fish consumption rates, the fish species and parts of the fish consumed, and the methods used to prepare the fish for consumption.

Personal interviews conducted on the four tribal reservations achieved an overall response rate of 69 percent from a sample size of 513 tribal members 18 years of age or older. Tribal adult respondents provided information for 204 children 5 years of age or younger. Since tribal population sizes were unequal, demographic weighting factors were applied to the pooled data in proportion to tribal population size, so that survey results would reflect the overall population of adult members of the four tribes. An unweighted analysis was performed for children, since the sample size was small. To derive consumption rates that represented the adult tribal population as a whole, the survey averaged the fish consumption for both consumers and non-consumers.

---

[36] As noted in the survey, conducting interviews over this period of time biased the consumption estimates low because of low availability of fish to harvest during that seasonal period of time.

All interviews were conducted at tribal offices, which could potentially select against individuals with mobility problems. It is possible that tribal elders, who may be more likely to practice subsistence consumption, were omitted from the survey. Since adults answered questions regarding children's fish consumption, the adult respondents may have mistakenly answered questions as if they were providing their own survey responses. Selected outliers were removed from the datasets.

CRITFC consumption rates represent consumption from all sources. Salmon and steelhead were consumed by the largest number of adult respondents, followed by trout, lamprey, and smelt. A seasonal variation in fish consumption was observed, with the most fish consumed April through July. The mean fish consumption rate was 108 g/day. There was a large seasonal variation in fish consumption. The reported mean rate of consumption during the high months (April–July) was three times the mean rate of consumption in low months (November–February).

The mean fish consumption rate for all surveyed tribal adults (consumers and non-consumers) throughout the year was 58.7 g/day. Seven percent of survey respondents did not consume fish. Excluding non-consumers of fish, the mean fish consumption rate for surveyed tribal adult fish consumers was 63.2 g/day. The average consumption rate for children (5 years old and younger) was 24.8 g/day. About 83 percent of the 204 children consumed fish. The 99th percentile fish consumption rates of adults and children (5 and younger) who consume fish were 389 g/day and 162 g/day, respectively.

Reanalysis of the CRITFC survey report by Ecology provides estimates of anadromous, non-anadromous, all finfish consumption estimates, and source of harvest (Table 21, Figures 3 and 4). Slight variations between can be attributed to procedures used to estimate rates and percentiles (Polissar et al., 2012).

Table 21. CRITFC Adult Fish Consumption Rates by Species Group and Source, Consumers Only

Population Tribal	Species Group	Harvest Source of Fish	Descriptive Statistics (g/day)				
			50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
The 4 Tribes Affiliated With The Columbia River Inter-Tribal Fish Commission	All finfish	all	40.5	63.2	64.8	130.0	194.0
	Non-anadromous	all	20.9	32.6	33.4	67.0	99.9
	Anadromous	all	19.6	30.6	31.4	63.1	94.1
	All finfish	Columbia River Basin	35.6	55.6	57.0	114	171
	Non-anadromous	Columbia River Basin	18.4	28.6	29.4	58.9	87.9
	Anadromous	Columbia River Basin	17.3	27.0	27.7	55.5	82.8

See Polissar et al., 2012, Table E-1.

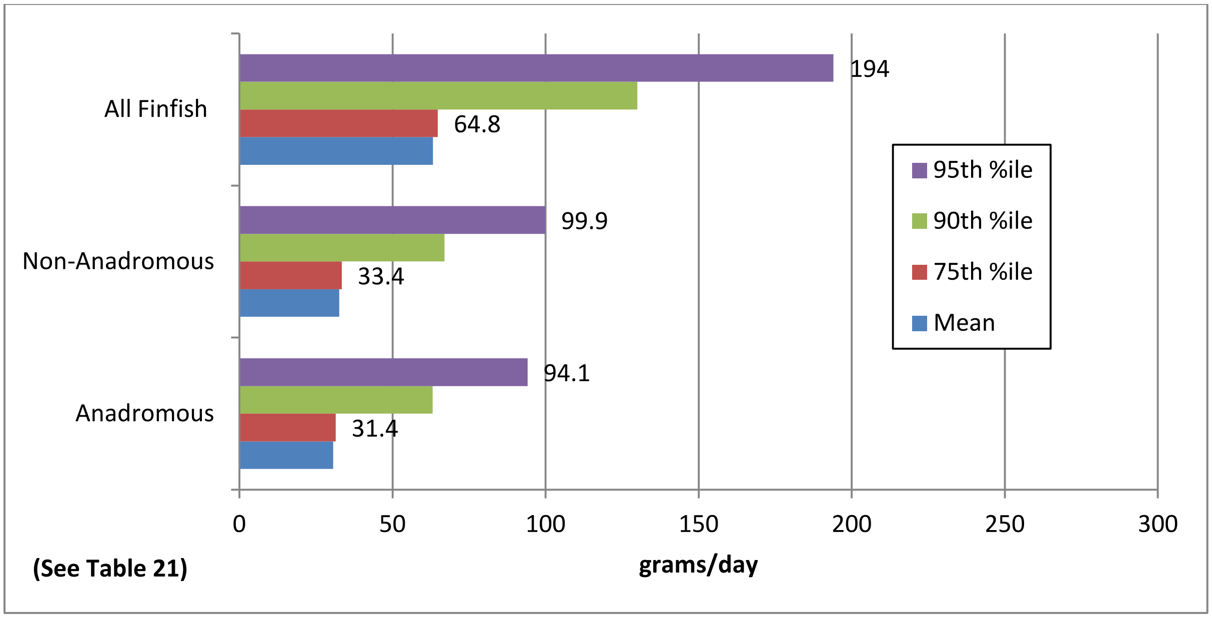

Figure 3. CRITFC Adult Fish Consumption Rates, Harvested from All Sources

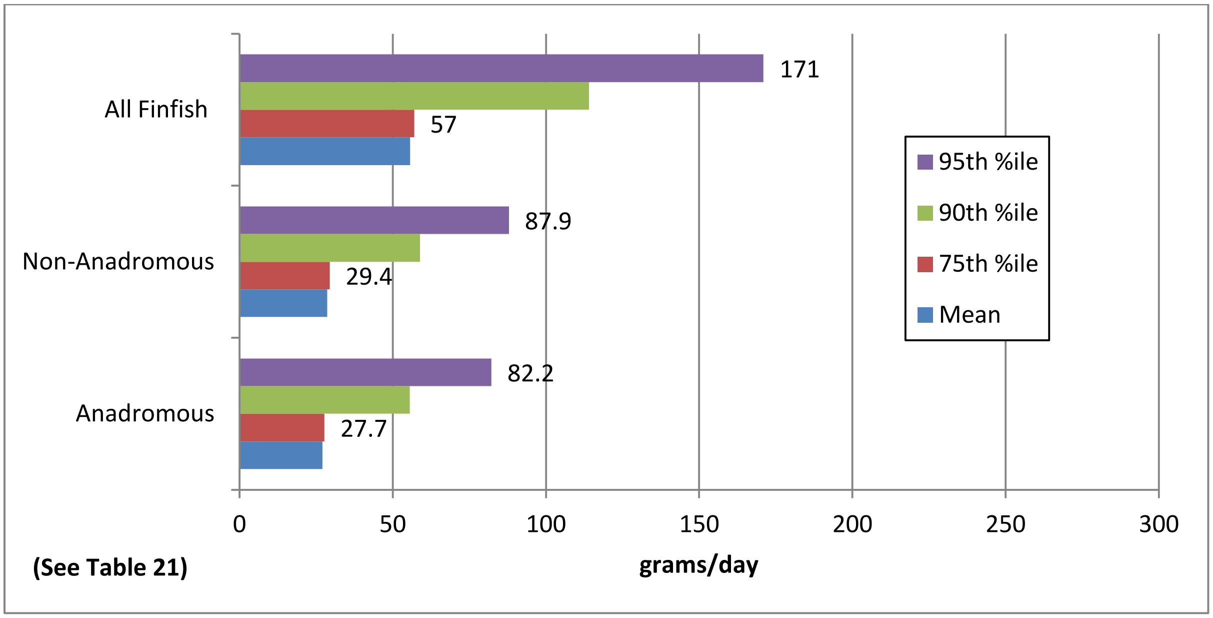

Figure 4. CRITFC Adult Fish Consumption Rates, Harvested from Columbia River Basin

Technical defensibility

As summarized in Table 22 below, Ecology has determined that the 1994 CRITFC survey is relevant to Washington and satisfies measures of technical defensibility.

Table 22. Columbia River Inter-Tribal Fish Commission Consumption Survey

Metric	Observations and Comments	Evaluation
1. Survey Method Development		
a. Type and description of survey vehicle	24-hour and seasonal dietary recall personal interview survey; respondents were randomly selected from Indian Health Service records; a large range of fish was considered in the survey (salmon, lamprey, smelt.)	The survey method and vehicle were developed in a technically defensible manner.
b. Collaboration and review	CRITFC staff developed the survey in collaboration with Washington DOH, EPA HQ & Region 10 staff, Indian Health Service staff; it was reviewed by tribal governments of the CRITFC member tribes (Nez Perce Tribe, Confederated Tribes and Bands of the Yakama Indian Nation, Confederated Tribes of the Warm Springs and Umatilla Indian Reservations).	
c. Beta testing	The survey was tested by tribal staff in consultation with EPA.	
2. Survey execution		
a. Establish and document execution standards	Execution of survey vehicle by native population documented; data gathered on adult respondents 18 years or older and children 5 years or younger.	The survey vehicle was appropriately executed and documented; use of fish models was documented.
b. Document staff training	Native staff trained personnel in collaboration with and with technical oversight provided by state/federal agencies.	
c. Finish/shellfish models used	Fish models were employed to aid in identifying the amount of finfish and shellfish consumed.	
3. Publication of results		
a. Where were results published? Are they clear and complete?	Results were published in a CRITFC tribal government publication. The population surveyed, method used, conclusions, and tabulations were well-defined, presented, and documented. The highest fish consumers were considered outliers and were dropped from the survey data and, therefore, were not statistically evaluated.	The data presented are sufficient to develop consumption distributions with percentiles.
b. Methodology reported	The methodology used is clearly described and documented.	
c. Results tabulated and stated	Survey results are reported and summarized in a tabular format suitable for distributional descriptive statistics; the report documents an acceptable response rate (69%).	
d. Conclusions clearly reported	Conclusions are stated and correspond to data tabulated.	
e. Variability and uncertainty	Variability and uncertainty were qualitatively recognized and noted.	
f. How is the potential for bias addressed?	Different types of bias were identified and discussed in the survey.	
4. Applicability and utility for regulatory decision making		
a. Representation of target population	The survey provides a reasonable estimate of fish consumption for CRITFC member Native populations within the Columbia River Basin (Nez Perce Tribe, Confederated Tribes and Bands of the Yakama Indian Nation, Confederated Tribes of the Warm Springs & Umatilla Indian Reservations).	This survey meets the standards of relevance, applicability, and utility and is appropriate for use in regulatory decision making. Rigorous
b. Currency of information	Surveys were conducted in the early to mid-1990s; more recently, the CRITFC estimates were used by Oregon DEQ for developing water quality standards (2011).	

Metric	Observations and Comments	Evaluation
c. Sufficiency of data	The fish consumption estimates are sufficient to provide descriptive statistics for defined distributions and percentiles for risk-based decision making. However, it is unclear what portion of seafood consumed is harvested from local sources. CRITFC fish consumption rates are for seafood from all sources and include anadromous (migratory) species.	
5. Overall technical suitability for regulatory decision making		
a. Range of technical defensibility	Survey design, development of methodology, execution of survey, data interpretation, and conclusions for fish consumption provide a reasonable quantitative exposure estimate of fish consumption rates for target populations.	Ecology concludes survey is technically defensible.
b. Appropriateness for use in risk-based standards	The data are sufficient to provide distribution, average, and percentile estimates of fish consumption as required for risk-based decision making.	

Source: CRITFC, 1994.

The CRITFC fish dietary survey was one of the first tribal dietary surveys conducted in the Pacific Northwest. The technical rigor applied to the design and conduct of this survey has been mirrored by other regional-specific surveys conducted in Washington State. The March 19, 2012, correspondence from Babtist Paul Lumley, Executive Director of CRITFC, to Ted Sturdevant, Director, Washington State Department of Ecology, summarizes the efforts that support the scientific defensibility of the CRITFC fish dietary survey (CRITFC, 2012). As described in this correspondence, the salient features of the 1994 CRITFC survey design and analysis are provided below:

- A technical panel was established to assist in designing and implementing the survey. The panel consisted of 17 members and included technical staff from CRITFC, as well as toxicologists, epidemiologists, health scientists, and environmental scientists from the Indian Health Service (IHS), the Centers for Disease Control and Prevention (CDC), Washington and Oregon State health departments, EPA Region 10, and EPA Headquarters.
- During a three-day session, the CDC trained interviewers and instructed them in procedures and techniques for conducting surveys. The instructors reviewed each question on the questionnaire with the interviewers and helped them practice conducting interviews. Models of finfish and shellfish were used as visual aids to help identify types and amounts of fish consumed.
- A total of 513 tribal members at least 18 years old were directly surveyed. These respondents provided information for 204 children age 5 or younger (one child per household). The CDC used a systematic probability sampling method to randomly select respondents from Indian Health Service client lists of tribal members. Stratified systematic sampling was used to collect survey data, with each of the four tribes considered an independent stratum.

- Survey data were transferred from the questionnaires to an electronic database, and all data entries were reviewed for missing answers or mistakes. The CDC's statistical database package for analysis of epidemiological data was used to analyze the survey data. A private consulting firm conducted a second complete audit of the database, which involved a question-by-question review of each survey. Appropriate statistical tests were used to evaluate the data. The Shapiro-Wilk test was used because the sample size was less than 2,000 and indicated that the dataset was not a purely random distribution, but rather reflected meaningful trends. In the 1994 CRITFC analysis, outliers whose data points seemed unreasonably high due to discontinuity in distribution were ignored on all calculations. For highly positively skewed distributions, removing statistical outliers from the dataset may bias the upper percentile fish consumption estimates low.
- The study design, implementation strategy, and analyses were submitted to an independent peer review panel. The peer review panel consisted of the following members: Dr. Patrick West, Ph.D., University of Michigan; Dr. Douglas Robeson, Ph.D., Ottawa, Ontario; Dr. Clayton Stunkard, Silver Spring, MD; Dr. H. Joseph Sekerke, Jr., State of Florida Department of Health and Rehabilitation Services; Dr. Mary Yoshiko Hama, Ph.D., U.S. Department of Agriculture, Food Consumption Research Branch; Dr. Kenneth Rudo, Ph.D., State of North Carolina, Department of Environmental Health, Division of Epidemiology; Dr. Yasmin Cypel, Ph.D., U.S. Department of Agriculture, Food Consumption Research Branch; Dr. Rolf Hartung, Ph.D., Department of Environmental and Industrial Health, University of Michigan; and Dr. Dale Hattis, Ph.D., Clark University.
- The CRITFC survey design's credibility is further supported by its use as a template for other Pacific Northwest dietary surveys, with refinements specific for the populations being surveyed. In addition, the CRITFC survey has been referred to in national guidance for policies and procedures for evaluating exposures (EPA's Exposure Factors Handbook 2009 Update and 2011 Edition).

Additional information reviewed

- Harris and Harper (1997) report that a fish consumption rate of 540 g/day represents a reasonable subsistence fish consumption rate for CRITFC's member tribes who pursue a traditional lifestyle. They base this on their review of several nonsubsistence Native American studies, two subsistence studies, and personal interviews of members of the Umatilla and Yakama Tribes.
- A further examination of Columbia River basin tribal populations used information and data collected from the 1994 Columbia River Inter-Tribal Fish Commission's fish consumption survey (Sun Rhodes, 2006). Because of concerns due to chemical contaminants in water and fish for tribal fish-consuming populations along the Columbia River basin, the tribal populations' characteristics were examined for children, women of

child-bearing age, and tribal elders who may be susceptible to adverse health effects from exposure to contaminants due to high fish consumption. A multivariate analysis showed a positive association between fish consumption rates and factors including breastfeeding after the most recent births, percent of fish obtained non-commercially for women who recently gave birth, living off the reservation, and fish consumption for children and the elderly. About 50 percent of women, 80 percent of tribal elders, and at least 40 percent of children consume nonfillet fish parts. Although this reevaluation did not result in any changes or corrections in Columbia River basin tribal consumption rates, it provided additional information regarding susceptible tribal populations that consume fish.

4.3.2 Tulalip and Squaxin Island Tribes of the Puget Sound Region

A survey of finfish and shellfish consumption for the Tulalip and Squaxin Island Tribes living in the Puget Sound region was conducted in 1994 (Toy et al., 1996).

The target populations included adult tribal members (18 years or older), randomly selected from tribal enrollments who lived on or within a 50-mile radius of the reservation, and children aged 5 years or younger who lived in the enrolled member’s household. The survey reported consumption rates of anadromous, pelagic, bottomfish, and shellfish in grams per kilogram body weight per day (g/kg bw/day) over a 1-year period and the portion size of each meal. Adults who did not consume fish (less than 1 percent of those contacted) were not included in the survey. Finfish/shellfish models were used to estimate portion sizes. Finfish/shellfish preparation methods were identified, and sources of finfish and shellfish consumed were reported by tribe and species groups.

Species groups included:

- *Anadromous fish (Group A)*. Salmon (Chinook, pink, sockeye, coho, chum); smelt; steelhead.
- *Pelagic fish (Group B)*. Cod, dogfish, greenling, herring, perch, pollock, rockfish, sablefish, spiny.
- *Bottomfish (Group C)*. Halibut, sole/flounder, sturgeon.
- *Shellfish (Group D)*. Butter clam, clams (manila/littleneck), cockles, Dungeness crab, horse clam, moon snail, mussels, oyster, scallops, sea cucumber, sea urchin, shrimp, squid.
- *Other (Groups E and F)*. Abalone, barnacles, bullhead, chitons, crayfish, eel, geoduck, grunters, limpets, lobster, mackerel, manta ray, octopus, razor clam, shark, skate, trout.

A total of 190 successful interviews were completed from February 25 through mid-May for adult tribal respondents. A tribal parent or guardian answered questions about the fish consumption for children from the same household. Only one child per household, selected randomly, was included in the survey, for a total of 69 children. Results from half of the adult respondents in the Tulalip Tribes were dropped because one of the tribal interviewers did not follow the survey interview protocol. However, repeat interviews were conducted by telephone as a follow-up with 10 percent of the survey respondents. The timing of the survey period may bias the fish consumption estimates. Salmon are present in Puget Sound during different times of the year. The survey was administered during a low season for anadromous (salmon) fish harvest but prior to and during the shellfish harvest season. Because of the timing of the survey, respondents may have underestimated their salmon consumption and overestimated shellfish consumption.

Anadromous finfish and shellfish were most frequently consumed. The main source for the most frequently consumed fish (anadromous finfish and shellfish) was local water bodies of Puget Sound. Fish fillets with skin were consumed by up to 40 percent of the tribal respondents, with mean percent consumption of fish parts (head, bones, eggs, organs, and skin) for up to 11 percent of tribal respondents consuming anadromous fish. Although the survey identified fish parts consumed by respondents, it did not include complex tribal seafood recipes.

Weight adjusted consumption rates were calculated and reported by tribe, age, gender, income, and species group. The adult mean and median consumption rates for all forms of fish combined were 0.89 and 0.55 g/kg bw/day for the Tulalip Tribes and 0.89 and 0.52 g/kg bw/day for the Squaxin Island Tribe, respectively. Age-adjusted median fish consumption rates for the Tulalip Tribes were 53 g/day for males and 34 g/day for females. Age adjusted median fish consumption rates for the Squaxin Island Tribe were 66 g/day for males and 25 g/day for females. The mean and median consumption rate for children, 5 years and younger for both tribes combined, were 0.53 and 0.17 g/kg bw/day, respectively.

Ecology’s statistical analysis of the Tulalip survey data (individual level respondent data) provides estimates of anadromous, non-anadromous, shellfish, all finfish/shellfish consumption estimates, and source of harvest (Table 23, Figures 5 and 6).

Table 23. Tulalip Tribal Adult Fish Consumption Rates by Species Group and Source

Population Tribal	Species Group	Harvest Source of Fish	Descriptive Statistics (g/day)				
			50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
Tulalip	All Fish	All Sources	44.5	82.2	94.2	193	268
	Finfish	All Sources	22.3	44.1	49.1	110	204
	Shellfish	All Sources	15.4	42.6	40.1	113	141
	Non-anadromous	All Sources	20.1	45.9	52.4	118	151
	Anadromous	All Sources	16.8	38.1	43.3	92.1	191
	All	Puget Sound	29.9	59.5	75.0	139	237
	Finfish	Puget Sound	13.0	31.9	33.1	78.4	146
	Shellfish	Puget Sound	14.2	36.9	40.1	111	148
	Non-anadromous	Puget Sound	14.8	35.5	38.8	109	145
	Anadromous	Puget Sound	11.8	30.4	32.4	66.0	148

(See Table 23)

Figure 5. Tulalip Tribal Adult Fish Consumption Rates, Harvested from All Sources

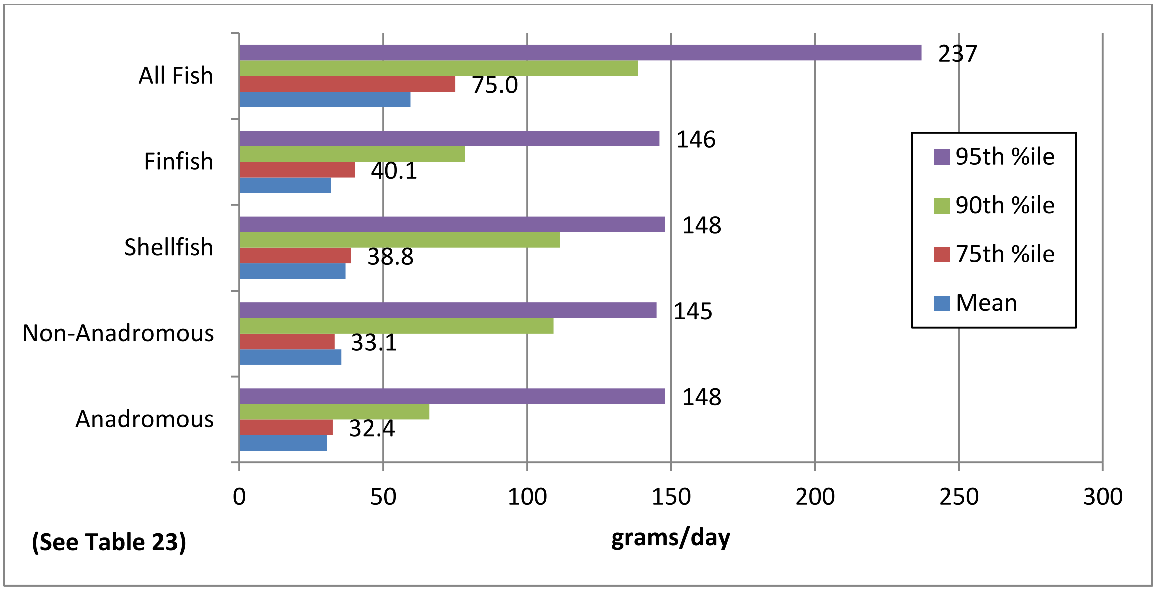

Figure 6. Tulalip Tribal Adult Fish Consumption Rates, Harvested from Puget Sound

Ecology's statistical analysis of the Squaxin Island survey data provides consumption estimates for anadromous, non-anadromous, shellfish, and all finfish/shellfish, and data on source of harvest (Table 24, Figures 7 and 8). Consumption rate estimates for the Squaxin Island adult fish consumers are based on published results of the fish dietary survey.

Table 24. Squaxin Island Tribal Adult Fish Consumption Rates by Species Group and Source

Population Tribal	Species Group	Harvest Source of Fish	Descriptive Statistics (g/day)				
			50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
Squaxin Island	All fish	All	44.5	83.7	94.4	206	280
	Finfish	All	31.4	65.5	82.3	150	208
	Shellfish	All	10.3	23.1	23.9	54.0	83.6
	Non-anadromous	All	15.2	28.7	32.3	70.5	95.9
	Anadromous	All	25.3	55.1	65.8	128	171
	All fish	Puget Sound	30.0	56.4	63.5	139	189
	Finfish	Puget Sound	21.6	45.0	56.5	103	143
	Shellfish	Puget Sound	6.4	14.3	14.8	33.5	51.9
	Non-anadromous	Puget Sound	6.5	12.3	13.9	30.3	41.2
	Anadromous	Puget Sound	20.2	44.1	52.6	103	137

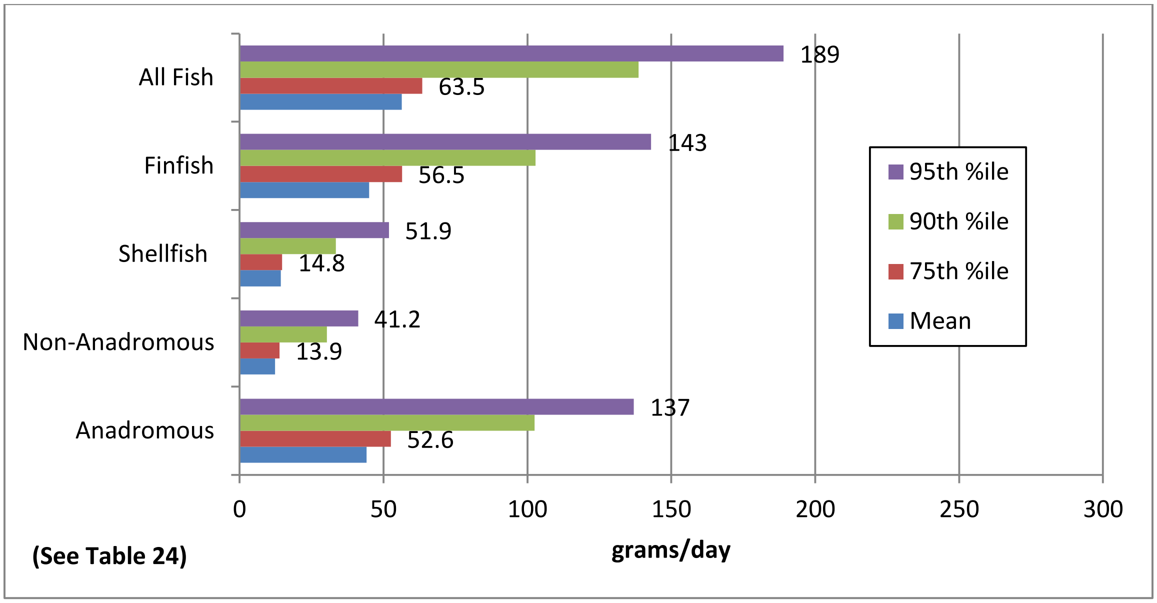

Figure 8. Squaxin Island Tribal Adult Fish Consumption Rates, Harvested from Puget Sound

Technical defensibility

As summarized in Table 25 below, Ecology has determined that the survey of Tulalip and Squaxin Island Tribes of the Puget Sound Region is relevant to Washington and satisfies measures of technically defensibility (Toy et al., 1996).

Table 25. Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region

Metric	Observations and Comments	Evaluation
1. Survey method development		
a. Type and description of survey vehicle	Personal interview survey; 24-hour and seasonal dietary recall; finfish/shellfish identification, portion, frequency, preparation, and harvest locations.	The survey method and vehicle were developed in a technically defensible manner.
b. Collaboration and review	Survey was developed in collaboration with Washington DOH, Ecology, EPA Region 10, Tulalip Tribal Department of Environment, Suquamish Tribal Fisheries Department, Board of Directors for Tulalip and Squaxin Island Tribes, Columbia River Inter-Tribal Fish Commission, and Fred Hutchinson Cancer Research Center in Seattle.	
c. Beta testing	Pilot survey and repeat interviews conducted	
2. Survey execution		
a. Establish and document execution standards	Execution of survey questionnaire documented with identifiable QA/QC procedures.	The survey vehicle was appropriately executed and documented; use of fish models was documented.
b. Document staff training	Two members from each tribe trained to conduct interviews.	
c. Finfish/shellfish models used	Finfish and shellfish models used for multiple species.	
3. Publication of results		
a. Where were results published? Are they clear and complete?	Finfish/shellfish identification, portion, frequency, preparation, and harvest locations documented and reported.	The data presented in the joint Tulalip and Squaxin Island tribal publication are sufficient to develop consumption distributions with percentiles.
b. Methodology reported	All phases of method development documented and reported.	
c. Results tabulated and stated	Tabulated species-specific consumption with descriptive statistics.	
d. Conclusions clearly reported	Conclusions reported with follow-up interviews for reliability and representation	
f. Variability and uncertainty	Noted and documented with note of “outliers” with reported rates for Tulalip and Squaxin Island Tribes.	
g. How is the potential for bias addressed?	The possibility for bias in the survey methodology is recognized and discussed. Survey results from one interview did not follow protocol and were eliminated.	
4. Applicability and utility for regulatory decision making		
a. Representation of target population	Included range of different rates for enrolled Tulalip and Squaxin Island tribal members	This survey meets the standards of relevance, applicability, and utility and is appropriate for use in regulatory decision making.
b. Currency of information	Survey conducted in 1996; more recently the consumption estimates were used by Oregon DEQ in developing water quality standards (2011). EPA Region 10 has also utilized the Suquamish survey in its internal policy on assessing tribal seafood consumption risks.	
c. Sufficiency of data	The data are sufficient to provide distribution and percentile estimates of fish consumption for Tulalip and Squaxin Island tribal populations.	

Metric	Observations and Comments	Evaluation
5. Overall technical suitability for regulatory decision making		
a. Range of technical defensibility	Technically defensible dietary survey of the Squaxin Island Tribe.	Ecology concludes the survey is technically defensible.
b. Appropriateness for use in risk-based standards	Data were reanalyzed by Nayak L. Polissar, Ph.D., to provide consumer-only consumption rates. It is sufficient to provide distribution and percentile estimates of fish consumption as required for risk-based decision making.	

Source: Toy et al., 1996.

The technical rigor applied to the design and conduct of the Tulalip and Squaxin Island tribal fish dietary survey illustrates a high level of collaboration across state and federal agencies and tribal governments, and closely parallels the CRITFC fish dietary survey. The salient features of this survey are noted below:

- A Technical Advisory Panel was formed to provide assistance and oversight for planning, developing methods, and conducting the dietary survey. Panelists included numerous professionals from the Washington State Departments of Health and Ecology, U.S. Environmental Protection Agency, and the U.S. Public Health Service.
- Tulalip and Squaxin Island tribal staff assisted with organizing and executing the survey. They also provided tribal consultations with other tribal governments and organizations including the Columbia River Inter-Tribal Fish Commission, Portland, Oregon.
- A toxicologist, epidemiologist, tribal biologists, and statistical consultants provided professional guidance and consultations.

4.3.3 Suquamish Tribe

The Suquamish Tribal Council conducted a fish consumption survey during July, August, and September 1998 of Suquamish tribal members living on and near the Port Madison Indian reservation in the Puget Sound area (The Suquamish Tribe, 2000). The survey was conducted to determine the finfish/shellfish consumption rates, habits, and patterns of the Suquamish Tribe. Also, the study was conducted to identify fish consumption-related cultural practices and tribal characteristics that might affect fish consumption rates, patterns, and habits. The survey was administered during months of high availability of fisheries, which may have had a positive bias on the reported fish consumption estimates.

Consumption data were based on a random sample of adults (16 years and older) selected from the tribal enrollment roster. Of 425 tribal members of all ages living on or near the reservation, 284 adults were identified as eligible to participate in the survey. Of these, 142 adults were randomly selected and 92 participated in the survey, for a 64.8 percent participation rate. Consumption data were collected for 31 children under the age of 6 who were living in the same household with adult respondents at the time of the survey. Some households had more than one child who was surveyed. The survey questionnaire was administered by trained tribal members using personal interviews and included two parts: a 24-hour dietary recall, and an assessment of fish consumption over the course of a year.[37] In addition, the survey included information on:

- Fish species identification, portion sizes, frequency of consumption, methods of preparation, harvest locations.
- Shellfish consumption, methods of preparation, harvest location.
- Changes in consumption over time, cultural information, physical information, and socioeconomic information.

Finfish/shellfish models were used to assist tribal respondents regarding amounts and types consumed. Booklets were used to assist in identifying harvest locations of seafood consumed. Finfish/shellfish were grouped into categories based on similarities in life history and practices of tribal members who fish for subsistence, ceremonial, and commercial purposes. The majority of finfish/shellfish consumed by the Suquamish Tribe was harvested from Puget Sound, with Pacific salmon and shellfish consumed more than other fish.

All 92 adult tribal respondents reported consuming some type of fish; hence, no non-consumers of fish were surveyed. Survey results were recorded as grams per kilogram per day (g/kg/day) along with the respondent’s body weight. Adult respondents reported a mean consumption rate of all finfish and shellfish consumption rate of 2.71 g/kg/day. For children under 6 years old, the mean consumption of all finfish and shellfish was 1.48 g/kg/day. Below are weight-adjusted survey results for Suquamish adult fish consumers.

Ecology’s statistical analysis of the Suquamish dietary data for Suquamish tribal adult fish consumers provides finfish, shellfish, and non-anadromous consumption rates by species groups and sources of fish consumed (Table 26, Figures 9 and 10).

---

[37] Estimates of maximum amounts of fish consumed, either as a rate or portion size, from a highly positively skewed dataset can be very large with estimates of several pounds of fish consumed. These maximum fish consumption estimates reflect the maximum amount of fish consumed by a subset of fish consumers within a larger indigenous fish-consuming population. Harper, Harris, and Donatuto have indicated that these very high fish consumers are true subsistence populations (fish consumption rate exceeding 454 g/day or 1 pound/day) within the larger indigenous fish-consuming populations (Harris and Harper, 1997; Harper and Harris, 2008; Donatuto and Harper, 2008).

Table 26. Suquamish Tribal Adult Fish Consumption Rates by Species Group and Source

Population Tribal	Species Group	Harvest Source of Fish	Descriptive Statistics (g/day)				
			50th Percentile	Mean	75th Percentile	90th Percentile	95th Percentile
Suquamish Tribe	All	All Sources	132	214	284	489	797
	Shellfish	All Sources	64.7	134	145	363	615
	Non-anadromous*	All Sources	102	169	219	377	615
	Anadromous	All Sources	27.6	48.8	79.1	133	172
	All	Puget Sound	57.5	165	221	397	767
	Shellfish	Puget Sound	52.4	109	118	294	499
	Non-anadromous*	Puget Sound	49.1	126	116	380	674
	Anadromous	Puget Sound	21.8	38.6	62.5	105	136

See Polissar et al., 2012

*Based on an assumed n = 90 consumers.

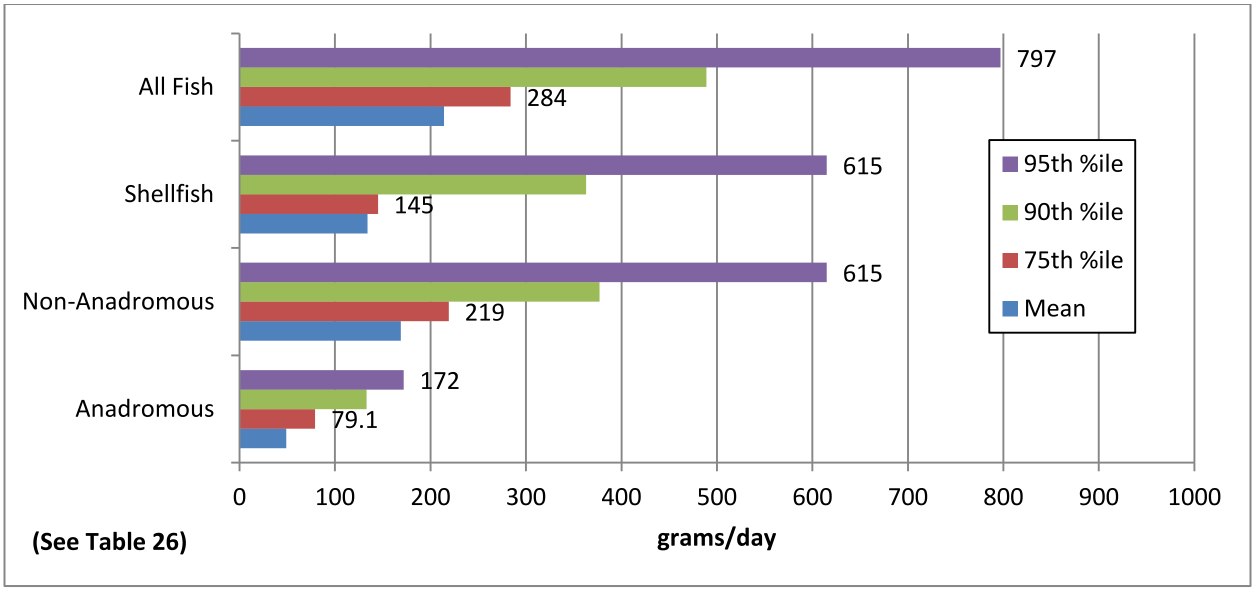

Figure 9. Suquamish Tribal Adult Fish Consumption Rates, Harvested from All Sources

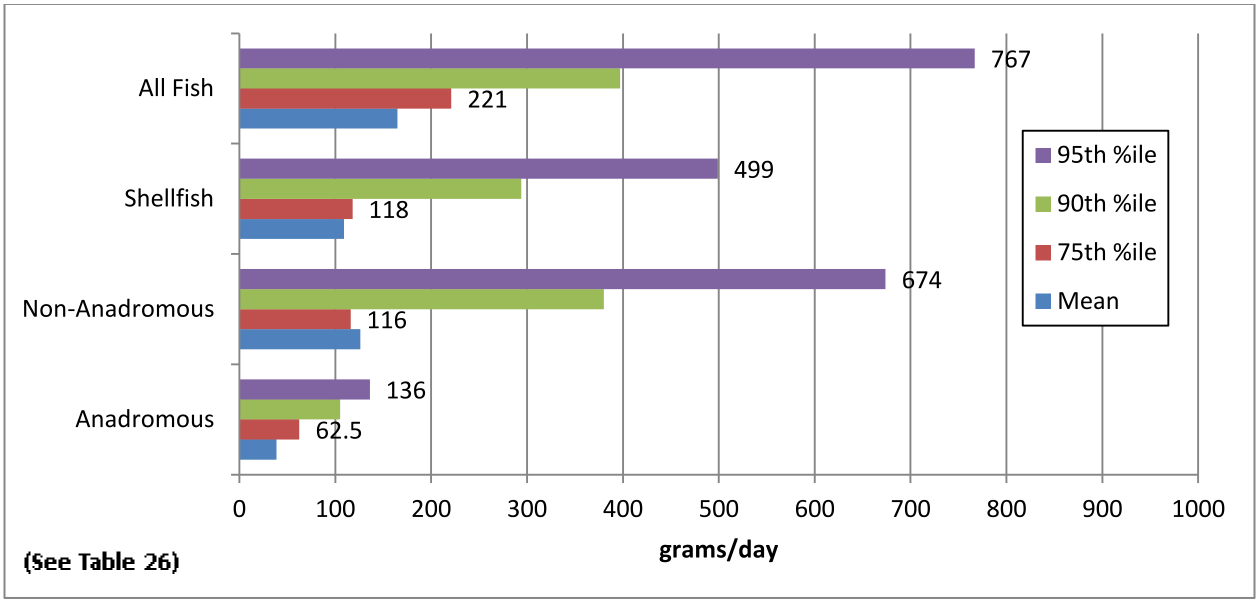

Figure 10. Suquamish Tribal Adult Fish Consumption Rates, Harvested from Puget Sound

Technical defensibility

As summarized in Table 27 below, Ecology has determined that the 2000 survey of the Suquamish Indian Tribe of the Port Madison Indian Reservations of Puget Sound is relevant to Washington and satisfies measures of technical defensibility.

Table 27. Fish Consumption Survey of the Suquamish Indian Tribe of the Port Madison Indian Reservation, Puget Sound Region

Metric	Observations and Comments	Evaluation
1. Survey method development		
a. Type and description of survey vehicle	Personal interview survey; 24-hour and seasonal dietary recall; finfish/shellfish identification, portion, frequency, preparation, and harvest locations.	The survey method and vehicle were developed in a technically defensible manner.
b. Collaboration and review	Survey was developed in collaboration with Washington DOH, Ecology, Agency for Toxic Substances and Disease Registry, University of Washington, EPA Region 10, and Suquamish Tribal Fisheries Department.	
c. Beta testing	Beta testing documented.	
2. Survey execution		
a. Establish and document execution standards	Execution of survey questionnaire documented with identifiable QA/QC procedures.	The survey vehicle was appropriately executed and documented; use of fish models was documented.
b. Document staff training	Training of personnel was conducted by trained Suquamish Tribe members.	
c. Finfish/shellfish models used	Seafood models and a display booklet of seafood illustrations for multiple species were used to aid in identifying the amount of seafood consumed.	

Metric	Observations and Comments	Evaluation
3. Publication of results		
a. Where were results published? Are they clear and complete?	Finfish/shellfish identification, portion, frequency, preparation, and harvest locations were documented and reported.	Suquamish Tribe publication with well-defined method, analysis of species consumed, clear data analysis and interpretation.
b. Methodology reported	The methodology used is clearly described and documented.	
c. Results tabulated and stated	Survey results are reported and summarized in a tabular format suitable for distributional descriptive statistics.	
d. Conclusions clearly reported	Conclusion reported with follow-up interviews for reliability and representation.	
e. Variability and uncertainty	Noted and documented with “outliers” identified and determined impact of outliers on consumption rate statistics of interest.	
f. How is the potential for bias addressed?	The possibility for bias in the survey methodology is recognized and discussed.	
4. Applicability and utility for regulatory decision making		
a. Representation of target population	Included range of different rates for enrolled Suquamish Tribe members.	This survey meets the standards of relevance, applicability, and utility and is appropriate for use in regulatory decision making.
b. Currency of information	The survey was conducted in 1999; more recently, the consumption estimates were used by Oregon DEQ for developing water quality standards (2011).	
c. Sufficiency of data	The fish-consumption estimates are sufficient to provide descriptive statistics for defined distributions and percentiles for Suquamish Tribal population. EPA Region 10 has also utilized the Suquamish survey information in its internal policy on assessing tribal seafood consumption risks.	
5. Overall technical suitability for regulatory decision making		
a. Range of technical defensibility	Technically defensible dietary survey of the Suquamish Tribe.	The survey is technically defensible with rates and portion sizes reinforced by independent technical documentation (Harper and Harris, 1997, 2008; Donatuto and Harper, 2008).
b. Appropriateness for use in risk-based standards	The data are sufficient to provide distribution and percentile estimates of fish consumption as required for risk-based decision making. Seafood consumption data provided are for consumption of seafood from all sources. EPA Region 10's tribal seafood consumption framework provides an approach for developing consumption rates of regionally harvested seafood.	

Source: The Suquamish Tribe, 2000.

Many features of the Suquamish tribal member dietary survey are similar to and reflect the experience gained during the development and conduct of the CRITFC dietary survey. These features were identified and described in the survey report, which confers and supports the technical defensibility of the study design, dietary methodology, execution of the survey, and results and conclusions drawn from the dietary survey (The Suquamish Tribe, 2000). The salient features of the technical review procedures for the Suquamish dietary review are noted below:

- The survey was funded through the Agency for Toxic Substances and Disease Registry (ATSDR), U.S. Department of Health and Human Services, and Washington State Department of Health with collaboration regarding the survey questionnaire design to elicit useful dietary information from tribal respondents.
- Technical review and oversight of the planning, design, execution, and evaluation of the data included biologists, epidemiologists, toxicologists, and statisticians from multiple agencies.
- The Suquamish Tribal staff included interviewers, biologists, and a principle investigator.
- Technical collaboration, consultations, and reviews were conducted by the Washington Departments of Ecology and Health, University of Washington, U.S. Department of Health and Human Services, Fred Hutchinson Cancer Research Institute, and the U.S. Environmental Protection Agency.
- Data analysis and review were conducted by two Seattle statistical consulting firms, Mountain-Whisper-Light Statistics and StatPro Consultants.

4.4 Asian and Pacific Islanders

An Asian and Pacific Islander (API) seafood consumption study was conducted during the spring and summer of 1997 in King County, Washington, to obtain information on consumption rates, species and seafood parts consumed, and preparation methods for first- or second-generation members of the API community (Sechena et al., 1999). Survey participants were API seafood consumers 18 years or older. The study was conducted in three phases:

- *Phase I:* Identify target API ethnic groups and develop appropriate questionnaires in the language required to administer the questionnaire to each API ethnic group.
- *Phase II:* Characterize seafood consumption for 10 API ethnic groups within the King County study area.[38]
- *Phase III:* Develop culturally appropriate health messages on risks related to seafood consumption and disseminate to API community.

Of the 202 respondents, 89 percent were first API generation (born outside the United States). API participants were interviewed by trained representatives from each of the 10 API ethnic communities represented and asked to report on the number of annual servings and portion size of the servings. Participants reported their own body weights. Fish consumption rate results were reported as grams per kilogram per day. Because the survey was based on dietary recall, the authors selected 20 API respondents to interview a second time, to assess the reliability of the

---

[38] The 10 API ethnic groups are Cambodian, Chinese, Filipino, Hmong, Japanese, Korean, Laotian, Mien, Samoan, and Vietnamese.

responses. The results suggest that the estimated consumption rates are reliable for the API community study area.

Table 28 provides the weight-adjusted survey results for API adult fish consumers.

Table 28. Adult Respondents to the Asian and Pacific Islander Survey

	Number of Adults Surveyed	Descriptive Statistics (g/day)					
		Mean	Median	Percentiles			
				75th	90th	95th	99th
Asian and Pacific Islanders	202	117	78	139	236	306	-

Source: Adapted from Oregon DEQ, 2008, Table 3. See also Polissar et al., 2012; Sechena et al.,1999, 2003.

Survey results indicate that shellfish were consumed more by the API community than any other group of fish. More than 75 percent of the respondents consumed shrimp, crab, and squid. Salmon and tuna were the most frequently consumed finfish. For all fish groups, 79 to 97 percent of the seafood consumed came from either groceries/street vendors or restaurants. Japanese consume a greater percentage of finfish than shellfish (52 percent), while Vietnamese consume more shellfish (50 percent). The mean and median consumption rates for all seafood combined for the 10 API ethnic groups were 1.9 g/kg bw/day and 1.4 g/kg bw/day, respectively. The average shellfish consumption rate for the API community was 0.87 g/kg bw/day. The API community consumed more shellfish than all of the combined categories of finfish consumed (average finfish consumption is 0.82 g/kg bw/day).

Technical defensibility

As summarized in Table 29 below, Ecology has determined that the 1999 survey of King County Asian and Pacific Islanders is relevant to Washington and satisfies measures of technical defensibility. The King County, Washington, API fish consumption survey is considered an outstanding model (gold standard) for culturally sensitive fish dietary surveys.

The fish dietary survey was administered in two phases:

- *Phase 1:* Identification of appropriate API ethnic groups to survey, design culturally sensitive fish dietary survey questionnaire, and then translate and pilot test the questionnaire for each API ethnic group.
- *Phase 2:* Established partnership between the Refugee Federation Service Center and the University of Washington's Environmental Health Department to help support the University of Washington Human Subjects Committee for the design, survey instruments, and execution of the survey.

Table 29. Asian and Pacific Islander Seafood Consumption Study

Metric	Observations and Comments	Evaluation
1. Survey method development		
a. Type and description of survey vehicle	Personal interview survey; 24-hour dietary recall; conducted in three phases.	The survey method and vehicle were developed in a technically defensible manner.
b. Collaboration and review	Survey was developed in collaboration with a Community Steering Committee (representatives of the API community, Washington DOH, Ecology, EPA Region 10, University of Washington, and Seattle Refugee Federation Service Center).	
c. Beta testing	The testing of the survey was conducted in phases with follow-up interviews to assess reliability of responses.	
2. Survey execution		
a. Establish & document execution standards	Seafood consumption studies for 10 API groups in King County, Washington. Technical execution guided by Community Steering, Technical, and Advisory Committees.	The survey was appropriately executed and documented; use of fish models was documented.
b. Document staff training	Trained bilingual interviewers from API community.	
c. Finfish/shellfish models used	Seafood models were used to represent approximate portion sizes.	
3. Publication of results		
a. Where were results published? Are they clear and complete?	Information on types of seafood consumed, source of seafood, preparation methods, frequency and portion size consumed, demographic information clearly reported.	Robust analysis and evaluation of API community fish consumption habits and patterns
b. Methodology reported	Phase II (fish consumption) followed from identification target API populations with ethnic and language-specific questionnaires.	
c. Results tabulated and stated	Tabulated species-specific consumption across 10 different API ethnic populations; included food preparation methods.	
d. Conclusions clearly reported	Conclusions clearly reported with follow-up interviews.	
e. Variability and uncertainty	Variability and uncertainty were qualitatively recognized and noted.	
f. How is the potential for bias addressed?	The possibility for bias in the survey methodology is recognized and discussed.	
4. Applicability and utility for regulatory decision making		
a. Representation of target population	The survey included a range of different API ethnic groups to evaluate consumption representative of API population.	This survey meets the standards of relevance, applicability, and utility and is appropriate for use in regulatory decision making.
b. Currency of information	The survey was conducted in 1999; more recently, the consumption estimates were used by Oregon DEQ in developing water quality standards (2011).	
c. Sufficiency of data	The consumption estimates are sufficient to provide descriptive statistics for defined distributions and percentiles for different API populations.	
5. Overall technical suitability for regulatory decision making		
a. Range of technical defensibility	Technically defensible dietary survey of API populations in King County, Washington.	Ecology concludes the survey is technically defensible.
b. Appropriateness for use in risk-based standards	The data are sufficient to provide distribution and percentile estimates of fish consumption as required for risk-based decision making. The API survey did not correct for cooking weight loss or regionally harvested seafood. See write-up on EPA Region 10's reanalysis of the API survey (Kissinger, 2005).	

Source: Sechena et al., 1999.

Sechena et al., 2003 provides a detailed description of the API fish dietary survey. Detailed descriptions of the survey methodology include:

- A methodology overview.
- Survey instruments.
- Sampling strategy including respondent selection criteria, API ethnic representation and recruitment, questionnaire administration, data analyses.
- Statistical methods used to derive fish consumption rates, treatment of outliers, hypothesis testing, and statistical significance and descriptive statistics.
- Results and discussion with tabulated results in g/kg/day for upper percentile estimates.

4.4.1 Reanalysis by EPA Region 10

EPA Region 10 reanalyzed the API data to correct for cooking weight loss, regional seafood harvest, and extrapolation from the survey to King County API populations (Kissinger, 2005). This reanalysis was used to establish cleanup levels in the Lower Duwamish Waterway (Windward Environmental, 2007). The EPA Region 10 reanalysis of the API 1999 survey included only data for individuals consuming seafood from King County. Weighting factors for King County consumers for various ethnic groups were a function of the percentage of that ethnic group as determined in the census and the number of individuals in that ethnic group that consumed seafood from King County. The 95th percentile ingestion rate (defined as the reasonable maximum exposure [RME] scenario) was developed from the consumer-only dataset of weighted ingestion rates. Adjustments were made to account for some of the shellfish consumption reported on a cooked-weight basis rather than on a wet-weight basis. Revised estimates of average raw shellfish consumption were made by using 25 and 50 percent cooking loss correction factors for those shellfish species for which consumption was reported on a cooked-weight basis. EPA calculated demographically weighted mean ingestion rates for each seafood category for individuals who consumed some seafood caught in King County. Demographically weighted mean ingestion rates were used to derive the percentage of consumption of each seafood category. These percentages were then applied to the total consumption rate (95th percentile of total King County API seafood consumption of 57.1 g/day) to derive consumption rates for each seafood category.

Anadromous fish were not included in the fish consumption scenario because it is problematic to apportion salmon (anadromous fish) contaminant body burden to site-specific chemical contaminants. To estimate the API central tendency consumption rate, the 50th percentile of total King County API consumption was multiplied by the percentage of consumption for the various seafood categories. Total non-anadromous seafood consumption for the API exposure scenarios was 51.1 g/day and 5.3 g/day for the RME and central tendency estimates, respectively.

Reanalysis of the consumption of shellfish (mussels, crabs, and clams) for the API exposures used average demographically weighted consumption of these shellfish species harvested only from King County. These shellfish consumption estimates were used to calculate the percentage of each shellfish type consumed. The demographic weighting factor was used to estimate the consumption of clams, mussels, and crabs. The crab consumption rates were apportioned among crab whole body and edible meat, and the benthic (demersal) fish consumption rates were apportioned among benthic fish fillet and whole body. EPA Region 10 provided demographically weighted average percentages of crab whole-body and crab edible-meat consumption by API populations consuming at least some King County seafood. Also, EPA Region 10 provided average demographically weighted percentages of whole-body and fillet consumption by API members consuming at least some King County seafood.

Technical defensibility

Ecology has determined that the EPA Region 10 reanalysis of the 1999 API survey is a relevant and technically defensible approach for a site-specific evaluation (Lower Duwamish Waterway).

Reanalysis of the API data by EPA Region 10 for King County API adult consumers provided central and upper bound estimates of fish consumption (Table 30). The reported consumption estimates include no adjustment for cooking and may be slightly biased low (i.e., underestimated).

The Kissinger (2005) demographic weighting methodology is not recommended for projecting fish dietary patterns for API populations beyond King County. Because of the small number of respondents for each API ethnic group, there would be a high level of uncertainty in projecting statewide API fish dietary patterns from King County API fish dietary information.

It should be noted that Asian and Pacific Islanders include a broad range of ethnicities[39] and that the Kissinger (2005) analysis presents fish consumption estimates determined from aggregating fish consumption data for small numbers of individuals from these varied ethnic groups. Future fish consumption survey efforts should consider more comprehensive analysis of quantitative fish consumption and cultural factors associated with fish consumption by individual ethnic groups.

---

[39] For the ethnicities listed here, the first number is the number of respondents from that ethnic group; the second number is the percentage of the total number of respondents represented by that group (Sechena et al., 2003, Table 1).

Cambodian	20/≈10%	Mien	10/≈5%

Filipino	30/≈14%	Samoan	10/≈5%
Japanese	29/≈14%	Vietnamese	26/≈13%
Korean	22/≈10%	All API Ethnicity	202
Laotian	20/≈10%		

Table 30. API Adult Seafood Consumption Rates by Species Group and Source

Population API	Species Group	Source of Fish	Descriptive Statistics (g/day)		
			50th Percentile	90th Percentile	95th Percentile
Asian-Pacific Islander (API)	Total seafood consumption	All sources	74.0	227	286
	All species	Harvested anywhere	6.5	25.9	58.8
	All species	Harvested from King County	5.7	22.2	48.4
	Non-anadromous species	Harvested anywhere	6.2	37.9	54.1
	Non-anadromous species	Harvested from King County	6.0	20.1	45.5

Sources: Adapted from Kissinger, 2005, Table 5. See also Polissar et al., 2012.

In recommending fish consumption estimates for API populations, EPA Region 10 proposed using estimates that accounted for weight lost during cooking. The EPA Region 10 rates included adjustments to account for cooking loss (Table 31).

Table 31. API Seafood Consumption Rates Adjusted for Cooking Loss

Population API	Species Group	Source of Fish	Descriptive Statistics (g/day)		
			50th Percentile	90th Percentile	95th Percentile
Asian-Pacific Islander (API)	Total seafood consumption	All sources	77.8	236	306
	All species	Harvested anywhere	6.9	49.1	76.3
	All species	Harvested from King County	5.8	25.5	57.1
	Non-anadromous species	Harvested anywhere	7.1	54.2	72.3
	Non-anadromous species	Harvested from King County	6.6	33.4	57.3

4.5 Recreational fishers

Recreational fishing is a popular activity and consideration of recreational fishers provides additional information about fish consumption from Washington waters. Although data for the general population is useful for evaluating fish consumption rates, data on recreational fishing are needed to assess exposure to individuals with potentially higher fish consumption levels. Recreational fishers may consume fish more frequently, and may consume larger portions at each meal, than the general population. In addition, they may frequently fish from a single contaminated source. These factors may put recreational fishers at higher risk of exposure to contaminants in finfish and shellfish.

Several studies have been conducted in Washington State to evaluate the fish consumption of recreational anglers. The Technical Issue Paper *Recreational Fish Consumption Rates* provides detailed information on these surveys and their findings. Many of the available recreational angler surveys were done in the 1980s and are not as current as the other surveys noted above. Additionally, recreational surveys are generally creel, rather than personal interview surveys. These fish consumption surveys can be used to provide an estimate of mean and upper (90th to 95th) percentile marine/estuarine and freshwater fish consumption rates for recreational fishers in Washington State, as follows:

- Mean consumption rates for both freshwater and marine/estuarine finfish and shellfish are in the range of 20 to 60 g/day.
- Upper percentile consumption rates are in the range of 200 to 250 g/day for marine/ estuarine finfish and shellfish, and in the range of 100 to 150 g/day for freshwater fish.

Ecology believes that recreational angler surveys employing a creel methodology are far less appropriate for regulatory use than surveys that utilize a personal interview approach (see Tables 9 and 10).

4.6 Additional fish consumption rate information evaluated by Ecology

In addition to the studies summarized in Section 4.1 to 4.5 above, Ecology considered a range of other sources of information about fish consumption in Washington, as listed in Table 32. These sources provide information on resource use and historical information about fish consumption, which provides a larger and more complete view of finfish and shellfish harvest and consumption in Washington. Appendix B provides a summary of additional tribal fish consumption evaluations reviewed during preparation of this Technical Support Document.

Table 32. Fish Consumption Information Relevant to Washington and Considered by Ecology

Tribal Surveys	Description
A Fish Consumption Survey of the Umatilla, Nez Perce, Yakama, and Warm Springs Tribes of the Columbia River Basin [a]	Fish consumption habits & patterns of selected Native American tribes that reside and harvest fish in the Columbia River Basin. Includes Yakama and Umatilla tribes from Washington; Nez Perce and Warm Springs tribes from Oregon State.
A Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region [b]	Puget Sound regional survey for two tribes. Provides information on both finfish and shellfish consumption.
Fish Consumption Survey of the Suquamish Indian Tribe of the Port Madison Indian Reservations, Puget Sound Region [c]	Puget Sound regional survey for two tribes. Provides information on both finfish and shellfish consumption.
Survey of Asian and Pacific Islander	
Asian and Pacific Islander Seafood Consumption Study [d]	King County specific fish consumption estimates for Asian and Pacific Islanders. Survey information has been used by EPA Region 10 to estimate rates for Asian and Pacific Islanders for other Puget Sound areas. Using Sechena et al., 1999, EPA Region 10 reanalyzed data to support Ecology in developing site-specific MTCA cleanup standards and risk assessment for the Lower Duwamish Waterway and Elliott Bay.[e]
U.S. General Population	
Estimated Per Capita Fish Consumption in the United States [f]	Includes fish consumers and non-consumers. (These data were used by Oregon DEQ to estimate the percentage of fish consumers and non-consumers in Oregon.)
State Assessments, Evaluations, and Advisories	
Washington State Department of Health Fish Advisories	Various water body-specific fish consumption rates. DOH advisories provide information on fish meals that should be avoided or can be safely eaten for analytically determined contaminant levels in fish tissue.
Lower Duwamish Waterway Baseline Human Health Risk Assessment [g]	Provides fish consumption information derived from Puget Sound surveys as incorporated in the EPA Region 10 framework describing tribal seafood consumption risk assessment for Resource Conservation and Recovery Act (RCRA) and Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) cleanup sites in Puget Sound and modified by tribal consultation. Develops sediment cleanup standards based on tribal RME scenarios.
Lower Elwha Klallam Tribe/Port Angeles [h, i]	In collaboration with Ecology and using the EPA Region 10 framework developed tribal fish consumption rate. Cleanup standards are based on a tribal RME.
Lake Roosevelt, DOH [j]	DOH in cooperation with the Spokane Tribe, water body- and angler-specific creel survey; 42 fish meals/year; assuming 8-ounce meal. This is approximately 26 g/day.
Sinclair Inlet Bremerton Naval Complex [k]	Risk-based screening levels based on Suquamish Tribe adult and children finfish/shellfish ingestion rates and recreational sport fishers (see Appendix A).
Lake Whatcom, DOH [l]	Provided estimated species-specific fish meals sizes for commonly caught and consumed Lake Whatcom fish species (crayfish, cutthroat trout, kokanee, yellow perch, smallmouth bass) with median rates in g/meal; from low (crayfish) of 24 g/meal and high (smallmouth bass) of 220 g/meal.
Rhone-Poulenc [m]	Cleanup standards based on Tulalip tribal and Asian and Pacific Islander seafood consumption data. Range of fish consumption rates referred to and documented in Lower Duwamish Waterway Human Health Risk Assessment.
South Aberdeen-Cosmopolis Area [n]	Chinook, coho, chum; anadromous steelhead and cutthroat trout commonly found and available for harvest. Evaluates fish habitat and recommends habitat restoration and enhancement.
Naval Base Kitsap – Keyport, Washington [o]	Based on Suquamish Tribe shellfish (clams, mussels, crabs, oysters) consumption rate. Based on U.S. general population rate 54 g/day to Suquamish rate 632 g/day for clams.
Oakland Bay, Shelton [p]	Water body-specific evaluation. A range of shellfish consumption rates used, 17.5, 60, 175, 260 g/day; based in part on Squaxin Island tribal consultations.
Umatilla Tribal Water Quality Standard [q]	Consumption rate of 389 g/day approved by EPA Feb. 2010. (Lummi Nation, Shoshone-Bannock Tribe and the Swinomish Tribe are eligible to adopt tribal water quality for their respective reservations.)
Lake Washington [r]	Anglers rate 10.8 g/day; angler 95th percentile 30.2 g/day; children anglers 9.5 g/day with 95th percentile 86.2 g/day. Allowable meal limits determined for northern pikeminnow, yellow perch, cutthroat trout, sockeye salmon.

4.7 Key Findings

Ecology reviewed finfish/shellfish dietary surveys and related information relevant to fish-consuming populations in Washington, including general population data from national surveys and regional fish consumption surveys.

1. *National survey data*

   Ecology analyzed general population survey data from national studies. A statistical methodology used by the National Cancer Institute (NCI) was applied to the national survey data to estimate long-term consumption rates from the short-term dietary records collected by these studies. It is noted, however, that national survey data may underestimate fish consumption in coastal states, such as Washington, which have large fish resources available for harvest and consumption.

2. *Regional survey data*

   Ecology identified the following Pacific Northwest tribal surveys as well-designed and well-conducted. They meet measures of technical defensibility and are directly applicable to Washington population groups.

   - *A Fish Consumption Survey of the Umatilla, Nez Perce, Yakama, and Warm Springs Tribes of the Columbia River Basin* (CRITFC, 1994).
   - *A Fish Consumption Survey of the Tulalip and Squaxin Island Tribes of the Puget Sound Region* (Toy et al., 1996).
   - *Fish Consumption Survey of the Suquamish Indian Tribe of the Port Madison Indian Reservations, Puget Sound Region* (The Suquamish Tribe, 2000).

   These surveys provide finfish and shellfish dietary information for Washington fish-consuming populations and identify and quantify consumption habits. Ecology believes that these surveys provide credible information about fish consumption in Washington..

3. *Asian and Pacific Islander survey data*

   The *Asian and Pacific Islander Seafood Consumption Study* (Sechena et al., 1999, including EPA’s 2005 re-evaluation) is well-designed and conducted, but represents only a very small sample of each of the Asian and Pacific Islander populations surveyed. Because of the differences in API populations across the state, it may not be appropriate to apply these results statewide.

4. *Recreational survey data*

   Recreational fish consumption surveys conducted in Washington were generally older and were conducted using less technically defensible methods (creel surveys).

Ecology has reviewed other surveys and fish consumption information used for health assessments for specific populations groups and water bodies throughout Washington State (see Appendix B). Although these surveys are technically sound and help support an evaluation and assessment of potential adverse effects from consuming contaminated fish from specific water bodies, their methodology does not allow for the projection of longer term estimates of fish consumption. Hence, these estimates are tabulated in this chapter to provide multiple lines of evidence, as a weight-of-evidence approach, that people in Washington State harvest and consume large amounts of fish.

Fish consumption rates for the general population and from the three Pacific Northwest tribal surveys identified above are listed in Table 33 below. The dietary survey methodologies employed for these studies are well documented and provide quantifiable dietary information. Ecology applied measures of technical defensibility to these fish dietary surveys to assess their suitability for estimating long-term fish consumption rates for Washington State fish-consuming populations. Ecology believes that these surveys provide credible information about fish consumption in Washington.

Table 33. Summary of Fish Consumption Rates from Studies Meeting the Measures of Technical Defensibility, All Finfish and Shellfish (g/day)

Population	Source of Fish	Number of Adults Surveyed	Mean		Percentiles		
				50th	75th	90th	95th
General population (consumers only)	All sources: EPA method	2,853	56	38	79	128	168
	All sources: NCI method	6,465	19	13	25	43	57
Columbia River Tribes	All sources	464	63	41	65	130	194
	Columbia River	–	56	36	57	114	171
Tulalip Tribes	All sources	73	82	45	94	193	268
	Puget Sound	71	60	30	75	139	237
Squaxin Island Tribe	All sources	117	84	45	94	206	280
	Puget Sound	–	56	30	63	139	189

Discussion

Based on the fish dietary surveys for Puget Sound and the Columbia River basin, fish-consuming populations within the Pacific Northwest consume comparable amounts of fish. The average fish consumption rates from all sources for the Columbia River, Tulalip, and Squaxin Island tribes are within a very small range of one another, about 60 to 80 g/day. Central tendency estimates of consumption, either average or median estimates, for Asian-Pacific Islanders, recreational anglers, and national (based on EPA information) estimates are also within this range. Fish consumption estimates from local harvests for tribal fish-consuming populations show a similar but slightly lower trend, around 55 to 60 g/day. The Puget Sound fish-consuming population that consumes the largest amount of fish is the Squamish Tribe, with higher central tendency estimates of consumption of about 130 to 215 g/day. For these fish-consuming populations, the trend for the upper 90th and 95th percentile fish consumption estimates shows a convergence that illustrates a consistently high rate of fish consumption.

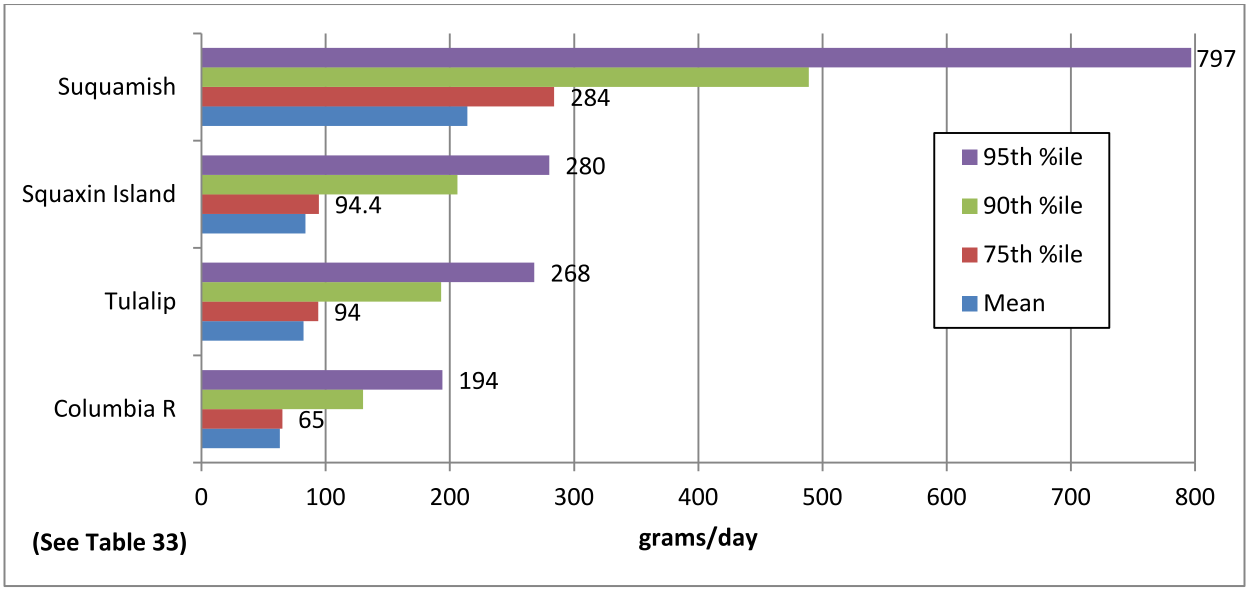

Figure 12. Regional-specific Adult Fish Consumption Rates, Harvested from All Sources

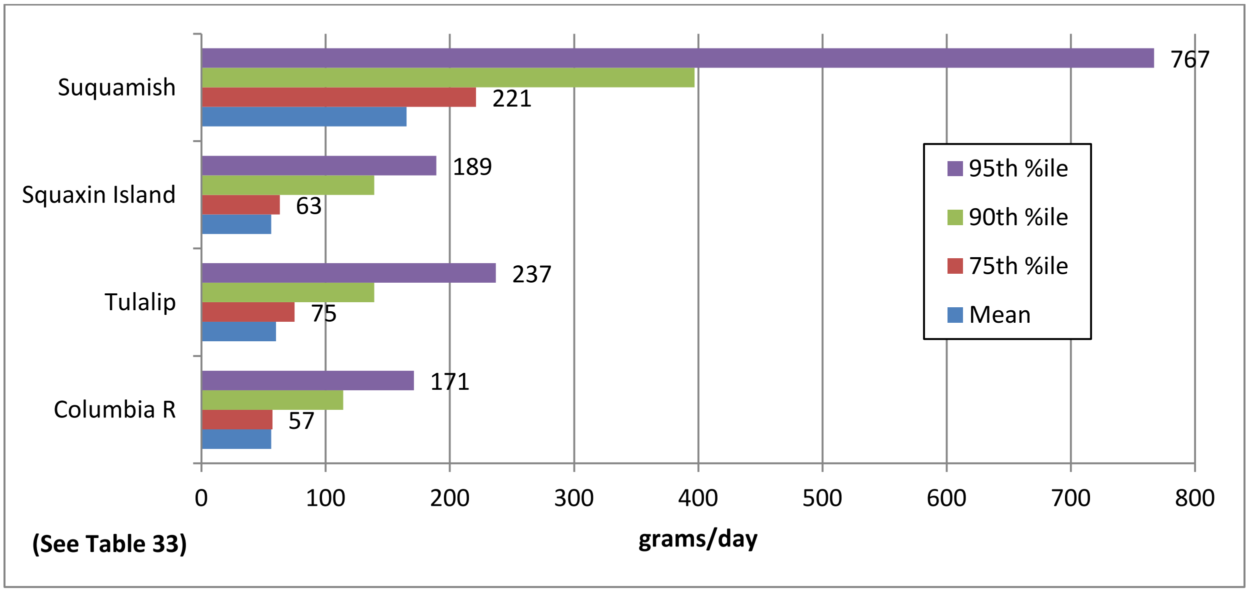

Figure 13. Regional-specific Adult Fish Consumption Rates, Harvested from Local Sources

Computations for all percent estimates of local fish harvests are based on estimates of fish consumption for tribal populations from Table 33. Percent estimates are derived based on upper percentile estimates of fish consumption from all sources compared with sources of fish harvested locally, such as Puget Sound or the Columbia River basin.

For all fish consumed. About 67 to 68 percent of total fish consumed by the Squaxin Island tribal population are locally harvested. The percentage of total fish consumed that is locally harvested is somewhat higher for the other tribal populations surveyed: approximately 88 percent for the Columbia River Tribes, 72 to 88 percent for the Tulalip Tribe, and 81 to 96 percent for the Suquamish Tribe.

Table 34. Percent of Tribal Fish Consumption Rate (All Sources) that is Locally Harvested

Population	At the 90th Percentile	At the 95th Percentile
Columbia River Tribes	88%	88%
Tulalip Tribes	72%	88%
Squaxin Island Tribe	67%	68%
Suquamish Tribe	81%	96%

For anadromous fish consumed. About 72 to 77 percent of anadromous fish consumed by the Tulalip tribal population are locally harvested. The percentage of anadromous fish consumed that is locally harvested is somewhat higher for the other tribal populations surveyed: approximately 88 to 89 percent for the Columbia River Tribes, and 80 percent for the Squaxin Island Tribe. Insufficient data were available on locally harvested anadromous fish consumption for the Suquamish Tribe.

Table 35. Percent of Tribal Anadromous Fish Consumption Rate (All Sources) that is Locally Harvested

Population	At the 90th Percentile	At the 95th Percentile
Columbia River Tribes	88%	89%
Tulalip Tribes	72%	77%
Squaxin Island Tribe	80%	80%
Suquamish Tribe	NA	NA

For shellfish consumed. About 62 to 63 percent of shellfish consumed by Squaxin Island tribal populations are locally harvested. The percentage of shellfish that is locally harvested is somewhat higher for the Suquamish Tribe (81 percent), and highest for the Tulalip Tribes (98 to over 99 percent).

Table 36. Percent of Tribal Shellfish Consumption (All Sources) that is Locally Harvested

Percent of tribal shellfish consumption (all sources) that is locally harvested		
Population	At the 90th Percentile	At the 95th Percentile
Columbia River Tribes	NA	NA
Tulalip Tribes	98%	>99%
Squaxin Island Tribe	63%	62%
Suquamish Tribe	81%	81%

Chapter 5: Sources of Uncertainty and Variability

Ecology and other agencies regularly use available scientific information on finfish and shellfish consumption rates to support regulatory decisions. In these situations, Ecology must generally select a particular value from a range of values. When making these decisions, it is appropriate to identify, recognize, and consider both the uncertainties associated with available data and the variability across individuals, fish species, and geographic areas.

Sometimes these two terms, uncertainty and variability, are lumped together. However, the nature of the errors (and consequences of over- or underestimating results) that arise due to uncertainty in the data is different than those errors that arise as a result of variability across populations, geographic areas, and time. Environmental agencies' responses to uncertainty are inherently different than responses to variability. Specifically:

- *Variability.* With variability, people and organizations know that there is a range of actual values for the parameter in question. In these situations, environmental agencies must simply decide how to characterize the range of values.
- *Uncertainty.* With uncertainty, people and organizations have limited knowledge on the magnitude and range of the parameter in question. In these situations, environmental agencies must decide how to address gaps in information and/or scientific knowledge.

This chapter summarizes important sources of uncertainty and variability in the scientific information used to estimate finfish and shellfish consumption rates.

- Uncertainty associated with dietary intake survey methods.
- Variability in consumption rates for individuals within a specific study population.
- Geographic variations and uncertainties associated with extrapolating survey results to different population groups and different areas.
- Temporal variability and uncertainties associated with estimating long-term exposure.
- Uncertainties associated with estimating future consumption rates and patterns.
- Uncertainties and variability in the relationships between cooked and uncooked tissue weights.
- Uncertainties and variability in sources of finfish and shellfish.
- Temporal variability in the availability of finfish and shellfish.

This chapter is designed to provide a high-level summary. There are several excellent resources that provide information on general sources of uncertainty and variability in risk assessments

(National Research Council, 1994, 2009; U.S. EPA, 2011a). In addition, other agencies and organizations (U.S. EPA, 2007b; Oregon DEQ, 2008; Windward Environmental, 2007) have evaluated sources of uncertainty and variability in fish consumption rates.[40] (Much of the information in this chapter is directly from the sources cited.) See also CalEPA (2001) for a particularly good discussion of sources of variability in fish consumption estimates.

5.1 Survey methodology

Dietary recall surveys are dependent on many factors, and the careful design and execution can minimize or eliminate sources of certain types of errors.

Chapter 3 discusses survey methodology, execution, publication of results, applicability and utility for regulatory decision making, and overall technical suitability to support regulatory decision making. Fish consumption surveys selected as applicable to Washington fish consumers were evaluated in Chapter 4.

Factors contributing to measurement error and bias include:

- Survey design (for example, accurate representation of the target population). Considers attributes of the survey relative to attaining accuracy and precision (e.g., are all species included, are visual aids utilized for portion sizes, will the survey be administered over an entire fishing season, are an appropriate number of individuals interviewed).
- Survey methodology (for example, considers the interaction between the survey methodology chosen and attributes of the target population taking into account literacy, language barriers, and cultural sensitivity).
- Survey execution (for example, coding errors, interviewer bias, recall bias).[41]
- Method of analysis (for example, if and how systematic error is identified and estimated; treatment of outliers and weighting factors).

Various survey types have inherent biases, strengths, and weaknesses that may contribute to variable results demonstrated across these different surveys. It should be noted that regulatory policies (for example, what questions are the surveys designed to answer) can influence the planning and design phases, which can in turn influence the results and conclusions. Furthermore, policy choices may not be consistent across various federal and state agencies and academic institutions.

---

[40] See also the National Cancer Institute discussions of measurement error related to dietary surveys. http://riskfactor.cancer.gov/measurementerror/

[41] Recall bias occurs when factors exist that may affect the respondent's memory of an event. For example, an individual that consumed fish in the last 24 hours may provide greater estimates of fish consumption on a seasonal or yearly basis.

EPA examined different fish consumption survey methods, identifying important considerations for survey design, selection of respondents, quality assurance, and statistical analysis (U.S. EPA, 1992). Additional guidance on fish and wildlife consumption surveys thoroughly examines survey instrument design, execution, and analysis (U.S. EPA, 1998).

Limited resources and differing objectives for organizations and groups interested in determining fish consumption rates can influence the design of the survey and how it is conducted. Plausible objectives for fish consumption surveys include: determining average consumption rates, fishing pressure on water bodies, and maximum consumption during the fishing season. Surveys designed to meet one objective may not be suitable for another. Ecology must consider a fish consumption survey's objectives, execution, and evaluation to determine the utility of a survey's use by Ecology for environmental regulation.

5.1.1 Differences due to survey design, terminology, and definitions

Some fish dietary surveys may not include all relevant species in the questionnaire. Terminology across different fish consumption surveys may be highly variable. A lack of a consistent terminology can contribute to variability and uncertainty. For example, *shellfish* usually refers to aquatic invertebrate organisms with a shell. Clams and oysters are easily identified as shellfish. However, selected aquatic animals (squid) have evolved such that the shell has become internal and/or reduced, while in others, the shell has disappeared (octopus). Furthermore, crustaceans (crayfish) have exoskeletons instead of true shells.

Seafood consumption may include finfish and/or shellfish obtained from a variety of sources. Surveys may not differentiate the sources of the finfish and/or shellfish. Indeed, some surveys may consider consumption of fish harvested from a single water body (e.g., Commencement Bay) while other studies determine rates for fish consumption from multiple water bodies. Also, consumption rates reported in different studies may or may not distinguish between consumption of marine, estuarine, and freshwater finfish and shellfish. These differences and their contributions to variability were summarized in a study published in the *Journal of Exposure Analysis and Environmental Epidemiology* (Ebert et al., 1994). This study noted that the consumption rate of an individual comprises the sum of the rates from different sources. It does not differentiate among sources of seafood. Estimates may vary substantially depending on how these different sources are evaluated.

5.1.2 Types of data and methods of collection

The method used to collect dietary information may lead to uncertainty. For example, data collected from creel surveys involve interviewing anglers at fishing locations to provide water body-specific data about fishing frequency, fish species, and sizes caught and/or consumed. Hence, the creel survey method may only provide data about specific species available during specific seasons. Creel surveys, like other surveys methods, are subject to biases. Poor catches, catches below legal size limits, or catches above total allowable limits may not be reported. Persons fishing without a license may avoid participating. See Table 9 for issues associated with creel surveys.

5.1.3 Cooked and uncooked tissue weights

A number of researchers have noted the uncertainty introduced by inconsistency regarding reporting of finfish and shellfish using cooked vs. uncooked weight. Raw fish tissue samples are used to determine chemical contaminant levels for use in human health risk assessments.

The EPA Region 10 Framework recommends that risk assessments be performed using the weight of uncooked fish, with no modification for potential contaminant losses or gains during cooking. This is consistent with the fact that uncooked fish consumption rates were measured in the tribal finfish and shellfish consumption studies cited. EPA notes:

> *Because of the many ways in which fish may be served, quantitative assumptions regarding preparation methods and their effects on contaminant concentrations would be unreliable. Depending upon the preparation and cooking procedures, and upon the nature of the contaminants in the fish, concentrations may decrease or increase [U.S. EPA, 1998]. For fat-soluble compounds such as PCBs, trimming and removing adipose tissue reduces the mass of contaminants in the consumed portion of the fish. Similarly, broiling, frying, or grilling fish is likely to result in reductions of fat-soluble compounds [Sherer and Price, 1993]. Cooking is not likely to change the level of exposure to mercury because it is bound to muscle tissue and is not lost by cooking, which mostly removes moisture and fat [Morgan et al., 1997]. Fish cooked with no prior preparation, as in a stew, might show negligible loss of contaminants, except perhaps for volatile contaminants. Because lead concentrates in bones, preparations where bones are discarded are likely to result in reductions in lead exposure [Ay et al., 1999].*

5.1.4 Variability within a population

A number of factors may contribute to variability in finfish and shellfish consumption survey results (Ebert et al., 1994). Dietary patterns vary within a population and between populations. Different population groups may have different fish consumption rates related to cultural or regional differences. Family preferences, recipes, and individual taste are sources of variability within a population; access to resources, tradition, and custom are sources of variability between populations.

5.1.5 Data analysis and statistical considerations

Without careful definition of the target population, it is possible to bias survey results. For example, to avoid characterizing the consumption for a population that is not at risk from consuming contaminated fish, surveys are designed to evaluate consumers only, with questions allowing identification of persons who never (or rarely) consume fish.

Various statistical techniques have been described to analyze consumption data. For example, different methods of treating missing data or non-response data may contribute to bias. Identification and treatment of potential outliers may contribute to biased datasets (this includes recording outliers as multiples of standard deviations above the mean or eliminating them from the dataset).

Defining subgroups within a larger population (stratification) differently can affect survey results and introduce different levels of bias. An important element of survey design is how well the survey sample population represents the selected target population or population of concern. Weighting schemes designed to make a sample more representative of the population should be carefully defined. Statistical methods should consider sampling rate, differences in sampling days, and other factors that may influence the results.

The fish consumption rates for a fish-consuming population should be sufficiently characterized to provide a population distribution and statistics that contribute to an understanding of the nature of a population exposure distribution such as the mean, median, and upper percentiles (90th or 95th percentile) or bounding estimates (99th or 99.9th percentile). It is essential to understand how these distributions were derived as distributions derived from consumers and non-consumers of fish have different meanings and applications.

It should be noted that 24-hour dietary recall surveys that include food frequency questionnaires enable calculating the upper percentiles with greater confidence (U.S. EPA 1992, 1998). Consistent with federal guidance on fish dietary survey methodologies, all regional Pacific Northwest fish dietary surveys (Tribal and Asian-Pacific Islander populations) employ some permutation of a food frequency questionnaire in their survey methodology to project long-term consumption estimates.

Fish dietary information may be reported as point estimates, usually a mean or median value to represent central tendency estimates of consumption, or as a distribution of values. When the estimates of fish consumption are normally distributed in a population, the mean and median will be close or approximately equal. When the distribution is skewed (e.g., lognormal distribution), the mean and median may be substantially different. The mean fish consumption estimate represents the average value for the sampled population and in a skewed distribution the mean will either be a higher or lower value than the median value. For a highly positively skewed distribution, as found in the Pacific Northwest fish-consuming populations, the mean is higher than the median estimates of consumption. The median value represents the 50th percentile (or midpoint) of the distribution where half of the sampled population consumes more and half consumes less fish, than the median value (Helsel and Hirsch, 2002).

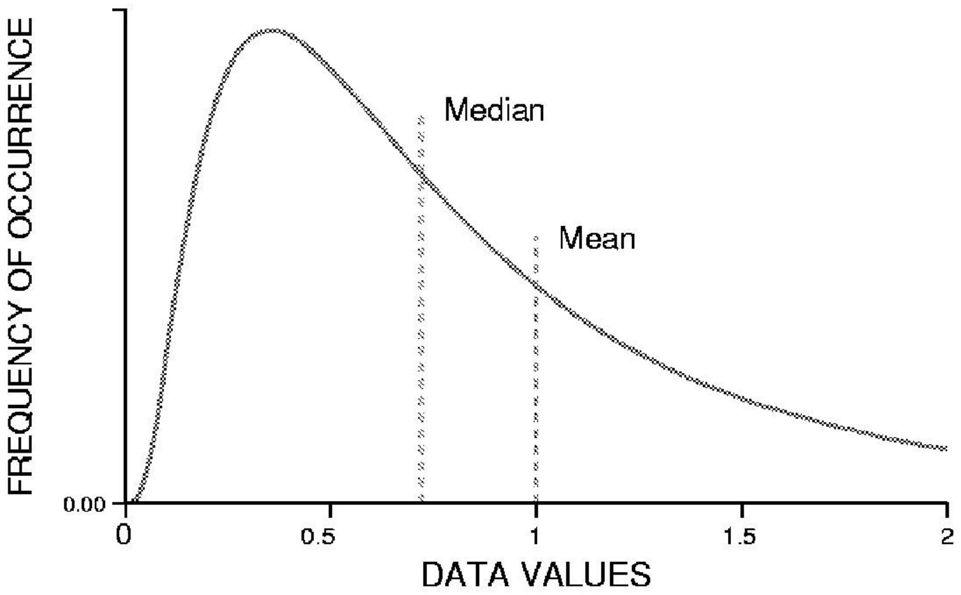

Figure 14. Density function for a positively skewed lognormal distribution

5.1.6 Target populations and characteristics of populations

Different population groups may have different fish consumption rates. Recognizing differences between fish consumption rates for whole populations (including both consumers and non-consumers) and consumption rates in actual consumers of fish is a critical distinction. For example, Oregon's Human Health Focus Group made the clear distinction between per capita fish consumption based on consumers and non-consumers of fish. High fish consumers make up a relatively small portion of the whole population, and may represent extreme upper percentiles in a distribution that includes both consumers and non-consumers of fish.

A distinction is generally made between (a) national per capita consumption estimates inclusive of both consumers and nonconsumers of fish and (b) estimates of fish consumption from local fish consuming populations (EPA Region-10 Framework, 2007; EPA, 2000; CalEPA, 2001; Oregon DEQ HHFG Report, 2008):

- "Per capita rates are primarily useful for trend analyses rather than representing actual consumption. Average per capita rates derived from national surveys for consumption of fish and shellfish by the general population ranged from 10 to 17.9 grams per day. Several analyses of data used to estimate per capita consumption of fish and shellfish found an increase of approximately 25% between 1970 and the early 1990s, indicating that the U.S. population as a whole consumed more fish in more recent years" (CalEPA, 2001, page 3).

- "Consumption rates derived for consumers are preferable to per capita rate for use in describing actual consumption of fish and shellfish in the U.S." (CalEPA, 2001, page 3).

Further distinctions are made between national per capita fish consumption estimates and consumer-only estimates by how consumers of fish and/or shellfish are defined. CalEPA, 2001, provides further insights regarding consumption estimates for populations that consume fish compared to estimates for the general national population as follows:

> *Rates reported for the general national population, usually referred to as per capita rates, differ from those reported for subpopulations such as individuals who catch and consume their own catch of fish and shellfish. It is essential to consider whether rates that apply on a per capita basis are appropriate to the study question or whether rates specific to particular subpopulations are needed. For example, some consumption rates have been derived by averaging over both consumers and nonconsumers, as compared to consumers only. These per capita estimates would not be representative of consumption by actual consumers or other specific subpopulations. Thus, exposure assessments and evaluation of potential risks to consumers must consider consumption rates appropriate for actual consumers.*
>
> *For groups of individuals who consume sport fish and/or shellfish, there is a continuum ranging from intermittent fishers, who may eat fish only occasionally, to those who fish regularly and/or heavily and consume large quantities of the fish that they catch. These "high-end consumers" could include recreational fishers with high rates of success and subsistence fishers who rely on their catch to feed themselves and their families. Therefore, within the subset of the population that fishes (i.e., fishers) there is likely to be a wide range of fishing effort and success, and a single value is unlikely to adequately describe consumption by the entire fishing population (CalEPA, 2001, page 13).*

5.2 Geographic differences

5.2.1 Variation and uncertainty associated with regional differences

Fish consumption surveys conducted across the United States have shown regional variations. There are differences between coastal areas and inland areas and regional preferences for certain types of finfish and/or shellfish. Local variations in climate, fishing regulations, accessibility to fisheries, and seasonal differences in availability of fish contribute to the variability in reported fish consumption rates (Ebert et al., 1994; Moya et al., 2008). Differences in habitat may be relevant (U.S. EPA, 2007b).

Comparing the results of surveys from different geographic locations, each with regional effects plus different methodologies, time frames, or other different survey design elements, makes the interpretation of differences between surveys problematic.

5.2.2 Uncertainty associated with extrapolating survey results to different population groups and different locations

The use of surrogate consumption rates can misrepresent actual finfish and shellfish consumption rates. For example, Puget Sound-harvested finfish and shellfish consumption rates derived using Tulalip and Suquamish tribal data as a surrogate for another tribe could lead to either an overestimate or an underestimate of the actual finfish and shellfish consumption.

For many reasons populations surveyed in a particular study may eat different quantities and ratios of finfish and shellfish than do those who harvest elsewhere. For example, differences in habitat type and quality between fishing grounds can affect the quantity of finfish and shellfish available for harvest.

The EPA Region 10 framework takes this into account. For purposes of the framework, if certain species or types of finfish and shellfish are not present, or will not be present in the future, tribal members are assumed to substitute other species or types of finfish or shellfish that may be equally affected by the site. This assumption of resource switching among local finfish and shellfish is incorporated into the framework by holding constant the total amount of finfish and shellfish consumed.

EPA's policy decision to assume that resource switching occurs is supported by limited data and examples in Puget Sound. For example, individuals in the Suquamish Tribe study (The Suquamish Tribe, 2000) eat "more geoduck now, because they are more available to us, but we used to dry oysters and clams...." Two other respondents reported "reduced consumption of butter clams, cockles, and other clams and shellfish due to pollution," but that this "reduced consumption was offset by the higher availability of geoducks from the Suquamish Tribe." Resource switching has been documented in other areas affected by contamination, such as Alaska (Fall and Utermohle, 1999).

The use of fisheries resources is important to tribes for economic, dietary, and cultural reasons. Tribes will likely use whatever fisheries resources are available to them.

The following observation is made in the National Environmental Justice Advisory Council Meeting report (U.S. EPA, 2002b):

> *For many communities of color, low-income communities, Tribes, and other indigenous peoples, there are no real alternatives to eating and using fish, aquatic plants, and wildlife. For members of these groups it is entirely impractical to "switch" to "substitutes" when the fish and other resources on which they rely have become*

> *contaminated. There are numerous and often insurmountable obstacles to seeking alternatives (e.g., fishing "elsewhere," throwing back "undesirable" species of fish, adopting different preparation methods, or substituting beef, chicken or tofu). For some, not fishing and not eating fish are unimaginable for cultural, traditional, or religious reasons. For the fishing peoples of the Pacific Northwest, for example, fish and fishing are necessary for survival as a people – they are vital as a matter of cultural flourishing and self-determination.*

If certain types of finfish or shellfish preferred by tribal members are not present in their usual and accustomed areas, the framework assumes that tribal members will substitute alternative local types of finfish or shellfish in their diets, generally within the same category of fish or shellfish. Thus, the total consumption rate remains the same, regardless of the availability of a particular type of finfish or shellfish. This is a reasonable and protective assumption for tribal members who, for economic, ceremonial, religious, or personal preference reasons, are likely to substitute one species for another.

The assumption that resources will be switched is likely to result in an overestimate of risks for other tribal members who may decrease their overall finfish and shellfish consumption rate because their preferred types are unavailable. Risks may be underestimated if the actual dietary practices of a tribe would result in consumption of species that have higher contaminant levels than the preferred or assumed types of finfish or shellfish.

5.2.3 Availability of finfish and shellfish

The abundance of finfish and shellfish resources available to a given population may be a source of uncertainty. Different water bodies vary in their capacity to support and sustain different species of finfish and shellfish. Furthermore, the capacity of the water body to support fish resources may change over time, for both natural and human caused reasons.

Regarding the use of surrogate data, the EPA Region 10 framework notes:

> *Although the degree to which site-related risks could be overestimated by the use of any of the fish and shellfish consumption rates presented in this Framework cannot be known precisely, these methods are preferable to alternatives that would be likely to underestimate site-related risks, such as basing a consumption rate (or site-related estimates of risk) on the size of the cleanup site, or reducing the site's estimated contribution to fish and shellfish contamination because nearby sites or sources are associated with similar contaminants. This Framework includes the assumption that the selected Tribal fish and shellfish consumption rates and their associated risk estimates will not be reduced based on consideration of the size of the cleanup site or the presence of additional sources of contamination.*

The use of a consumption rate based on all finfish and shellfish harvested from Puget Sound as a surrogate for a consumption rate based on finfish and shellfish affected by a cleanup site is likely to overestimate the risk of eating finfish and shellfish from the site, since only a portion of the finfish and shellfish diet will have actually come from the site in question. The degree of overestimation depends upon such factors as size and location of the site, type and degree of contamination, and habits of affected finfish and shellfish.

A potential data gap is the lack of information on commercial routes of distribution for locally harvested fish and/or shellfish to local food markets, restaurants, or other food outlets in Washington State. However, seafood supply availability as an indirect measure of consumption has very limited utility. As noted by CalEPA, 2001 (page 15):

> *Approaches to collecting data on fish consumption include both indirect and direct measures. Indirect measures primarily rely on data pertaining to food availability or food disappearance into marketing channels or households, and are best regarded as a measure of food availability into commercial markets and only a rough indicator of consumption. Data from studies on food availability generally have been collected for purposes other than to estimate consumption rates, and data gaps are most serious at the level of the individual consumer; therefore, these types of data are inappropriate for estimating consumption rates for consumers (Anderson, 1986; U.S. EPA, 1992). Additionally, food availability data do not account for waste or spoilage, and interpretation of the results is highly specialized; however, the results from these types of surveys can be useful to assess trends over time (Anderson, 1986).*

On the other hand, some of the finfish and shellfish consumed in restaurants or obtained in grocery stores may have been harvested in Puget Sound, which could lead to an underestimate of exposure.

5.3 Temporal uncertainty and variability

Although estimates of consumption using short-term dietary recall may be reported as g/day, the values may not be the same as long-term consumption rates averaged over time and presented as a daily rate. Study methodologies that consider fish consumption over a longer period of time may be more likely to represent the fish consumption patterns of the population studied.

5.3.1 Using short-term data to estimate long-term exposure

Current health risk models are designed to evaluate health risks associated with exposure over long periods of time. Risk assessors typically use the results from short-term dietary surveys to characterize the amounts of finfish and shellfish eaten on a regular basis over longer periods of time intervals (years).

This approach works well when average values are used in the health risk model. However, regulatory approaches based on concepts like *reasonable maximum exposure* are typically based on the use of upper percentile values (e.g., 90th percentile or above). In this situation, the use of short-term survey results is complicated because the distribution of estimated fish consumption rates over a short period of time will be more spread out than the actual fish consumption over a longer period of time. This means that estimates of the 95th percentile of the fish consumption rates observed over a short period of time (one or two days) will be higher than the 95th percentile of the average daily fish consumption over the longer periods of time considered in health risk assessments (years). This narrowing of the distribution of estimates is called *regression to the mean*.[42]

5.3.2 Temporal factors biasing estimates of fish consumption

The collection of fish consumption information may be subject to temporal biases. Use of 24-hour recall data to estimate fish consumption rates over longer periods are subject to potential biases from the effects of the day of the week or seasonal variations in the availability of fish. Longer term estimates of fish consumption reported by individuals may be subject to recall bias. Rates will be overestimated if fish consumption habits are surveyed when fish are readily available relative to periods when fish are not readily available. Consumption data obtained on consecutive days may be biased due to the consumer correlation with the fish consumed on adjacent days.

Recall bias for estimates of long-term fish consumption is more of an issue for populations where fish may be infrequently consumed and consumption patterns are episodic in nature. In contrast, recall bias in estimating long-term fish consumption rates is minimized for populations in which fish is a primary dietary protein source, is consumed frequently, and where consumption information is hence easily recalled.

The timing of survey administration may or may not account for the biases introduced by seasonal variations in fish availability. Extrapolating estimates of long-term fish consumption from 24-hour recall data or from evaluations of yearly fish consumption may be improved by interviewing fractions of the survey populations during different seasons or by re-interviewing individuals.

Short-term estimates of food intake rates for infrequently consumed items for the general population (e.g., fish) from national short-term surveys are bimodal, varying between zero and the amount typically consumed at a meal. This results in an overestimate of the prevalence of

---

[42] Regression to the mean is encountered in many areas of science and everyday life. For example, baseball batting averages have a much larger distribution early in the season compared to the end of the season. The following case study illustrates the implications of this situation. There were 177 major league players with at least 400 plate appearances during the 2011 season. Consider the players' batting averages after their first game and at the end of the 162 game season. The first day estimates for the median and average provide a reasonably good estimate of those values for the whole season. However, the first day estimates for the 90th and 95th percentiles of the distribution of batting averages are much higher than the end-of-the season values. As with many situations, players who did extremely well on the first day of the season also had days where they were hitless. Conversely, players who went hitless on opening day had games later in the season where they had one or more hits.

low and high intake rates relative to those that would be seen over a longer observation period. This variation is particularly relevant for assessments of food chemical exposure where the parameters of interest are at the extremes of the exposure distribution rather than at the center (Lambe, 2002).

Attempts to account for the variability and uncertainty associated with the use of short-term consumption studies have generally included qualitative evaluation of data from a range of sources, coupled with consideration of the intended use of the data. To evaluate long-term (habitual) seafood intake, longer-term survey data are preferable to short-term dietary survey data.

Ecology conducted a statistical reanalysis of short-term national fish consumption data to estimate long-term (usual) national fish consumption rates, using the methodology of Tooze et al., 2006 (as cited in Polissar et al., 2012). National fish consumption rate estimates based on this reanalysis are significantly lower than estimates based on simple extrapolation of the short-term fish consumption data. See also the Technical Issue Paper, *Estimating Annual Fish Consumption Rates Using Data from Short-term Surveys* (Ecology, 2012).

5.3.3 Issues using currently suppressed fish consumption data to predict future fish consumption

The presence (or absence) of finfish and shellfish adversely affected by site-related contamination could suppress consumption rates observed during surveys.

The Oregon DEQ Human Health Focus Group discussed some of the factors that may contribute to depressing fish consumption rates compared to historic rates. They noted (1) significant reductions in fish populations, (2) the belief that fish that reside in polluted waters will bioconcentrate pollutants and are contaminated and unsafe to eat, and (3) the intended impact of local fish advisories or the unintended consequences of national fish advisories of commercial fish species that are not applicable to local waters.

The Human Health Focus Group also noted that some studies excluded or discounted high fish consumers by identifying them as statistical outliers. This would have the effect of underestimating the true range in fish consumption rates. If the rates are already suppressed, the elimination of the highest values may be reporting an artificially low fish consumption rate.

Where tribal members have already reduced their harvest of finfish and shellfish from impaired habitat, the use of current consumption rates could result in underestimations of potential finfish and shellfish consumption rates. As noted in the National Environmental Justice Advisory Council Meeting report (U.S. EPA, 2002b):

> *A suppression effect occurs when a fish consumption rate for a given subpopulation reflects a current level of consumption that is artificially diminished from an appropriate baseline level of consumption for that subpopulation . . . When agencies set environmental standards using a fish consumption rate based upon an artificially diminished*

> *consumption level, they may set in motion a downward spiral whereby the resulting standards permit further contamination and/or depletion of the fish and aquatic resources.*

Cleanup levels in the local aquatic environment, if they are based on current finfish and shellfish consumption rates in the vicinity of the cleanup site, may not reflect the potential for the water body to rebound from its current, relatively contaminated state. This should be considered when deciding whether the use of a surrogate tribal finfish and shellfish consumption rate would better represent potential future consumption rates than would consumption rates that represent only current or near-term contamination and habitat conditions.

Studies indicate that tribal fish consumption rates are suppressed compared with historical rates and presumable rates that would exist given historical fishing stocks. The recommendations in this report, however, were developed using existing data from published studies.

For Native American populations in Washington, evaluating fish consumption rates using common survey methodology may be problematic (Donatuto and Harper, 2008). Surveys and the exposure models they develop provide information only about current consumption patterns. The number of tribal members practicing traditional lifestyles is below known historical levels. Survey data do not provide information on historical fish consumption rates and resource use, which may be more indicative of consumption rates.

Researchers suggest that suppression happens for various reasons (Donatuto and Harper, 2008). Two reasons are contamination and lower abundance. When the fish are contaminated or absent, tribal members may eat less fish and/or substitute other types of fish. While, historically, fish provided the main dietary source of protein, this is true today for only a small subset of the tribal population (Harper et al., 2007; Harper and Harris, 2008; Harris and Harper, 2001). Tribal health experts suggest that current tribal fish consumption rates are suppressed due to diminished access to historical quantities of finfish and shellfish, and some researchers believe that historical rates represent the appropriate baseline level of consumption. Effects of suppression due to chemical contamination should be accounted for in environmental cleanup regulations. However, accounting for suppression in environmental cleanup regulations may be problematic when suppression is due to permanent loss or modification of habitat due to urban infrastructure. Where habitat can be restored, then environmental cleanup regulations need to account for suppression effects in revising fish consumption estimates to help support cleanup decisions.

5.4 Uncertainty in Pacific Northwest fish-consuming populations

Ecology has identified numerous fish dietary surveys in Washington State that reflect high rates of consumption for certain ethnic groups (CRITFC, 1994; Toy et al., 1996; Sechena et al., 1999; The Suquamish Tribe, 2000). Consumption estimates vary among subpopulations by age, sex, mode of harvesting, and by region within Washington State. Washington State fish-consuming populations have been identified (tribal populations, Asian-Pacific Islanders, recreational fishers) and levels of consumption have been estimated from these surveyed populations. These higher fish-consuming ethnic populations and other high-end fish consumers are represented by upper percentile consumption estimates (90th and 95th percentile) derived from distributional analysis of the fish dietary data (CalEPA, 2001; Polissar et al., 2012).

Many of the Pacific Northwest regional-specific surveys note differences in patterns of fish consumption (e.g., eating different fish parts) and fish harvesting techniques, which demonstrates a level of variability across and among these fish-consuming populations (CalEPA, 2001; CRITFC, 1994; Toy et al., 1996; Sechena et al., 1999; The Suquamish Tribe, 2000; EPA EFH, 2011). Central tendency estimates of consumption for these populations are very similar (all fish from local harvests) with upper percentile estimates (90th and 95th percentile) within an order of magnitude.

There is considerable uncertainty inherent in evaluating and estimating fish consumption rates for northwest fish-consuming populations. Much of the uncertainty is because the available information, although substantial, nonetheless provides only a partial picture of fish consumers in Washington. Sources of uncertainties can include the following:

- Whether the available surveys provide a complete picture of the variety of fish consumption practices among various fish consuming populations.
- Evolving and changing lifestyle patterns for various populations across the state.
- Data gaps around dietary habits for other potentially high fish-consuming populations; for example, various ethnic groups, *pescadarians* (people who eat fish but not meat), subsistence fishers, and low income groups.
- Using information about one group as a surrogate for another group’s consumption rate based on evaluation of the similarity or differences in, say, species available or the extent of local shellfish habitat.
- The degree to which lifestyle (ethnic, tribal, subsistence, etc.) is recognized and accounted for in consumption studies.
- Whether or how information from the national fish dietary dataset may be inadequate for understanding fish consumption along coastal states with significant fishery resources.
- Whether and how a particular study addresses consumption of anadromous fish species.

It is expected that as the body of information grows some of these data gaps will be filled and uncertainty about Pacific Northwest fish-consuming populations will decrease.

Chapter 6: Using Scientific Data to Support Regulatory Decisions

The purpose of this Technical Support Document (Version 2.0) is to compile and evaluate available information on fish consumption in Washington State. There are risk management issues related to regulatory decisions based on this information. This is a technical document; it is not designed to resolve policy issues associated with using that information to make regulatory decisions. Ecology will be considering those issues in separate documents and processes.

This chapter is intended to provide context. It offers a brief introduction for people who are interested in the multiple and interrelated questions that arise during regulatory decision making. The Conservation Foundation has stated that it is important that environmental agencies distinguish between scientific and policy choices when making regulatory decisions (Conservation Foundation, 1984, p. 310):

> *A key to understanding the risk assessment process is to distinguish between those aspects of the process that are scientific and those that are matters of policy or personal values, and to appreciate their complex interrelationships …. A risk assessment process that is defensible from both a scientific and a policy standpoint must accurately identify which aspects of the assessment are policy and which are science. The difficulty is that both scientists and policy makers tend to define their realm in the broadest terms.*

The interaction between science and policy in regulatory decision making is complicated. Several equally valid scientific options may resolve a particular issue. In these situations, the regulatory decision essentially represents a policy choice that must take into account statutory directives, implementation issues, and value judgments on how to deal with scientific uncertainty and variability in exposure and susceptibility. As Victor Hugo once wrote, “Science says the first word on everything, and the last word on nothing,” (Hugo and O’Rourke, 1907).

Chapters 4 and 5 of this report provide Ecology’s evaluation and conclusions regarding current scientific information on fish consumption rates in the Pacific Northwest. As the wealth of knowledge continues to grow, additional information will be available in the future. Science-based regulations may have built-in requirements to periodically review and update standards based on new information. This chapter highlights some of the policy choices that will be needed when using this information to support regulatory decisions. The chapter is organized into sections. Each section provides a brief description of a particular regulatory issue and a range of examples to illustrate how agencies have resolved that issue. The issues are:

- Population groups.
- Individual variability in fish consumption rates.
- Geographic variations in fish consumption rates.
- How anadromous species (e.g., salmon) are included in fish consumption rates used for environmental regulation.
- Locally caught vs. store-bought finfish and shellfish.
- Development of regulatory fish consumption rate estimates from consumer-only vs. per capita surveys.
- Other exposure factors (e.g., body weight and exposure duration).
- Acceptable risk.

This is a partial list. Other issues may hold equal or greater importance for particular decisions. In addition, agencies typically do not consider individual policy choices in isolation from other choices. In other words, a decision on one issue may impact the decisions on other issues. For example, decisions on what constitutes an acceptable level of risk may influence decisions on how to address the uncertainties and variability in fish consumption rates.

6.1 Population groups

When developing a regulatory standard based on health protection, agencies must decide what population groups that standard is designed to protect. This is a policy choice that can be made on a programmatic (or statewide) or site-specific basis. This choice can have large implications given the differences in fish consumption rates calculated using information summarized in Chapter 4.

This policy choice is influenced by many factors including statutory requirements, environmental equity, and the nature of the decision (programmatic vs. site-specific). Options typically considered by agencies include:

- *General population.* Environmental and health agencies have established regulatory requirements or fish advisories that are based on the amount of finfish and shellfish consumed by members of the general population. For example, the EPA has adopted guidance for implementing the Clean Water Act that includes a default fish consumption rate of 17.5 g/day. The data used to establish this rate include individuals who do not eat fish. Several states have used this value to develop state water quality standards and cleanup standards for individual sites.
- *Recreational anglers.* Environmental and health agencies have established regulatory requirements or fish advisories using information on the amount of finfish and shellfish consumed by recreational anglers. For example, Ecology in 1991 adopted a default fish

consumption rate (54 g/day) in the MTCA rule that is based on a recreational fish consumption survey.

- *High exposure population groups.* Environmental and health agencies have established regulatory requirements or fish advisories using information on the amount of finfish and shellfish consumed by members of high exposure population groups (such as Native Americans and Asian Pacific Islanders). For example, the Oregon DEQ has adopted a fish consumption rate (175 g/day) that is based on concerns about tribal populations. Ecology has also established sediment cleanup standards for individual sites that are based on assessing exposure for tribal populations.
- *Susceptible populations.* Environmental agencies also establish regulatory requirements or advisories using information on groups that are more susceptible to the effects of toxic chemicals (e.g., children, pregnant women). For example, EPA and DOH have issued fish advisories that are based on limiting mercury exposure for pregnant women.

6.2 Individual variability in fish consumption rates

No two individuals are exactly alike. Exposure to hazardous substances is influenced by multiple factors and may vary widely among individuals within a given population group. Chapter 4 provides information on the variability in fish consumption rates in several study populations. When using that information to support regulatory decisions, Ecology will need to decide which values within this range of variability to use to characterize fish consumption, and consequently the degree of protectiveness Ecology offers when characterizing exposure and making regulatory decisions.

Ecology has compiled information on the distribution of fish consumption rates among the general population, and for participants in the three primary studies identified in the Technical Support Document. The study results were compiled in Table 37 below.

Table 37. Summary of Fish Consumption Rates, All Finfish and Shellfish

Population	Source of Fish	Number of Adults Surveyed	Mean	Percentiles		
				50th	90th	95th
General population (consumers only)	All sources: EPA method	2,853	56	38	128	168
	All sources: NCI method	6,465	19	13	43	57
Columbia River Tribes	All sources	464	63	41	130	194
	Columbia River	–	56	36	114	171
Tulalip Tribes	All sources	73	82	45	193	268
	Puget Sound	71	60	30	139	237
Squaxin Island Tribe	All sources	117	84	45	206	280
	Puget Sound	–	56	30	139	189
Suquamish Tribe	All sources	92	214	132	489	797
	Puget Sound	91	165	58	397	767

See Polissar et al., 2012, Table E-1.

Choosing a summary measure to characterize population exposure reflects an explicit (or implicit) policy choice on the appropriate balance between over- or underestimating exposure levels for particular individuals within the population group. Agencies typically choose one of two approaches for addressing this issue:

- *High end of the distribution.* Many agencies develop standards that are based on protecting more highly exposed individuals within a population group. For example, state and federal cleanup standards are typically based on a reasonable maximum exposure (RME).[43] The RME is defined as reasonable because it is a product of several factors that are an appropriate mix of average and upper-bound estimates. RME estimates typically fall between the 90th and 99.9th percentile of the exposure distribution. This reflects a policy choice that emphasizes the protection of the more highly exposed individuals in a population group. EPA used a similar approach when updating the Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (U.S. EPA, 2000b). The EPA methodology provides a broader range of fish consumption rate statistics for tribes and states to choose from than does the Superfund (CERCLA) program. The EPA methodology allows for both upper percentile and central tendency policy choices. The Ambient Water Quality Criteria for the Protection of Human Health does include upper bound and central tendency exposure parameter choices that reflect an RME approach (e.g., 90th percentile drinking water ingestion rate and an average body weight). The EPA methodology provides a default fish consumption rate for the general population (based on protection of recreational fishers). This value (17.5 g/day) reflects the 90th percentile values protective of consuming estuarine and freshwater fish. It is derived for adults only using data from the USDA's CSFII Survey for the years 1994 to 1996.
- *Middle of the distribution.* Agencies also develop standards that are based on protecting the "average" person in a population. Under this approach, individual exposure parameters are selected to represent the middle of the exposure distribution, which may be defined in terms of the mode, median, or mean.[44] Ecology applied this policy option

---

[43] The MTCA Cleanup Regulation defines the RME as "the highest exposure that is reasonably expected to occur at a site under current and potential future site use." The RME is designed to represent a high-end (but not worst-case) estimate of individual exposures.

[44] Several scientific advisory committees (National Research Council, 1994, 2009) and scientists have discussed the use of summary statistics to describe variable quantities. For example, Finkel (1989) noted that "…all summary estimators of an uncertain quantity are value laden. Summary measures are little more than ways to interpret facts in light of a subjective calculus of the costs of error…" (pp. 436-437). He described several common statistical measures, which he observed will strike different balances between overestimating and underestimating a particular value.

- Statistical mode (most frequently measured value), which embodies the value judgment that one should minimize the probability of error, without regard to its type (over- or underestimation) and magnitude.
- Statistical median (the 50th percentile value), which embodies the value judgment that the costs of the two types of errors are exactly equivalent.
- Statistical mean (the average of the measure values), which embodies the value judgment that larger errors are more important than smaller errors independent of the direction of the error. He noted that when dealing with highly skewed distributions, the mean of the

when selecting many of the exposure parameters used to calculate Method C cleanup levels in the MTCA rule.

6.3 Geographic variability

Chapter 4 indicates that there is substantial variation in the amount of finfish and shellfish consumed in different parts of Washington. Several factors contribute to these variations:

- Water body characteristics.
- Fish species (shellfish vs. finfish vs. salmon).
- Local communities.

Ecology believes that a certain amount of flexibility is needed to address this type of geographic variability. The question is where to build in the flexibility and where it is most needed. Flexibility is important for considering questions around current and future habitat and resource abundance, as well as the variability of fish species present at a site and their life cycle, including where contaminants are obtained. Ecology also acknowledges that some (but not all) water bodies are large enough to sustain moderate to high fish consumption rates.

Agencies have several options for addressing the geographic variations in fish consumption rates. These options include:

- *Single statewide fish consumption rate.* Regulatory agencies may adopt uniform statewide values that do not fully account for geographic variability in fish consumption rates. (For example, the current Water Quality Standards for Surface Waters are based upon a single fish consumption rate of 6.5 grams/day. Similarly, the MTCA Cleanup Regulation includes a single default fish consumption rate of 54 grams/day.) However, this approach ultimately requires several policy choices regarding the appropriate statewide value.
- *Multiple regional fish consumption rates.* Regulatory agencies may adopt regulatory requirements that use several fish consumption rates that reflect the diversity of fish consumption from various water bodies in Washington. Several people who provided comments on Version 1.0 of this Technical Support Document recommended that Ecology consider this option.
- *Site-specific fish consumption rates.* Regulatory agencies develop site-specific fish consumption rates that are used to establish regulatory requirements that are applicable to specific cleanup sites or dischargers. This approach can be implemented in combination with a default value established on a programmatic basis. As noted above, the MTCA

---

distribution will often (but not always) fall at the upper end of the distribution. In some cases, the mean may approach the 95th percentile of the distribution.

Cleanup Regulation includes a default fish consumption rate (54 g/day) that is used to calculate site-specific cleanup standards. However, the rule also provides the flexibility to establish cleanup standards using a site-specific fish consumption rate.

6.4 Salmon

Ecology has evaluated current information on salmon consumption and life cycles in Chapter 4 and Appendix C of this report. Ecology also prepared a separate report that provides additional information and evaluation of this topic. Two main points emerged from those analyses:

- Salmon are a primary fish species consumed by Washington fish consumers.
- In contrast to other species, a significant part of salmon body burden is potentially received in waters and from sources outside of individual MTCA sites or the waters of the state[45] that are regulated under the Clean Water Act (CWA)-based criteria.

Information about salmon is discussed in various places throughout this Technical Support Document, including Chapter 4, Chapter 6, and Appendix C. In addition, a more detailed discussion of salmon is presented in the Technical Issue Paper, *Salmon Life History and Contaminant Body Burdens* (Ecology, 2012). This is an artifact of the ongoing dialogue in response to comments as Ecology continues to consider the various scientific, policy, and regulatory issues.

There are several important issues associated with deciding whether and how consumption of salmon should be taken into account when developing default fish consumption rates used in regulatory decisions. Two key questions are:

- How should the default rates take into account the consumption of fish species like salmon that spend much of their life outside of Washington waters?
- How should the complex life cycle and biology of the different anadromous species like salmon be considered when making regulatory decisions?

Several different approaches are available for resolving these questions. Although others exist, options typically considered by state and federal agencies include:

- *Salmon considered.* Some agencies have established regulatory requirements that are based on fish consumption rates that take into account consumption of all types of finfish and shellfish. In other words, the regulatory requirement is based on a fish consumption rate that includes finfish, shellfish, and anadromous fish. For example, the Oregon DEQ has adopted a fish consumption rate (175 g/day) that includes salmon.
- *Salmon considered when establishing regional rates.* Ecology could establish regional fish consumption rates that reflect the diversity of water bodies, species, and fish consumption patterns. Under this approach, Ecology could include salmon in the rates

---

[45] *Waters of the state* include lakes, rivers, ponds, streams, inland waters, underground waters, salt waters, and all other surface waters and watercourses within the jurisdiction of the state of Washington (RCW 90.48.020).

applicable to some water bodies while excluding salmon in the rates for other water bodies. Ecology is not aware of examples where this approach has been used.

- *Salmon considered when establishing site-specific rates.* Ecology could establish site-specific fish consumption rates that include salmon for some (but not all) cleanup sites. Under this approach, Ecology would consider the cleanup site's contribution to salmon body burden when establishing site-specific cleanup standards.
- *Salmon NOT considered.* Some agencies have established regulatory requirements that are based on fish consumption rates that do not include salmon. For example, the EPA used this approach when establishing the default fish consumption rates that are included in the EPA Region 10 framework. Most states have adopted human health-based water quality criteria that do not include anadromous salmon in the fish consumption rate.

6.5 Sources of finfish/shellfish

In some surveys, people are asked to provide information on the source of the finfish and shellfish they have consumed. Sources of finfish and shellfish are generally categorized as self-harvested or purchased from stores or restaurants. Not all locally harvested fish may be affected by site-specific contamination. Chapter 4 summarizes information from the four key regional fish consumption surveys conducted in the Pacific Northwest. Section 4.7 summarizes available information on the source of finfish and shellfish. For these tribal populations, locally or regionally harvested finfish and shellfish represents 67 to 96 percent of total finfish and shellfish consumed.

Several different approaches are used by federal and state regulatory programs to account for patterns of exposure from different sources. Options typically considered by agencies include:

- *Fish consumption rates based on consumption of all finfish and shellfish.* Some agencies establish default and site-specific fish consumption rates using study results that reflect the total amount of finfish and shellfish consumed by study participants (independent of whether the finfish/shellfish were locally harvested or store-bought). For example, the Oregon DEQ used this approach when they revised Oregon's Water Quality Standards for Surface Waters.
- *Fish consumption rates based on consumption of locally harvested finfish and shellfish.* Some agencies establish default and site-specific fish consumption rates using study results that reflect locally harvested finfish and shellfish consumed by study participants. For example, the EPA Region 10 framework explicitly recognizes source contribution issues by adjusting total fish consumption rates to account for fish harvested and consumed from Puget Sound (U.S. EPA, 2007b).
- *Fish diet fraction.* Some agencies make site-specific adjustments to account for the amount of locally harvested finfish and shellfish caught at or near an individual sediment cleanup site. For example, the MTCA rule currently considers the fish diet fraction when

calculating site-specific surface water cleanup standards. The fish diet fraction is defined in the MTCA rule as "….the percentage of the total finfish and/or shellfish in an individual's diet that is obtained or has the potential to be obtained from the site" (WAC 173-340-708(10)(b)). Applying the 0.5 default fish diet fraction under MTCA to the 54 g/day default fish consumption rate (see Figures 15 and 16) results in an effective fish consumption rate of 27 g/day.

6.6 Consumer vs. per capita

Fish consumption surveys typically include people who eat fish and people who don't eat fish. People who don't eat fish are termed *non-consumers*. Those that do eat fish are considered *consumers*. The proportion of non-consumers included in the survey will vary depending on the population being interviewed.

The results from fish consumption surveys can be reported in terms of *consumer-only* rates and *per capita* rates. Consumer-only intake rates refer to the quantity of finfish and shellfish consumed by individuals during the survey period. These data are generated by averaging intake across only the individuals in the survey who consumed finfish and shellfish during the survey period. Per capita intake rates are generated by averaging intake rates over the entire survey population (including those individuals that reported no intake).

There can be large differences in study results reported on a consumer-only and per-capita basis when a large percentage of study participants report that they did not eat any finfish or shellfish during the survey period. For example, EPA evaluated national data from approximately 20,000 individuals (3 years and older). Approximately 28 percent were fish consumers. When expressed on a per-capita basis, the 90th percentile of the reported results was 17.5 g/day. When expressed on a consumer-only basis, the 90th percentile of the reported results was 250 g/day (U.S. EPA, 2002a).

However, there are much smaller differences in studies where a high percentage of study participants reported they ate some amount of fish during the survey period. For example, the per-capita and consumer-only rates from the CRITFC study are virtually identical.

Federal and state environmental agencies have used both types of information to establish regulatory requirements. Options include:

- *Per capita data.* Environmental agencies have used per capita fish consumption rates to establish regulatory requirements. For example, several states have adopted surface water quality standards that are based on the 90th percentile of 17.5 g/day.
- *Consumer-only data.* Environmental agencies have used consumer-only fish consumption rates to establish regulatory requirements. For example, the EPA Region 10 framework includes several default fish consumption rates that are based on consumer-only information.

6.7 Other exposure variables

Ecology uses a risk assessment approach to establish cleanup standards and water quality standards based on human health protection. Risk-based concentrations can be calculated for both cancer and non-cancer health effects using standard risk assessment equations. This document is not designed to provide a detailed discussion on individual exposure parameters and the relationships between those parameters and the fish consumption rate used to calculate risk-based concentrations. However, when selecting fish consumption rates used in regulatory decisions, it is important to consider the following points:

- Regulatory choices on individual parameters need to be based on a common exposure scenario. It is important that agencies select fish consumption rates that are consistent with other exposure parameters. For example, if risk calculations are performed using a child's body weight, the fish consumption rate should be based on the amount of finfish and shellfish eaten by children.
- Regulatory choices on individual exposure parameters need to recognize the value judgments embedded in those parameters and the cumulative impact of those choices. For example, selecting upper percentile values for all exposure parameters will result in a risk estimate that does not represent a "reasonable" maximum exposure scenario (RME).
- Values should be concordant with the populations chosen to represent regulatory exposure scenarios, for example body weight for tribal populations or particular ethnic groups. Similarly, exposure duration should reflect the duration of times populations selected for evaluation use water bodies for fishing. Tribes have Usual and Accustomed fishing areas they may use over long periods of time. Individuals may relocate over limited geographic areas and still utilize water bodies for fishing with the implication that times in a single residence may not be an appropriate exposure duration.
- How bioaccumulation is accounted for is also a source of uncertainty and variability. The use of bioconcentration factors (BCFs) that relate contaminant concentrations in aquatic biota to those in water are being replaced by bioaccumulation factors (BAFs) that relate contaminant concentrations in aquatic biota to those from all sources.
- Figures 15 and 16 illustrate other exposure parameters. Shown are equations used to establish MTCA surface water cleanup standards based on non-cancer hazard and cancer risks (Figures 15 and 16, respectively). In addition to a default fish consumption rate, the equation includes default values for body weight, exposure duration, and fish diet fraction. A similar (but not identical) equation is used to establish water quality standards. Several of the exposure assumptions used to establish water quality standards are different than those used under the MTCA rule.

$$CUL = \frac{(RfD * ABW * UCF1 * UCF2 * HQ * AT)}{(BCF * FCR * FDF * ED)}$$

Where:

CUL = Surface water cleanup standard (µg/L)

RfD = Reference Dose as specified in WAC 173-340-708(7)

ABW = Average body weight During the exposure duration (70 kg)

UCF1 = Unit conversion factor (1000 µg/mg)

UCF2 = Unit conversion factor (1000 g/liter)

BCF = Bioconcentration factor as defined in WAC 173-340-708(9) (liters/kilogram)

FCF = Fish consumption rate (54 g/day)

FDF = Fish diet fraction (0.5, unitless)

HQ = Hazard quotient (1 unitless)

AT = Averaging times (30 years)

ED = Exposure duration (30 years)

Figure 15. MTCA Surface Water Cleanup Standards Equation (Non-Carcinogenic Hazards)

$$CUL = \frac{(RISK * ABW * AT * UCF1 * UCF2)}{(CPF * BCF * FCR * FDF * ED)}$$

Where:

CUL = Surface water cleanup standard (µg/L)

RISK = Acceptable cancer risk level (1 in 1,000,000) (unitless)

ABW = Average body weight during the exposure duration (70 kg)

AT = Averaging time (75 years)

UCF1 = Unit conversion factor (1,000 µg/mg)

UCF2 = Unit conversion factor (1,000 grams/liter)

CPF = Carcinogenic Potency Factor as specified in WAC 173-340-708(8) (kg-day/mg)

BCF = Bioconcentration factor as defined in WAC 173-340-708(9) (liters/kilogram)

FCR = Fish consumption rate (54 grams/day)

FDF = Fish diet fraction (0.5) (unitless)

ED = Exposure duration (30 years)

Figure 16. MTCA Surface Water Cleanup Standards Equation (Carcinogenic Risk)

6.8 Acceptable risk levels

Washington’s current Water Quality Standards and MTCA Cleanup Regulation are both based on an acceptable cancer risk of 1 in 1 million and a hazard quotient of one. These are central policy choices that will continue to be discussed and debated. By necessity, decisions on acceptable risk levels are informed by science but require consideration of a wide range of other factors. For example:

- Statutory requirements.
- Social preferences on risk avoidance and distinctions between voluntary and involuntary risks.
- Uncertainties associated with risk assessment methods.
- Risk tradeoffs, including the health benefits associated with eating finfish and shellfish.
- Risk comparisons, including the risks associated with other common activities.
- Economic impacts of attaining target risk levels.

This technical support document focuses on information about fish consumption. It does not provide a detailed discussion on risk policy. Ecology acknowledges that when selecting fish consumption rates for use in regulatory decisions it will be important to consider the relationships and interactions between the various policy choices.

6.9 Summary

Agencies must address many scientific and policy issues when selecting a fish consumption rate for use in particular regulatory situations. Chapters 3 through 5 compile the currently available information on fish consumption rates in Washington. This chapter describes eight policy choices that should be addressed when using this information in a regulatory context. These policy choices must take into account statutory mandates and values that inevitably reflect explicit or implicit choices on how to deal with scientific uncertainty and variability. There are often multiple answers to these questions surrounding these issues. This chapter provides examples of how Ecology or other agencies have resolved those issues in the past.

Appendices

Appendix A Information on Bioaccumulation, Fish Consumption by Children, and Species Consumed

This appendix includes information on:

1. Bioaccumulation
2. Children's fish consumption rates
3. Data on species consumed

This information is included in this document to provide additional context for considering fish consumption rates. For additional information readers are referred to references cited.

A.1 Bioaccumulation

Bioaccumulation of contaminants in finfish/shellfish

A detailed discussion regarding the bioaccumulation of chemicals in aquatic biota is beyond the scope of this appendix. The EPA's Methodology for Deriving Ambient Water Quality Criteria for the Protection of Human Health (2000) dedicates an entire chapter on the subject of bioaccumulation and changes in methodologies since the 1980s to assess and predict the bioaccumulation of chemicals in aquatic biota. Federal and state guidance documents are available that provide detailed analysis to assess and predict the bioaccumulation of chemicals in aquatic biota (U.S. EPA, 2000b, 2000c, 2007a; State Water Resources Control Board of California, 2004; CalEPA, 2006). An 800-page appendix to EPA's *Bioaccumulation Testing and Interpretation for the Purpose of Sediment Quality Assessment* provides chemical-specific information relevant to the bioaccumulation of chemicals in aquatic biota (U.S. EPA, 2000c, Appendices).

EPA makes a clear distinction between the terms bioaccumulation and bioconcentration. The term bioaccumulation "refers to the uptake and retention of a chemical by an aquatic organism from all surrounding media (e.g., water, food, sediment)." The term bioconcentration "refers to the uptake and retention of a chemical by an aquatic organism from water only" (U.S. EPA, 2000b). The 2000 EPA guidance reflects the use of bioaccumulation factors (BAFs) to reflect the uptake of a contaminant by fish from all sources rather than just from the water column reflected by the use of bioconcentration factors (BCFs). For chemicals that are persistent and hydrophobic, the magnitude of bioaccumulation by aquatic organisms may be substantially greater than the magnitude of bioconcentration. The 2000 EPA Ambient Water Quality Methodology provides important concepts regarding the bioaccumulation process as follows (U.S. EPA, 2000b, p. 5–2):

> *Another noteworthy aspect of bioaccumulation process is the issue of steady-state conditions. Specifically, both bioaccumulation and bioconcentration can be viewed as the results of competing rates of chemical uptake and depuration (chemical loss) by an aquatic organism. The rates of chemical uptake and depuration can be affected by various factors including the properties of the chemical, the physiology of the organism in question, water quality and conditions, ecological characteristics of the water body (e.g., food web structure), and the concentration and loadings history of the chemicals. When the rates of chemical uptake and depuration are equal, tissue concentrations remain constant over time and the distribution of the chemical between the organism and its sources(s) is said to be at steady-state. For constant chemical exposures and other conditions, the steady-state concentration in the organism represents the highest accumulation potential of the chemical in that organism under those conditions. The time required for a chemical to achieve steady state has been shown to vary according to the properties of the chemical and other factors.*

The EPA further notes that…"criteria for the protection of human health are typically designed to protect humans from harmful lifetime or long-term exposures to waterborne contaminants, the assessment of bioaccumulation that equals or approximates steady-state accumulation is one of the principles underlying the derivation of national BAFs. For some chemicals that require relatively long periods of time to reach steady-state in tissue of aquatic organisms, changes in water column concentrations may occur on a much more rapid time scale compared to the corresponding changes in tissue concentrations. Thus, if the system departs substantially from steady-state conditions and water concentrations are not averaged over a sufficient time period, the ratio of the tissue concentration to a water concentration may have little resemblance to the steady-state ratio and have little predictive value of long-term bioaccumulation potential" (U.S. EPA, 2000b).

There are several important factors that may affect a chemical's bioavailability and influence its bioaccumulation in fish. These factors include a wide range of physical, chemical, and biological characteristics associated with the contaminants, sediments, and aquatic biota (U.S. EPA, 2000c).

Chemical bioavailability. Chemical bioavailability is a complex interplay between the physical-chemical properties of the contaminant as well as the behavior and physiology of the aquatic biota.

Physical factors of sediments affecting bioavailability and bioaccumulation. Sediments are complex and dynamic environments with a wide range of interacting biological and chemical processes that influence a chemical's bioavailability and bioaccumulation into fish tissues.

Variable rates of mixing surficial sediment layers by physical processes of turbulence and bioturbation compete with rates of sedimentation. In addition, resuspension of sediments may also impact the bioavailability of sediment-associated contaminants by exposing filter feeders to contaminated particulates or by increasing the aqueous concentration of a contaminant via desorption from the particulates within the water column.

Chemical factors affecting bioavailability and bioaccumulation. The physical-chemical characteristics of a contaminant (molecular size and polarity) may influence the degree of association with particles and affect the chemical's bioavailability. Many persistent and bioaccumulative toxic chemicals (PBTs) are large, nonpolar compounds, with low water solubilities and a strong tendency to be associated with dissolved and particulate organic matter. Hydrophobic chemicals, those that are strongly lipophilic, are a critical factor in determining the bioaccumulation behavior of organic chemicals in aquatic systems.

Biological factors affecting bioavailability and bioaccumulation. EPA notes that bioaccumulation is a multi-factorial process that combines the chemical with the biological (U.S. EPA, 2000c, p. X):

> *Bioaccumulation is a function of the bioavailability of contaminants in combination with species-specific uptake and elimination processes. Toxicity is determined by the exposure of an animal to bioavailable contaminants in concert with the animal's sensitivity to the contaminant. These processes have been shown to be a function of the organism's lipid content, size, growth rate, gender, diet, and ability to metabolize or transform a given contaminant, as well as the chemical conditions of the surrounding medium. Other biological factors that can affect a contaminant's bioavailability include the burrowing and feeding behavior of the individual organism or species. The depth to which an organism burrows, the type of feeding mechanism it uses (e.g., filter feeding, particle ingestion), the size range of sediment particles it consumes, and its diet all have a large influence on the concentration of contaminant to which the organism will be exposed.*

A.2 Children's fish consumption rates

The *Child-Specific Exposure Factors Handbook* and the *Highlights of the Child-Specific Exposure Factors Handbook* summarize children's fish consumption rates for different age groups. The mean and 95th percentile consumer-only total fish (marine, estuarine, freshwater) consumption rate for 16 to less than18 years of age for the general population is 2.1 grams per kilogram per day (g/kg/day) (136 g/day) and 6.6 g/kg/day (357 g/day), respectively (U.S. EPA, 2008, 2009b). The mean and 95th percentile consumer-only total fish (finfish and shellfish) consumption rate for 3 to under 6 years old for the general population is 4.2 g/kg/day (78 g/day) and 10 g/kg/day (186 g/day), respectively (U.S. EPA, 2009b, Table 1).[46] The *Interim Report Child-Specific Exposure Factors Handbook* summarizes the fish consumption rates among Native American children (consumers only, 5 or 6 years old or younger) using Pacific Northwest fish consumption survey information (U.S. EPA, 2002a).

Table A-1. Fish Consumption Rates of Native American Children 5 or 6 Years of Age or Less

Survey (Native Populations)	Mean (g/day)	90th Percentile [a] (unless otherwise noted, g/day)	95th Percentile (g/day)
CRITFC, 1994 (Umatilla, Yakama, Nez Perce, Warm Springs)	25	63	73
Toy et al., 1996 (Tulalip and Squaxin Island Tribes) [b]	11	21 (86th percentile)	
Suquamish Tribal Survey, 2000 [c]	21	48	103

a. Values are the 90th percentile unless otherwise noted.

b. Consumption rate calculated using the average body weight of 15.2 kilograms reported in Toy et al., 1996.

c. Consumption rate calculated using the average body weight of 14.1 kilograms from the general population.

Although the age groups and body weights may differ across the general and Native American children population groups, the fish consumption rates for the children begin to approximate one another at the upper percentiles (78 to 186 g/day and 63 to 103 g/day). EPA has noted that there is a high degree of variability in fish consumption rates across the Pacific Northwest tribes (U.S. EPA, 2009a). The 2008 Oregon DEQ Human Health Focus Group Report referenced EPA's *Per Capita Fish Consumption in the U.S.* (2002) as supporting documentation for the children's fish consumption rate (consumers only) of 191 g/day (Oregon DEQ, 2008; U.S. EPA, 2002a, Section 5.2.1.1, Table 4). The same documentation and children's fish consumption rate (190 g/day) is used to recognize the variability expressed by different fish consumption rates for different fish-consuming populations.

The following tables summarize analysis of fish consumption rate data for surveys identified by Ecology as meeting measures of technical defensibility. These tables are included here to show age group data.

---

[46] This consumption rate uses a body weight of 18.6 kilograms for children 3 to <6 years of age.

Table A-2. Tribal Fish Consumption Rates

Fish Consumption Rate by Age Group From Selected Pacific Northwest Tribes				
Age Group	Mean	50th Percentile	90th Percentile	95th Percentile
Columbia River Basin Tribes (g/day)				
Adults	58.7			
18–39	57.6			
40–59	55.8			
60 and over	74.4

A.3 Data on fish species consumed

The EPA Region 10 framework for establishing site-specific fish consumption rates for use at Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) sites provides the following information related to types of seafood consumed.

For adult members of the Tulalip Tribes, a 95th percentile total consumption rate of 194 g/day is obtained after adjusting the total consumption rate of 243 g/day to include only finfish and shellfish harvested from Puget Sound (Table A-5). This is based on information from the EPA Region 10 framework (U.S. EPA, 2007b, as cited in Windward Environmental, 2007, Appendix B).

Table A-5. Seafood Consumed by Adult Members of the Tulalip Tribes

Seafood Category	Examples	Central Tendency Estimate (g/day)	95th Percentile (g/day)	Percent of Fish Diet
Anadromous fish	Salmon/steelhead	14.9	96.4	49.7
Pelagic fish	Smelt, mackerel, cod, perch	1.3	8.1	4.2
Benthic/demersal fish	Halibut, sole, rockfish, snappers	1.2	7.5	3.9
Shellfish	Crabs, clams, mussels, bivalves	12.5	81.9	42.2
	Total ingestion rate	30	194	100

For adult members of the Suquamish Tribe, a 95th percentile total consumption rate of 766.8 g/day is obtained after adjusting the total consumption rate of 796 g/day to include only finfish and shellfish harvested from Puget Sound (Table A-6). This is based on information from the EPA Region 10 framework (U.S. EPA, 2007b, as cited in Windward Environmental, 2007).

Table A-6. Seafood Consumed by Adult Members of the Suquamish Tribe

Seafood Category	Examples	95th Percentile (g/day)	Percent of Fish Diet
Anadromous fish	Salmon/steelhead	183.5	23.9
Pelagic fish	Smelt, mackerel, cod, perch	56.0	7.3
Benthic/demersal fish	Halibut, sole, rockfish, snappers	29.1	3.8
Shellfish	Crabs, clams, mussels, bivalves	498.4	65
	Total ingestion rate	766.8	100

Freshwater fish make up 8.3 percent of the API seafood consumption, based on information from the API fish consumption survey from King County, Washington, as cited in Windward Environmental, 2007 (Table A-7).

Table A-7. Seafood Consumed by Adult Asian-Pacific Islanders (API)

Seafood Category	Central Tendency Estimate (g/day)	95th Percentile (g/day)	Percent of fish diet
Anadromous fish	0.56	5.5	9.6
Pelagic fish	0.5	4.9	8.6
Benthic/demersal fish	0.24	2.4	4.2
Shellfish	4.6	44.2	77.5
Total	5.9	57	99.9

This page purposely left blank for duplicate printing.

Appendix B
Additional Fish Consumption Studies

This appendix includes information on additional studies considered by Ecology:

1. Background information
2. Biometric studies of Japanese and Korean populations in Washington State
3. Additional studies evaluated:
    a. Makah Tribe
    b. Port Gamble S'Klallum Tribe
    c. Muckleshoot Indian Tribes
    d. Upper Columbia River Resources Survey – Confederated Tribes of the Colville Reservation
    e. Spokane River Surveys of Selected Ethnic Populations
    f. Swinomish Tribal Study: Bioaccumulative Toxics in Subsistence-Harvested Shellfish – Contaminant Results and Risk Assessment
4. Additional technical publications by Pacific Northwest tribal staff

B.1 Background information

Ecology identified a number of studies that provide information meeting measures of technical defensibility and that are appropriate for consideration of statewide fish consumption rates. Other studies are useful in providing multiple lines of evidence with respect to fish consumption. That is, numerous other studies, designed for various purposes, provide additional information that may be of value for particular evaluations or considerations. Although these studies may not have been conducted to identify specifically fish consumption rates of the population of interest, they assist in providing a robust picture of the importance of finfish and shellfish to the people of Washington.

The studies discussed in this appendix are comprehensive but not exhaustive. For example, from July 2003 through December 2011, The Lands Council as part of the Spokane River Toxics Outreach, completed approximately 5,300 surveys, distributed about 10,000 health advisories, and participated in public education outreach of nearly 16,000 individuals in the Spokane area. This public outreach is to educate and increase public awareness of the health risks of PCBs in the Spokane River fish and heavy metal contamination in the Spokane River sediments. These surveys have targeted Slavic (eastern European, Russian) and Hispanic populations because they frequently harvest and consume fish from the Spokane River. Spokane River fish advisories recommend only one fish meal per month of fish from the river's middle section and avoid eating any fish from the Spokane River's upper stretches.[47] As noted in Chapters 3 and 4 of this Technical Support Document, these water body-specific surveys provide important information to support health protective advisories for people who harvest and consume fish from specific water bodies. All water body-specific fish dietary surveys, usually some form of a creel survey, are not detailed in this Technical Support Document. For a more detailed review of all of the water body-specific surveys and fish advisory information, the reader is referred to the Washington Department of Health's website on fish advisories.[48] The fish consumption related information provided in this appendix is important and credible information used to evaluate and assess the potential health risks from eating contaminated fish (seafood). The additional fish dietary information provided in Table 33 and this appendix provide multiple lines of evidence, as a weight of evidence approach, that people in Washington State harvest and consume large amounts of fish. The estimates of fish consumption detailed in Chapter 4 are based on fish dietary information based on survey methodology that allows for the projection of fish consumption estimates over a long period of time with descriptive statistics for percentile estimates. This type of information is important to help support health protective decisions to clean up contaminated sediments.

B.2 Biometric studies of Japanese and Korean populations in Washington State

Several studies have been conducted in Washington State to evaluate the fish consumption of Japanese and Korean populations (Tsuchiya et al., 2008a, 2008b, 2009; Cleland et al., 2009). These studies were conducted as part of the Arsenic Mercury Intake Biometric Study in collaboration with the University of Washington's Institute for Risk Analysis and Risk Communication and the Washington State Department of Health. The studies were designed to evaluate mercury exposure within the Japanese and Korean communities and arsenic exposures within the Korean community of Washington State. Japanese and Korean populations in Washington State consume fish at higher rates than the national average (Sechena et al., 1999). These high fish-consuming populations may be exposed to mercury and arsenic from the consumption of finfish and shellfish.

The fish consumption survey was based on surveys previously conducted for several other Pacific Northwest fish-consuming populations (tribal surveys and Sechena et al., 1999). The food frequency questionnaire was a validated dietary tool used and developed by the Fred Hutchinson Cancer Research Center and was self administered by the participants of this study. As part of the fish dietary survey, participants were provided a pictorial fish booklet, printed in three languages, containing pictures with names of various fish species commonly consumed by

---

[47] Spokane River Toxics Outreach, web location: http://www.landscouncil.org/water/river_toxics.asp?template=false

[48] Washington State Department of Health Fish Advisory Information: http://www.doh.wa.gov/CommunityandEnvironment/Food/Fish.aspx

Japanese and Koreans and seafood commonly found in the Pacific Northwest. Interview questions included frequency of consumption and serving sizes (based on fish models of fish steaks, fillets, sushi pieces, and shellfish samples). Also, participants were asked if they consumed any other fish not listed in the fish booklet. Survey participants were weighed unless they were pregnant. Pregnant women were asked to report their pre-pregnancy body weights.

The survey instrument included a series of questions that allowed for a cross-check of participant response about fish consumption. Mercury fish tissue concentrations were determined from fish commonly consumed by Japanese and Korean communities in the Puget Sound area from local Asian grocery stores. Fish or fish portions were purchased from multiple locations over a 4-week period. Analysis was conducted on skinless edible portions consisting of steaks or fillets.

Results from the Japanese and Korean fish dietary survey are shown in Table B-1 with comparisons made between the mean combined finfish and shellfish consumption rates (in red) with the 95th percentile national consumption rates (in red).

Table B-1. Fish Consumption Rates for Japanese and Korean Washington Populations

Population	Finfish Consumption (g/day)			Shellfish Consumption (g/day)		
	Mean	50th	95th	Mean	50th	95th
Japanese (n = 106)	60	43	159	14	9	59
Korean (n = 108)	59	42	147	23	13	84
Population	**Finfish and Shellfish Combined Consumption (g/day)**					
	Mean	50th	75th	90th	95th	99th
Japanese (n = 106)	73	55	100	164	188	241
Korean (n = 108)	82	64	112	170	230	329
CSFII	14	----	19	47	72	121
NHANES	----	----	0	43	87	----

Source: Adapted from Tsuchiya et al., 2008b, Table 1.

Both Japanese and Korean respondents from this survey consume almost the same amounts of finfish (mean fish consumption of 60 g/day for Japanese and 59 g/day for Koreans). Also, this similarity in fish consumption for Japanese and Koreans is reflected in the finfish consumption distribution with 95th percentiles being 159 g/day for Japanese and 147 g/day for Koreans. Differences in amounts of total fish consumption for these two fish-consuming populations is due to the Koreans consuming nearly 70 percent more shellfish on a daily basis (22.7 g/day/person) compared to the Japanese (13.5 g/day/person). The mean total fish consumption for Japanese (73 g/day) and Koreans (82 g/day) is almost identical to the 95th percentile estimates from CSFII and NHANES national fish dietary data. Based on comparison with national data, the authors noted (Tsuchiya et al., 2008b):

> *The Koreans and Japanese women consume fish in quantities that exceed the national average. Mean values for the average values for the Japanese and Korean cohorts are significantly higher (73 and 82 g/day, respectively). Values of significance within the NHANES and CSFII distributions are the 95th percentile values (87 and 72 g/d, respectively) because the remaining 5% represent many persons. The average consumption values for the Koreans and Japanese approach or exceed these 95th percentile values, indicating that these 2 populations may be contained within the remaining 5th percentile of the NHANES and CSFII distributions. On the basis of the percentile values for the consumption distributions from CSFII and NHANES, the 2 populations investigated by us have central estimate shifts in consumption, leading to distribution patterns displaced to the right and further down the abscissa. Specifically, all the percentile consumption rates representing the national fish consumer were below those determined for the Japanese and Koreans.*

Mean fish consumption estimates for Japanese and Korean women respondents for each of the clinic visits are provided in the table below. Additional details regarding the finfish species consumed and differences in rates from one clinic visit to another are provided in the Technical Issue Paper, *Health Benefits and Risks of Consuming Fish and Shellfish* (Ecology, 2012).

B.3 Additional studies evaluated

Makah Tribe

The Makah Indian reservation is located on the northwestern tip of the Olympia Peninsula in Washington State. The Makah Tribal usual and accustomed areas for harvesting finfish and shellfish extends east to the Elwha River, south to a geographic point between Ozette and the Quileute reservation, and north to the Canadian international border and the Swiftsure Bank. The geographic position of the Makah Indian reservation provides access to diverse terrestrial, freshwater, and marine resources to support subsistence practices.

An examination of the Makah subsistence practices was conducted by the University of Washington, Department of Anthropology, between 1997 and 1999. Jennifer Sepez's 2001 dissertation documents and evaluates the subsistence hunting, fishing, and shellfishing practices of the Makah Indian Tribe. For the purposes of this research, subsistence was defined as "the local harvest of natural resources for local consumption" (Sepez, 2001, p. 9). A random ethnographic survey sample of 15 percent of reservation households provided information on the contemporary subsistence harvests, uses, and consumption of finfish, shellfish, land mammals, marine mammals, and birds. Results indicate that 99 percent of the reservation households participate in some type of subsistence activities. 71 percent of the households engaged in harvesting resources, while 94 percent received resources harvested by another household. This comprehensive examination of Makah Tribal subsistence practices included hunting for deer, elk, and grouse, and fishing for salmon, halibut, rockfish, black cod, and other species (Table B-2). Low tides in Neah Bay or adjacent tide flats provide areas for tribal harvesting of clams, mussels, barnacles, chitons, urchins, and other shellfish. Seal hunting occurs in conjunction with net fishing and canoeing. Regarding the Makah Tribal subsistence practices, the thesis noted (Sepez, 2001, p. 19):

> *There is no homogeneous or even typical subsistence profile of Makahs. However, there are identifiable patterns of resource use in the community, and an accumulated history of legal, political, and ecological circumstances that frame contemporary subsistence activities as a place-and time-specific manifestation of ongoing traditions.*
>
> *Although land-based subsistence harvesting is important, the majority of resources come from the sea. One saying around town that captures this orientation is "when the tide is out, the table is set."*

Table B-2. Percent of Households Using Subsistence Resources during 1997–1998

Percent of Reservation Households	Subsistence Resource
76–100%	Halibut, salmon, clams, crab
51–75%	Mussels, deer, elk, goosenecks [boots], seal (meat and/or oil), salmon eggs, barnacles
26–50%	Steelhead, lingcod, olive shells, chitons [slippers], octopus, rockfish, smelt, black cod, herring eggs, grouse
1–25%	Urchins [sea eggs], lingcod eggs, local cow, petrale, trout, tuna, bear, scallop, oysters, sole/flatfish, sea cucumber, squid, sturgeon, true cod, shrimp, rabbits, abalone, duck, pigeon, skate, sea lion, small gastropods, wolf eel.

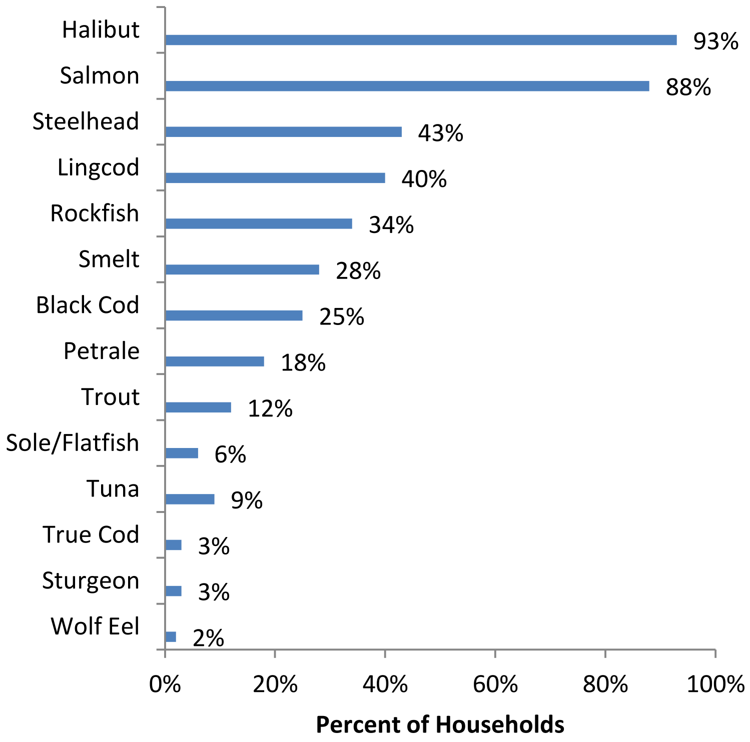
Source: Adapted from Sepez, 2001, Table 4, p. 126.

The Makah tribal subsistence diet is composed mainly of finfish and shellfish. Shellfish contribute 14 percent and finfish contribute 58 percent of the Makah tribal subsistence diet. The percent contribution of fish to the Makah subsistence diet is approximately eight times more than the percent contribution of fish consumed by the average American diet. Halibut is consumed at home by 93 percent of the households. Historical information suggests a strong dietary reliance on halibut, which differentiated the Makah Indian Tribe from other Pacific Northwest tribes whose main fish subsistence resource was salmon. However, 88 percent of the Makah tribal households consume salmon, which surpasses halibut consumption when measured as pounds consumed per household. Table B-3 and Figure B-1 below illustrate the harvest and consumption practices of the Makah Tribe for fish resources in pounds. Salmon and halibut contribute more to the subsistence Makah diet by weight than any other types of fish combined.

Table B-3. Makah Indian Tribe Per Capita Harvest and Consumption of Subsistence Fish (pounds)

Fish Species	Mean per capita harvest (all households)	Mean per capita consumption (all households)	Mean per capita consumption (consumers only)
Halibut	55.6	27.4	28.9
Salmon	49.3	40.1	44.9
Steelhead	3.1	3.8	8.6
Lingcod	2.5	2.9	6.9
Rockfish	2.5	3.3	8.9
Smelt	2.4	2.7	10.0
Black Cod	1.3	1.2	5.9
Trout	0.04	0.1	0.4
Sturgeon	1.0	0.8	28.0
Skates	0.1	NA	NA

Source: Adapted from Sepez, 2001, Table 6, p. 140.



Source: Adapted from Sepez, 2001, Figure 3, p. 139.

Figure B-1.Percent of Makah Tribal Households Consuming Subsistence Fish

The survey vehicle administered to the Makah tribal reservation households obtained subsistence fish harvest and consumption information based on household harvest and consumption practices. Ecology did not use this information because the metrics from the results of the survey of tribal households (percent of tribal household consuming fish) is different than the metrics (grams/day) used for risk-based decision making. Furthermore, since information was not available regarding the number of residents per household, and the residency of the same household may vary depending on the extended family relationship within the Makah Tribe, it is not possible to determine an individual's grams/day fish consumption rate based on this thesis. However, this thesis provides a comprehensive documentation of the composition of subsistence Makah tribal diet and subsistence lifeways and practices.

Port Gamble S'Klallum Tribe

Ecology consulted with the Port Gamble S'Klallam Tribe to determine a tribal fish consumption rate to establish sediment cleanup standards protective of human health. The Port Gamble S'Klallam Tribal fish consumption rates were based on the Suquamish Tribe Fish Consumption Survey using the EPA Tribal Fish Consumption Framework. The daily tribal seafood consumption rate of 499 g/day was determined for selected shellfish only and did not include salmon or other finfish. Tribal consultations are continuing to provide additional information regarding the amounts and types of shellfish consumed. Based on Port Gamble S'Klallam Tribal consultations and the application of the EPA Tribal Fish Consumption Framework, the following shellfish species are consumed:

- Total shellfish consumption (no finfish) is 499 g/day:

Geoduck	96.8 g/day
Littleneck clams	255.9 g/day
Oysters	62.4 g/day
Dungeness crab	83.9 g/day assuming 25% hepatopancreas (20.9 g/day) and 75% meat (62.9 g/day).

Ecology did not use this information to derive a default fish consumption rate because Port Gamble S'Klallam Tribal consultations are continuing to establish an accurate tribal fish consumption rate (Ecology, 2011a).

Muckleshoot Indian Tribes

The Muckleshoot Indian Tribe has not performed a tribal fish consumption survey.[49] However, the Muckleshoot Indian Tribe requested that EPA Region 10 develop a tribal exposure scenario to assist in characterizing the range of seafood consumption risks for the Lower Duwamish Waterway. In consultation with the Muckleshoot and Suquamish Indian Tribes, EPA Region 10

---

[49] Public Health Assessments and Health Consultations. ATSDR. http://www.atsdr.cdc.gov/hac/pha/pha.asp?docid=1312&pg=2#path

and Ecology used EPA guidance to develop a tribal exposure scenario and derive fish consumption rates based on the Suquamish and Tulalip seafood consumption data. Using the EPA Region 10 guidance framework tribal exposure scenarios were developed for the Lower Duwamish Waterway for tribal adults consuming anadromous and pelagic finfish, benthic/demersal finfish, and shellfish. The Lower Duwamish Waterway Remedial Investigation Report provides a range of tribal consumption rates specific for the risk management decisions for the Lower Duwamish Waterway (Windward Environmental, 2007). The Lower Duwamish Waterway fish consumption rates are not applicable for Washington State high fish-consuming populations. Hence, the Lower Duwamish Waterway fish consumption rates were not used to derive a default MTCA fish consumption rate to establish surface water cleanup standards.

Upper Columbia River Resources Survey–Confederated Tribes of the Colville Reservation

Background information

The Confederated Tribes of the Colville Reservation and the EPA, Region 10 and Headquarters, collaborated on the Upper Columbia River Resources Survey (Confederated Tribes of the Colville Reservation and U.S. EPA, 2012). The upper Columbia River and Lake Roosevelt areas have been affected by contaminants from Teck Cominco lead-zinc smelter operations for over 100 years. Residents of the Colville Reservation, located 50 miles downstream from Teck Cominco mine, may have been exposed to these contaminants and have collaborated with the EPA to assess and measure exposure pathways from the consumption of natural resources (including fish) that may be contaminated from the Teck Cominco operations. This information will be used by the EPA to conduct a human health risk assessment for the Upper Columbia River and Colville reservation residents. The resource use survey was conducted to support efforts to evaluate and assess the human health risks from exposures to contaminants from the Teck Cominco lead-zinc smelter located just north of the U.S. Canadian border.

Survey methodology

The Upper Columbia River Resources Survey is composed of two survey vehicles designed to investigate the food consumed and non-food uses harvested from local resources by residents of the Colville Reservation located in eastern Washington State. The Food Questionnaire was administered by trained personnel to Colville Reservation residents regarding the consumption over the preceding 12-month period of several types of food groups: fish, birds, wild animals, farm animals, dairy products, fruits, vegetables, and wild plants. The Food Questionnaire survey method was a 24-hour dietary recall and included a previous 12-month food frequency recall and non-food use recall associated with resident uses of the reservation’s natural resources. Out of a pool of 5,893 people, 1,139 people over the age of 2 responded to the Food Questionnaire—approximately 20 percent of the total resident population. A demographic weighting was applied to each respondent to account for the variance in response rate for residence location and age. The percentages and numbers of consumers provided in the Food Questionnaire data report will vary from the percentage of individual respondents because of this demographic weighting of each respondent. The demographic weighting allows the calculation of numbers and percentages of Colville Reservation residents over the age of 2 years that consume selected types of foods.

Results

Selected results of the Food Questionnaire related to fish consumption from Upper Columbia River Tribal Exposure Survey are presented in Table B-4.

Table B-4. Summary of Fish Type Consumed, Percentage of Population that Consumed Fish Type, and Percentage Harvest Source from Local Areas by Colville Reservation Residents

Fish Type	Percentage of Residents Consuming Fish Type	Frequency of Consumption (times/year)	Percentage Consumers Harvest from Local Areas
Salmon	73	15	74
Trout	46	13	92
Walleye	13	9	91
Smallmouth Bass	11	21	93
Crawfish	9	13	85
Mussels	8	9	12
Largemouth Bass	7	22	85
Panfish	6	25	79
Burbot	4	9	30
Sturgeon	3	40	68
Lake Whitefish	2	9	91
Mountain Whitefish	1	8	69
Lamprey	1	12	13
Aquatic Animals	1	18	100
Northern Pikeminnow	1	7	87
Other fish/aquatic animal	<1	6	100
Sucker [a]	<1	head/skin/organ/eggs	0%

Source: Adapted from Confederated Tribes of the Colville Reservation and U.S. EPA, 2012, Table 3.

a. Sucker was the only fish for which the head/skin/organ/eggs were reported to be consumed more frequently than the meat of the fish. However, a very low number of respondents reported eating suckers and all respondents were unsure of the harvest source of suckers consumed.

The 24-hour dietary recall survey provides information on food (fish) portion sizes while the previous year recall provides information on frequency of consumption for specific types of food consumed from local resources. Information about specific consumption rates is not yet available. However, important observations can be made from the above table. About 83 percent of the Colville Reservation residents ate fish in the previous year the survey was administered. The average number of local fish species consumed was 3 species with a maximum number of 13 species consumed by residents. 73 percent of Colville Reservation residents ate salmon on an average of 15 times per year. Also, almost 20 percent ate the head, skin, organs, or eggs of salmon. 61 percent of the respondents noted that all of their salmon was harvested from on or near the Colville Reservation and another 12 percent harvested part of their salmon catch locally.

Freshwater mussels and crawfish are also harvested and consumed by Colville Reservation residents. 8 percent of the Colville Reservation residents ate mussels sometime during the previous year of the administered survey and 9 percent ate crawfish. 13 percent of the mussels were harvested all or partly locally. 81 percent of the crawfish were harvested entirely from local areas.

Many Colville Reservation respondents noted that they do not eat as much local fish as they would prefer because of concerns about smelter contaminants. Suppression of resources and reduced fish consumption remains an important concern by tribal populations. Tribal fish consumption and corresponding rates are artificially reduced due to concerns about contaminants and their associated effects.

Spokane River Surveys of Selected Ethnic Populations

Numerous and different types of surveys have been conducted for the Spokane River by the collaborative efforts of Spokane Regional Health District, Assessment/Epidemiology Center, Washington State's Department of Health, and the Lands Council – Center for Justice. From July 2003 through December 2011, The Lands Council – Center for Justice as part of the Spokane River Toxics Outreach, completed approximately 5,300 surveys, distributed about 10,000 health advisories, and participated in public education outreach of nearly 16, 000 individuals in the Spokane area.[50] Surveys have focused on ethnic populations that may be exposed to legacy contaminants from mining operations (arsenic, lead, cadmium) and PCBs by harvesting and consuming fish from the Spokane River. Two types of surveys are briefly reviewed: (1) 1998 Fish Consumption Survey, Spokane River, Washington (Spokane Regional Health District, 1998), and (2) Lands Council – Center for Justice risk communication and public outreach survey (Robinson Research, 2007), which was directed to specific ethnic communities that harvest and consume fish from the Spokane River.

1998 Fish Consumption Survey, Spokane River

A 1998 Fish Consumption Survey was conducted by the Spokane Regional Health District, Assessment/Epidemiology Center to evaluate how people access the Spokane River for harvesting fish and to assess the fish consumption habits of Russian, Hmong, and Laotian populations. The objectives of the survey were to: (1) identify different types of fish caught from the Spokane River, (2) identify locations where fish are harvested, (3) identify populations who consume fish from the Spokane River, and (4) identify amounts of fish consumed and meal preparation methods. A mail survey questionnaire sampled two fish-consuming populations based on a random sample of Spokane County fishing license holders (2000 sample population)

---

[50] Spokane River Toxics Outreach, web location: http://www.landscouncil.org/water/river_toxics.asp?template=false

and individuals from a particular Spokane area fishing club (180 sample population from The Walleye Club). Russian and Laotian community representatives were hired by the Spokane Regional Health District to convene a focus group, serve as interpreters, translate the written survey, and coordinate the survey distribution within Russian and Laotian communities. Key findings for each of the two ethnic communities surveyed are provided below.

Key Russian Community Findings:

- Harvest locations: Upriver Dam, the old Walk in the Wild Zoo, River Front Park, downtown Spokane area, T.J Meenach Bridge, Nine Mile Bridge, and Long Lake.
- Fish harvested: rainbow trout, German (brown) trout, suckers, catfish, crayfish, pike minnow, smallmouth bass, and perch.
- Fish consumption: about 4 pounds per month (about 65 g/day or 2.3 ounces of fish per day).

Key Laotian Community Findings:

- Harvest locations: Nine Mile Bridge where the little Spokane and Spokane River meet.
- Fish harvested: catfish, rainbow trout, perch, bass, walleye, and crawdads.
- Fish consumption: two to three meals of Spokane River fish per month (assuming a fish meal equals an 8-ounce serving, then two to three fish meals per month is about 16 to 24 g/day or less than 1 ounce of fish per day).

2007 Spokane River Toxins Survey

Lands Council – Center for Justice conducted a telephone survey for adults living in Spokane, Lincoln, and Stevens Counties who live close to the Spokane River. The purpose of the survey was to evaluate public attitudes and perceptions regarding pollution in the Spokane River. A total of 600 telephone interviews were completed from December 2006 to January 2007 with 67 percent conducted in Spokane County, 17 percent in Lincoln County, and 17 percent in Stevens County. This telephone survey is part of a broader public outreach and education effort by the Lands Council directed to low-income families, indigenous people, and recent immigrant populations (Hmong, Vietnamese, Slavic, and Hispanic populations). Selection of these populations was based on previous work conducted by the Spokane Regional Health District, and State Departments of Health and Ecology, and suggests these ethnic populations may be at potential health risks from exposure to contaminants in fish harvested from the Spokane River.

There are a significant number of people catching and/or eating fish from the Spokane River. For those eating fish, few are taking precautionary measures in preparation of the fish. Results of the Lands Council – Center for Justice provides insights into public outreach and education challenges:

- 19 percent of respondents fish in the Spokane River.
- 12 percent catch and eat fish. Over half eat two or more fish in months they are regularly fishing.
- Of those who said they eat fish from the Spokane River in a typical year, nearly two-thirds (65%) took no precautions in how they prepared the fish for cooking.
- The majority of fishing that includes eating what is caught takes place below Long Lake Dam (80%), where there are no fish advisories regarding consumption.
- Some fish consumption not in accordance with the Washington Department of Health fish advisory is occurring between Lake Spokane and the Idaho Border.

The harvest locations from the Spokane River are as follows:

- 80 percent below Long Lake Dam.
- 10 percent from Spokane Falls to Long Lake Dam.
- 4 percent from Upriver Dam to Spokane Falls.
- 3 percent from the Idaho State Line to Upriver Dam.
- 3 percent reported as Don’t Know/Refused.

The Laotian anglers were not evaluated for this survey since fewer than five surveys were returned from the 17 mailed surveys to the Laotian community.

Sampling and analysis reports that evaluated for metals and PCBs in the Spokane River, combined with findings from focus groups, established the questionnaire framework for the development of questions concerning fish harvest location and types of fish harvested. A mail survey questionnaire sampled two fish-consuming populations based on a random sample of Spokane County fishing license holders (2000 sample population) and individuals from a particular Spokane are fishing club (180 sample population from The Walleye Club). The mail survey questionnaire included an introductory letter asking participants to complete the survey if they harvest and consume fish from the Spokane River. A $50 gift certificate was included as an incentive to participate when the survey was completed and returned. There was about a 31 percent response rate to this mail survey.

Swinomish Tribal Study: Bioaccumulative Toxics in Subsistence-Harvested Shellfish – Contaminant Results and Risk Assessment

The Swinomish Indian tribal community is a federally recognized Indian tribe; the Swinomish Indian reservation is located on interior Puget Sound, Skagit County, Washington. The Swinomish Tribal Indian Community is a maritime fishing community with strong cultural and dietary dependence on fish and, particularly, shellfish. Shellfish are an abundant resource harvested by the Swinomish Tribal Indian Community throughout their usual and accustomed fishing areas.[51]

The Swinomish Tribal Community Office of Planning and Community Development conducted a study to evaluate the toxicity and assess the risks from the consumption of contaminated clams, crabs, and fish (Swinomish Tribe, 2006). Chemicals of concern evaluated in this study include polychlorinated biphenyls (PCBs), arsenic, dioxins/furans, mercury, polycyclic aromatic hydrocarbons (PAHs), and selected chlorinated pesticides and metals. Focused sampling and analysis was conducted for sediments, clams, and crabs from North and South Skagit Bay, Padilla and Fidalgo Bays, and Crescent Harbor.

An ethnographic-style survey (seafood diet interviews to evaluate current consumption pattern) was conducted for the Swinomish Tribal Community. Based on the ethnographic dietary survey, the Swinomish Tribal Indian Community documents 260 g/day (approximates an 8-ounce fish meal) for all seafood consumed harvested locally. The 260 g/day fish consumption rate was used for both adults and children to assess risks of individual clam and crab samples. Cumulative risks were based on a total of 300 g/day associated with the Swinomish Tribal Community consumption of 100 grams consumed daily each of clams, crab, and salmon. The risks from the consumption of contaminated seafood for the Swinomish Tribal Community are provided in Table B-5 below. The report notes “The ingestion rate of a total of 300 gpd [grams per day] is assumed for children as well as adults, which may overestimate intake for younger children. However, children are more sensitive to health effects, so assuming a higher per capita intake more accurately represents risks for younger children than simply scaling down the intake rate but not correcting for children’s increased sensitivity.” (Swinomish Tribe, 2006, p. 64)

The finfish/shellfish contaminants that contributed the most to human health risks were PCBs, arsenic, and dioxin/furans. Risks attributable from consuming 100 grams (3.5 ounces) of each species daily (total 300 g/day) are in the range of concern with non-cancer risk (HQ) for adults and children above 1 (ranging from 3 to 20), and lifetime cancer risks in the range of 1 in a 1,000.

---

[51] United States v. Washington, 459 F Supp. 1020, 1049 (W.D. Wash. 1979) “The usual and accustomed fish places of the Swinomish Tribal Community include the Skagit Rivers and its tributaries, the Samish River and its tributaries, and the marine areas of northern Puget Sound from the Fraser River south to and including Whidbey, Camano, Fidalgo, Guemes, Samish, Cypress, and the San Juan Islands, and including Bellingham Bay and Hale Passage adjacent to Lummi Island.”

Table B-5. Cumulative Risks to Swinomish Tribal Finfish- and Shellfish-Consuming Populations

Sampling Location and Seafood Type	HQ Child (6 Years)	HQ Adult (70 Years)	Cancer Risk (70 years lifetime)
Clams (Skagit Bay)	4	1	7E-04
Clams (Fidalgo and Padilla Bays)	5	1	9E-04
Crab (Skagit Bay)	3	0.7	8E-05
Crab (Fidalgo and Padilla Bays)	3	0.8	1E-04
Puget Sound Salmon	11	2	5E-04
Total Risk Ranges	17 to 21	3-5	1E-03 to 2E-03

Source: Adapted from Swinomish Tribe, 2006, Table 29.

Lummi Nation

The Lummi Indian nation conducted a survey to estimate seafood consumption for Lummi Indians living on the Lummi Indian Reservation and in surrounding areas of northwestern Washington State (Lummi Natural Resources Department 2012). The survey instrument used in the study was developed by the Lummi Natural Resources Department. The survey instrument used 54 species of seafood with questions on amount, seasonality, and frequency of consumption for each species. Separate information was obtained regarding seafood consumption at home and at tribal gatherings, demographic information, and information about fishing activity and patterns of consumption. The study evaluated historical fish dietary practices and rates in 1985 because current rates for the tribe are suppressed (Lummi Natural Resources Department 2012):

> *The environmental baseline chosen for the Lummi Seafood Consumption Study was 1985, as this was the peak fish harvest year for the Lummi Nation in recent history and a goal of the Lummi Natural Resources Department is to restore fish habitat so that at least the 1985 harvest levels can be sustained. As a result, the Tribal Advisory Committee determined that fish consumption rates from 1985 should be used to develop water quality standards and to support risk assessments of clean-up options for contaminated sites along Bellingham Bay. While not at Treaty-time levels, seafood abundance and availability was less of a limiting factor for seafood consumption during 1985 than in 2012. Consequently, the seafood consumption rate would be less suppressed due to environmental degradation or the lack of available fish. A literature review showed that appropriate data could be elicited in recall studies that reach back 25 years.*

The survey results are summarized below:

- Eighty-two (82) participants were interviewed over the May 2011 through March 2012 survey period.

- Outliers were removed before the final calculation, which reduced the overall sample size used to compute the daily seafood consumption rate to 73 respondents. Outliers were defined by the Tribal Advisory Committee as respondents who reported consumption rates above the 90th percentile of the daily seafood consumption rate of all respondents.
- The resultant average Lummi seafood consumption rate was calculated to be 4.73 grams per kilogram per day (g/kg/day) or approximately 383 grams per day (g/day) (0.84 pounds per day [lb/day] or 13.5 ounces per day [oz/day]) for all seafood consumed.
- The median seafood consumption rate was calculated to be 3.82 g/kg/day or approximately 314 g/day (069 lb/day or 11 oz/day).
- The 90th percentile seafood consumption rate was calculated to be 10.03 g/kg/day or approximately 800 g/day (1.76 lb/day or 28.2 oz/day).
- The 95th percentile seafood consumption rate was calculated to be 11.28 g/kg/day or approximately 918 g/day (2.02 lb/day or 32.4 oz/day).
- The final precision of the survey was ± 16.5%.

B.4 Additional technical publications by Pacific Northwest tribal staff

A Native American exposure scenario

This paper (Harris and Harper, 1997) documents a tribal-based subsistence exposure scenario for a variety of different foods and exposure parameters for use at the Hanford nuclear reservation cleanup. A subsistence fish consumption of 540 g/day is based on selected tribal interview from members of the Confederated Tribes of the Umatilla Indian Reservation and other published studies.

Lifestyles, diets, and Native American exposure factors related to possible lead exposures and toxicity

This article (Harris and Harper, 2001) documents that any assessment of the risk from lead exposure to tribal communities requires an understanding of the tribal community, resource base, and culture. Differences in patterns of exposure between different communities or groups of people are noted with documented additional sources of lead exposure for Native Americans.

A possible approach for setting a mercury risk-based action level based on tribal fish ingestion rates

Risks from the consumption of mercury-contaminated fish were evaluated with a recommended action level for mercury protective of Native American tribes in the Columbia River Basin at 0.1 ppm or less (Harper and Harris, 2008). The recommendation is based on the combined risks from mercury exposure plus other fish contaminants and exposures, the higher fish consumption rates associated with tribal populations, the existing cultural deficit due to loss of salmon, the health benefits from fish, and the cultural and economic importance of fish to tribal populations. To assess the risks from the consumption of mercury-contaminated fish, Harper and Harris (2008) defined the following fish consumption rates:

- Less than 100 g/day is the low tribal fish ingestion rate.
- 100 to 454 (1 pound per day) g/day is the moderate tribal fish ingestion rate.
- Above 454 g/day is the true tribal subsistence rate.

Non-cancer and cancer risk to tribal populations from the consumption of mercury-contaminated fish was documented and within a risk range of concern.

Issues in evaluating fish consumption rates for Native American tribes

As a continuation and further refinement of the ethnographic survey conducted for the Swinomish Indian tribal community study, *Bioaccumulative Toxics in Subsistence-Harvested Shellfish – Contaminant Results and Risk Assessment*, Donatuto and Harper (2008) provide a Swinomish seafood dietary interview template as an alternative to conventional fish dietary surveys to estimate contemporary consumption. For traditional subsistence tribal fishers, a multidisciplinary method to reconstruct tribal heritage dietary practices and patterns is recommended. Donatuto and Harper identified several problems associated with conventional fish dietary surveys that are insensitive to cultural tribal practices and may lead to tribal misunderstanding about current fish dietary level and underestimate tribal consumption.

Appendix C
The Question of Salmon

Salmon—showcase of the policy dilemma

The question of whether or how to include salmon in a fish consumption rate highlights the policy choices facing a regulatory agency. Multiple regulations—in this case MTCA and CWA—provide differing approaches to account for anadromous fish, with MTCA providing greater flexibility for site-specific modifications to regulatory standards.

Salmonids employ a complex life strategy. Most – but not all – adult salmon spend a portion of their lives outside of Washington waters. The inclusion of Pacific salmon in fish consumption rates is complicated by the question of where and to what extent salmon assume site-specific contaminants that contribute to their body burdens.

Scientific knowledge related to the biology of the life history for the multiple salmon species has increased considerably with efforts to restore salmon in Puget Sound and throughout Washington. This once abundant resource has been reduced, and wild stocks of some species are endangered. Dams are being removed to restore once great salmon runs, and culvert work by necessity now involves salmon friendly design considerations. Effects of riparian zones, temperature, even predators like seals are studied. Understanding has increased of the differing strategies of fall and spring runs from Chinook, chum, coho, sockeye, and pink salmon, and whether they migrate through estuaries or directly from streams to the ocean. The recycling of contaminants means that when uptake occurs in the open ocean those chemicals are deposited by the dying salmon in their natal streams. In the face of this growing and sophisticated body of knowledge the classification of salmon as a *marine species* lacks subtlety and leads to regulatory dilemma.

For example, Ecology's Toxics Cleanup Program will consider several factors related to risk management when deciding how to address the question of salmon. Some of these factors are discussed in this appendix:

- The abundance of salmon.
- Salmon life cycles.
- Chemical contaminants in ambient waters and sediments.
- The unique quality of Puget Sound and other Washington waters.

Considerations of the complex life cycle and survival strategies of anadromous fish species like salmonids complicate and influence many risk management decisions. For example, risk management cleanup decisions in Port Angeles Harbor and the Lower Duwamish Waterway are influenced by the presence/absences of salmonids in the harbor or waterway, migratory patterns, and contaminant body burdens attributable to site contaminants (Ecology, 2011b; Windward Environmental, 2007). The complication arises because it is difficult to attribute salmon contaminant body burdens to site-specific contaminants.

This appendix describes the life cycle and survival strategies of salmonids. This information is related to policy and technical considerations regarding how to appropriately address the question of salmon when developing fish consumption rates for regulatory purposes.

C.1 Background

Salmon is consumed in abundance. On a global scale, over the last two decades, advances in farmed-salmon production have tripled the world's supply of salmon. In 1985, 6 percent of all salmon consumed around the world was farmed. In 1988, farmed salmon production surpassed wild fisheries. In 2000, 58 percent of all salmon consumed around the world was farmed, almost a tenfold increase from 1985 levels. In the United States, between 1987 and 1999, salmon consumption increased nine times (Institute for Health and the Environment). During that time period, salmon consumption increased annually at a rate of 14 percent in the European Union and 23 percent in the United States (Hites et al., 2004).

Over half the salmon sold globally is farm-raised in Northern Europe, Chile, Canada, and the United States. The annual global production of farmed salmon (Atlantic salmon, *Salmo salar*) has increased from approximately 24,000 to over 1 million metric tons during the past two decades (Institute for Health and the Environment; Charron, 2004, as cited in Hites et al., 2004). Contaminant body burdens in farm-raised salmon have been well documented and compared to wild salmon. European farm-raised salmon have significantly greater organochlorine (dioxin, dioxin-like PCBs, and selected pesticides) contaminant body burdens than those salmon raised in North and South America (Hites et al., 2004).

C.2 Factors influencing the health risk from consuming salmon

There are multiple factors to consider when assessing the risk from consuming salmon. Most Washington salmon spend the largest part of their lives in the open ocean, where exposure to contaminants originating from Washington sources is minimal. Salmon life cycles are complex, and the many species have different survival strategies.

Ecology recognizes that salmon are an available Washington State resource for harvest and consumption. It is appropriate to consider:

- Washington State estimates of recreational and commercial salmon harvests.
- Estimates of Washington State fish-consuming populations.
- Cultural and religious significance of salmon to different Native American fish-consuming populations in Washington State.
- The complexity of the salmon life cycle and survival strategies, local and global salmon contaminant body burdens, and Puget Sound resident and nonresident salmon populations.
- Federal and state regulatory policies and procedures.

Ecology notes that similarities between bioaccumulative and persistent contaminant (organochlorines) salmon body burdens from local and global distributions would preclude the ability to define a chemical fingerprint to attribute salmon body burdens to site-specific bioaccumulative and persistent contaminants

C.3 Information about salmon consumption in Washington

To determine how to appropriately address salmon when developing one or more default fish consumption rates, Ecology examined the regional fish dietary survey information regarding salmon-related consumption. These surveys show that salmon is consumed frequently and in large amounts.

Based on Pacific Northwest regional-specific fish dietary surveys, salmon and selected types of shellfish are the most frequently consumed and consumed in the largest amounts of all seafood. Salmon is the most frequently consumed finfish (more than 90 percent) for all adult respondents from all of the regional-specific fish dietary surveys. (This observation follows the national trend where U.S. salmon consumption grew from 9.5 percent to 15 percent from 1996 to 2005 as a share [percentage] of finfish and shellfish consumption.[52])

For the API populations surveyed, 96 percent of the survey respondents consume anadromous fish comprising greater than 10 percent of all seafood consumed (Sechena et al., 2003, Tables 2 and 5). Also, 99 percent of the survey participants consume shellfish comprising more than 45 percent of all seafood consumed. The API survey participants consume a large variety of finfish and shellfish.

---

[52] Fish and Shellfish Consumption data from National Marine Fisheries Service, Salmon Consumption data from National Fisheries Institute. Web location: http://www.fas.usda.gov/ffpd/Newsroom/Salmon.pdf, as cited in USDA, 2006.

For the Tulalip Tribes and the Squaxin Island Tribe, 72 to 80 percent of anadromous fish consumed and 62 to 72 percent of shellfish consumed were harvested in the Puget Sound area (Toy et al., 1996). When fish harvests are accounted for outside of the Puget Sound area, greater than 90 percent of the seafood harvested was anadromous. Of both the Tulalip Tribes and the Squaxin Island Tribe surveyed, greater than 90 percent of the survey respondents consume anadromous fish, which comprises almost 50 percent of all seafood consumed. The Tulalip dataset was adjusted for the harvest and consumption of finfish and shellfish from Puget Sound in the EPA Region 10 framework. With the adjusted rates used in the EPA Region 10 framework, salmon and shellfish comprise about 50 percent each of the Tulalip tribal seafood diet, with salmon consumed in slightly greater amounts than shellfish. Hence, if the total fish ingestion rate did not account for salmon consumption, then the fish consumption rate would be reduced by about 50 percent, from 194 g/day to 97.6 g/day (U.S. EPA, 2007b, Appendix B-1, Table B-1).

The Suquamish fish dietary survey identified the largest variety, most frequently consumed, and consumed in the largest amounts of finfish and shellfish for all of the Pacific Northwest tribal fish-consuming populations surveyed (The Suquamish Tribe, 2000). Fifty percent or more of the respondents consumed various types of anadromous fish and about 10 different types of shellfish. The Suquamish dataset was adjusted for the harvest and consumption of finfish and shellfish from Puget Sound in the EPA Region 10 framework. With the adjusted rates used in the EPA Region 10 framework, salmon and shellfish comprise about 25 percent and 65 percent, respectively, of the Suquamish tribal seafood diet. Hence, if the total fish ingestion rate did not account for salmon consumption, then the fish consumption rate would be reduced by about 25 percent, from 766.8 g/day to about 583 g/day (U.S. EPA, 2007b, Appendix B-2, Table B-2).

The fish dietary survey for the Columbia River tribal populations identified a variety of fish harvested and consumed in large amounts (CRITFC, 1994). However, this survey did not include any questions regarding shellfish consumption. Salmon is consumed by the largest number of adult respondents (92 percent), followed by trout (70 percent), lamprey (54 percent), and smelt (52 percent). Using the weighted mean fish consumption rate for adult fish consuming CRITFC tribal populations, salmon would contribute about 50 percent of the tribal seafood diet (≈25/63 g/day). Hence, if the total fish ingestion rate did not account for salmon consumption, then the fish consumption rate would be reduced by more than about 50 percent, from a weighted mean of 63 to about 40 g/day.

C.4 Pacific salmon life cycle and survival strategies

Salmonids have complex life cycles and survival strategies, with large variations across and among different species (Quinn, 2005). The geographic distribution of Pacific salmonids extends from San Francisco Bay northward along the Canadian and Alaskan coasts to rivers draining into the Arctic Ocean, and southward down the Asian coastal areas of Russia, Japan, and Korea.[53]

Although variation exists, generally, Chinook, coho, and steelhead have migratory patterns along the Pacific continental shelf and remain in freshwater and estuarine environments for longer periods of time than other Pacific salmonid species.

After pink, chum, and sockeye salmon enter the ocean environment, they rapidly migrate northward and westward through coastal waters of North America and are found in the open waters of the North Pacific, Gulf of Alaska, and the Bering Sea by the end of their first year at sea.

Table C-1. Pacific Salmon Life Cycle

Salmonid Life Cycle Environment	← Salmon Species →						
	Chinook	Coho	Sockeye	Chum	Pink	Steelhead	Cutthroat
Riverine rearing	X	X	X			X	X
Estuarine rearing	X	X	X			X	X
Lacustrine rearing			X				X
Nearshore migration	X	X	X	X	X	X	X
Continental shelf migration	X	X				X	
Mid-oceanic migration			X	X	X		

Salmonid contaminant body burden

All seven Pacific salmon species are biotranporters of pollutants to and from the Pacific Ocean and their spawning sites in freshwater (Ewald et al., 1998). During river ascent, salmonids use their muscle lipid and triacyglycerol deposits for energy and gonadal development. Particularly in female salmonids, the organic pollutant body burden redistributes and accumulates in the lipid-rich gonads and salmon roe. Furthermore, the lipid depletions and redistribution during the river ascent are not coupled with a simultaneous elimination of the organic pollutant body burden in the salmonids.

The pollutants in the salmonids are readily available for bioaccumulation, because the migrating salmonids, salmon roe, and salmon carcasses are a direct food source for predators (birds, mammals, and other fish). Hence, salmonids redistribute their pollutant body burdens back to their spawning grounds, to the open-ocean predators, or to the food web as bioaccumulation.

The redistribution, biotransportation, and bioaccumulation of the salmonid pollutant body burden helps contribute to food web contamination.

---

[53] The definition and usage of terms *freshwater*, *estuarine*, and *marine* may vary according to context, with different writers using the terms differently. Readers should always verify how any terms are being defined.

Persistent bioaccumulative toxics

Persistent bioaccumulative toxics (PBTs) are a group of chemicals that, because of their chemical and physical properties, exist within the environment for long periods of time, are lipophilic and bioaccumulate in fish tissue and animal fat, and are highly toxic to animals and humans (Puget Sound Action Team, 2007). The unique geologic and hydrogeologic nature of Puget Sound, in combination with the bioaccumulative, persistent, and toxic nature of the PBT-type contaminants, creates additional risks to the Puget Sound ecosystem. Some of the PBTs that continue to contaminate, threaten, or harm the Puget Sound ecosystem include PCBs, PAHs, dioxins and furans; polybrominated diphenyl ethers (PBDEs), and hormone-disrupting chemicals (e.g., bisphenol A). PBTs are contaminants throughout the entire pelagic food web in Puget Sound (Puget Sound Action Team, 2007).

Of the different PBTs that permeate the Puget Sound food web, PCBs are well-documented contaminants in coho and Chinook Pacific salmon (O'Neill et al., 1998). Pacific salmon exposure to PBTs, and PCBs in particular, is in part contingent on migratory patterns, residency time in Puget Sound, proximity of the salmon to contaminated sediments and waste sites, and different behavior and dietary patterns as the fish mature (Puget Sound Action Team, 2007; O'Neill et al., 1998). PCBs were detected in composite samples of adult Chinook and coho salmon collected from various in-river and marine locations in Puget Sound. Chinook salmon PCB tissue concentrations were greater than coho salmon PCB concentrations collected from in-river and marine locations.

Table C-2. Average PCB Concentrations for Coho and Chinook Salmon from In-River and Marine Locations, Puget Sound (µg/kg)

Salmon Species	Location		Mean Concentration
	Marine	In-River	
Chinook	74.2	49.1	53.9
Coho	35.1	26.5	28.3
Mean	55.3	38.6	41.85

Source: Adapted from O'Neill et al., 1998. p. 316, Table 1.

The authors of a 1998 study investigating different factors and correlates associated with PCBs in muscle tissue of Chinook and coho salmon from marine and in-river locations in Puget Sound observed "…that Chinook salmon had significantly higher PCB concentrations than coho salmon and within each species, PCB concentrations were higher in fish caught in marine areas than in-river areas" (O'Neill et al., 1998, p. 323). Taking into account differences in their anadromous life cycles, age, and information from other studies evaluating contaminant exposures of salmon in the Puget Sound estuaries, this study suggested "…that Chinook and coho salmon accumulate most of their PCB body-burden in the marine waters of Puget Sound and the ocean, and because

Chinook salmon live longer and stay at sea longer than coho salmon they accumulate higher PCB concentrations in their muscle tissues" (O'Neill et al., 1998).[54] The authors further noted that the salmon contaminant body burden attributable to freshwater and estuarine environments was negligible compared with residency time, growth patterns, and feeding habits of the salmon at sea. A 2005 study on the behavior and ecology of Pacific salmon and trout noted that salmon have high metabolic rates, feed heavily, and grow fast in the ocean (Quinn, 2005).

Salmon can double their body length and increase their body weight tenfold during their first summer at sea. More than 98 percent of the final body weight of most salmon is attained at sea. For example, pink salmon entering the ocean may have a body weight of 0.2 gram but return from the sea weighing 2 kilograms, a ten thousand-fold increase. Further study also associates the percent contaminant body burden with fish biology (O'Neill et al., 2006). Coho and Chinook salmon populations that have more coastal migratory distributions have higher tissue concentrations of PCBs compared with those salmonids with more oceanic migratory distributions (chum, pink, and sockeye). Variations in the contaminant body burdens were noted and attributed to the marine distribution of the species (O'Neill et al., 2006, pp. 3–4):

> *…Chinook salmon returning to Puget Sound had significantly higher concentrations of PCBs and PBDEs compared to other Pacific coast salmon populations we sampled. Furthermore, Chinook salmon that resided in Puget Sound in the winter rather than migrate to the Pacific Ocean ("residents") had the highest concentrations of POPs [persistent organic pollutants], followed by Puget Sound fish populations believed to be more ocean-reared. Fall Chinook from Puget Sound have a more localized marine distribution in Puget Sound and the Georgia Basin than other populations of Chinook from the west coast of North American and are more contaminated with PCBs (2 to 6 times) and PBDEs (5 to 17 times).*

Residence time in Puget Sound

Ecology evaluated a variety of information related to the residence time of salmon in Puget Sound and different river systems of Puget Sound. Several factors have a bearing on the salmon residence time:

- Biological variability exists across and within salmon species regarding migratory habits and behavior patterns.
- The location of rivers or streams within Puget Sound. Locations deep within the sound lengthen the time the salmon reside in the sound.

---

[54] Chinook and coho salmon occupy three distinct habitat types during their life cycle: (a) Freshwater habitats (eggs hatch and fry develop); (b) Puget Sound (smolts enter marine waters to feed and reside during migration); and (c) Ocean habitat.

- Selected salmonid species do not die after spawning, and may spawn more than once, migrating to and from the same river/stream in Puget Sound.
- With considerable species variability, selected salmonid populations do not migrate to the open ocean and, instead, remain in Puget Sound.

Different residency times of salmon within Puget Sound will result in more or less exposure to chemicals that contaminate the sound and, therefore, contribute to the contaminant body burden of salmon. Some salmon (resident “blackmouth” or Chinook salmon populations) may spend significant portions of their lives in Puget Sound.

Salmon abundance

Interpreting salmon abundance records and historical records on salmon counts is complicated. Salmon are difficult to count because salmon populations are variable due to continual changes in freshwater and marine environments or to the cyclic nature of salmonid behaviors. Very long time-series records (a decade or longer) of catch or escapement are required for detecting large changes (50 percent or greater) in population abundance. Also, long-term changes in abundance may not occur as a continuous linear series of events and, therefore, are not accounted for with standard statistical evaluations. Therefore, records of abundance for short periods of time may suggest an increase or decrease in salmonid populations when, in fact, long-term trends are the reverse. The inherent biological variability of salmonids confers a level of uncertainty about the abundance counts and records associated with the different salmonid species (National Research Council, 1996, pp. 77–79).

Puget Sound salmon

The Puget Sound Basin includes the river systems in Puget Sound, Hood Canal, and the Strait of Juan de Fuca. As shown in the tables below (which provide the status of Washington and Puget Sound Salmon Stocks), there is a wide range of salmon population conditions in Puget Sound ranging from critical to healthy.[55] Generally, for Puget Sound, the Washington Department of Fisheries (now referred to as the Washington Department of Fish and Wildlife) in 1993 classified about 44 percent of the salmon stocks as healthy, about 21 percent as depressed, about 5 percent as critical, and about 30 percent unknown. Puget Sound is considered to have more depressed salmon stocks compared to the Washington coastal regions but fewer depressed stocks than the Columbia River Basin (National Research Council, 1996, pp. 86–90). Many wild salmon, steelhead, and bull trout stocks have been listed under the Endangered Species Act by the National Marine Fisheries Services or the U.S. Fish and Wildlife Service. As of 1998, less than 50 percent of Washington’s salmon stocks were considered to be healthy (Governor’s Salmon

---

[55] Stock is defined by Governor’s Salmon Recovery Office (http://www.governor.wa.gov/gsr0/glossary/default.asp) as “fish spawning in a particular lake or stream(s) at a particular season which to a substantial degree do not interbreed with any group spawning in a different place at the same time, or in the same place at a different time.” The National Research Council (1996, pp. 12–13) notes that salmon stocks refers to a geographic aggregate of salmon populations that includes many local breeding populations of varied size and productivity.

Recovery Office, 1999, pp. II.9 – II.10). The tables below summarize the status of salmon stocks for Puget Sound and Pacific Coastal areas and percentages associated with the different regional salmon stocks.

Table C-3. Status of Washington Salmon Stocks as of 1992

Status	Puget Sound		Washington Coasts		Columbia River		All Of Washington	
	Number of Stocks	%	Number of Stocks	%	Number of Stocks	%	Number of Stocks	%
Healthy	93	44.7	65	56.5	29	26.1	187	43.1
Depressed	44	21.2	8	7.0	70	63.1	122	28.1
Critical	11	5.3	0	0	1	0.9	12	2.8
Unknown	60	28.8	42	36.5	11	9.9	113	26.0
Total	**208**	**100**	**115**	**100**	**111**	**100**	**434**	**100**

Source: Adapted from National Research Council, 1996, Table 4-4. Original data source is WDF et al., 1993.

Note: Status descriptors defined by the Washington Department of Fisheries (status criteria descriptors may change depending on regulatory agency or publication); as used by National Research Council, 1996:

Healthy: Stock of fish experiencing production levels consistent with its available habitat and within the natural variations in survival for the stock.

Depressed: Stock of fish whose production is below expected levels based on available habitat and natural variations in survival rates but above the level where permanent damage to the stock is likely.

Critical: A stock of fish experiencing production levels that are so low that permanent damage to the stock is likely or has already occurred.

Unknown: There is insufficient information to rate stock status.

Table C-4. Status of Puget Sound Salmon Stock as of 1992

Status	Chinook	Chum	Coho	Pink	Sockeye	Steelhead	Total
Healthy	10	38	20	9	0	16	93
Depressed	8	1	16	2	3	14	44
Critical	4	2	1	2	1	1	11
Unknown	7	13	9	2	0	29	60

Source: Adapted from National Research Council, 1996, Table 4-3. Original data source is WDF et al., 1993.

The 1992 Salmonid Stock Inventory (SaSI) recognized 435 stocks of salmon and steelhead, one of which was extinct (WDF et al., 1993). When the 2002 data were published, WDFW made this information available online. Queries were available by Water Resource Inventory Area (WRIA), species, and stock. The 2002 update recognized an additional 54 stocks for a revised total of 489 salmon and steelhead stocks. However, the summary table for these stocks provided by WDFW on the SaSI 2002 update website only included 486 stocks. The 2002 status of these 486 Washington State stocks is provided in Table C-5.

Table C-5. 2002 By-Species Summary Update of WDFW's Salmonid Stock Inventory (SaSI) Status for Washington State Salmon and Steelhead Stock Classifications.

Status	Chinook (2002)	Chum (2002)	Coho (2002)	Pink (2002)	Sockeye (2002)	Steelhead (2002)	Total
Healthy	35	41	47	6	4	33	166
Depressed	39	9	9	4	4	58	123
Critical	14	2	2	2	0	2	22
Extinct	1	8	0	0	0	0	9
Unknown	10	23	34	1	1	97	166
Total	99	83	92	13	9	190	486

Source: http://wdfw.wa.gov/conservation/fisheries/sasi/sasi_2002_introduction.html

When the geographic scale changes from Puget Sound to broader geographic areas of Pacific salmon habitat for the Northwest, the picture of abundance changes but still reflects declining populations. There is a drop in Pacific adult salmon returning to rivers to spawn. Historically, 56 to 65 percent of the Pacific salmon returned to Alaska's streams, 19 to 26 percent returned to streams in British Columbia, and 15 to 16 percent returned to streams in Oregon, Washington, Idaho, and California. Currently in the Pacific Northwest only 1 percent of Pacific salmon are returning (Lichatowich, 1999, pp. 206–207).

WDFW hatchery release estimates to Puget Sound:

WDFW provided Ecology with hatchery releases of yearling Chinook salmon into Puget Sound from 1993 to 2005. Chinook salmon released as yearlings tend to remain in the Sound for their entire life cycle. Although the Chinook salmon release estimates may be subject to revision, the queried data by WDFW provide the most current estimates for Chinook salmon releases in the Puget Sound area and from the Dungeness and Elwha River hatcheries. Total hatchery releases of yearling Chinook salmon into Puget Sound (the Straits and North and South Puget Sound) ranged from a low of 1,835,320 in 2005 to a high of 3,367,106 in 1994 (WDFW, 2008b).

C.5 Chemical contaminants in Puget Sound

Chemical contamination of Puget Sound has occurred over a long period of time (150 years by some estimates) with various chemicals posing risks to the environment, aquatic life, and humans.

Ecology noted at the March 2008 Science Advisory Board meeting, that PBTs pose a significant threat to the Puget Sound ecosystem. This section provides information about the presence, transport, and fate of chemical contaminants in and throughout Puget Sound. These chemicals may be factors to consider when evaluating the chemical contaminant body burdens of salmon acquired on a site-specific basis.

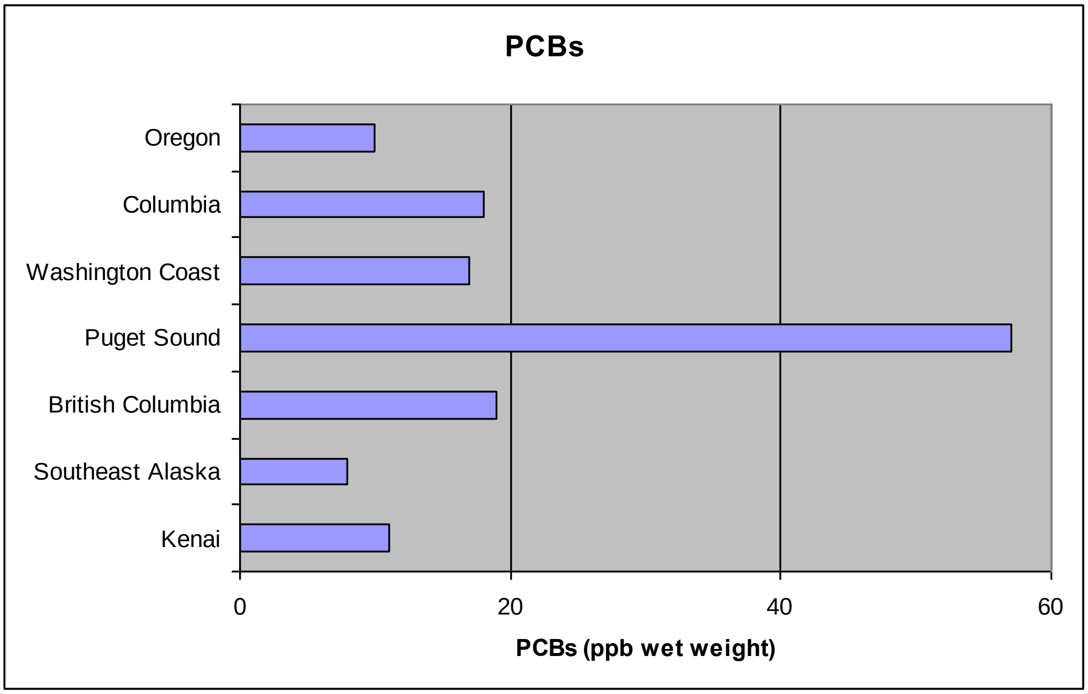
Some of the chemical contaminants of concern for Puget Sound are:

Metals (Inorganic Contaminants)	Organic Contaminants
∗ Lead	∗ Polychlorinated biphenyls (PCBs)
∗ Cadmium	∗ Polycyclic aromatic hydrocarbons (PAHs)
∗ Tributyl tins	∗ Dioxins and furans
∗ Copper	∗ Selected pesticides
∗ Mercury	∗ Phthalate esters
∗ Arsenic	∗ Polybrominated diphenyl ethers (PBDEs)
∗ Others	∗ Hormone disrupting chemicals (Bisphenol A)
	∗ Petroleum and petroleum by-products
	∗ Pharmaceuticals

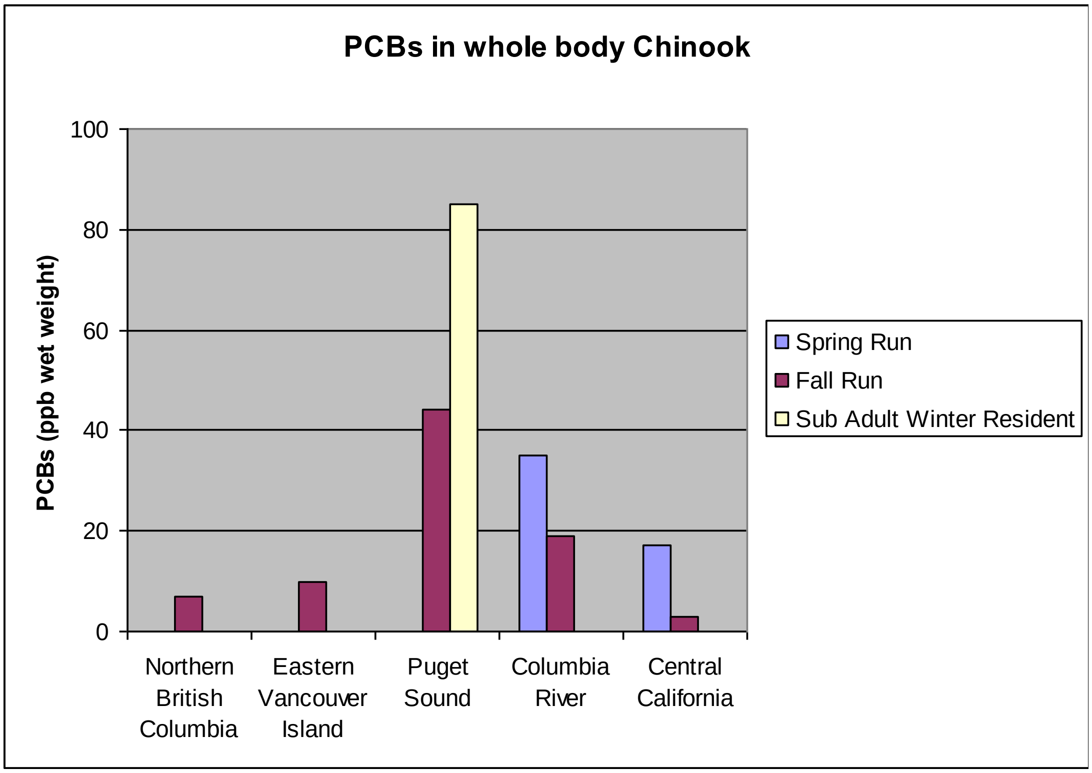
Sources: Puget Sound Action Team, 2007, Table 4-1; West et al., 2011a, 2011b.

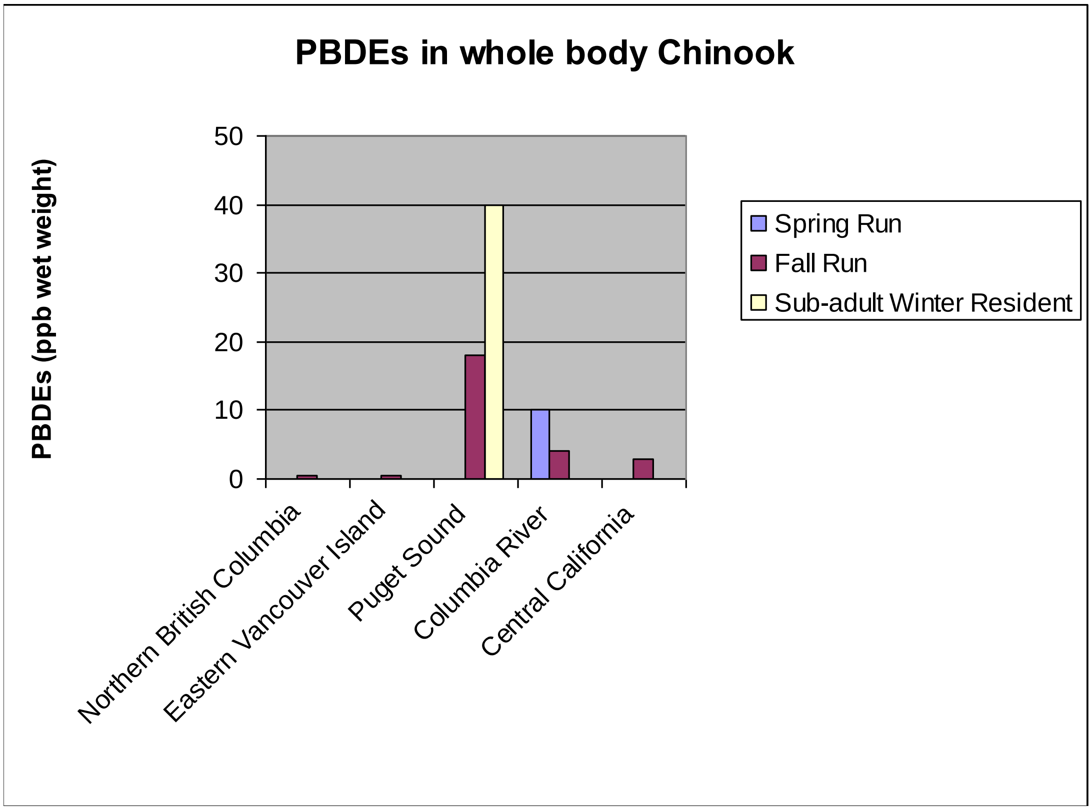
Polychlorinated biphenyls

PCBs are persistent, bioaccumulative, and toxic chemicals found throughout Puget Sound. The bar chart below compares PCBs sampled in Chinook salmon fillets from Puget Sound and Chinook salmon fillets sampled for PCBs from other Pacific west coast areas. Puget Sound Chinook salmon fillets are almost three times more contaminated than fillets of Chinook salmon from other Pacific west coast areas (Puget Sound Action Team, 2007, adapted from Figure 4-18, p. 156).



The bar charts below illustrate differences in contaminant body burdens for salmon from Pacific West Coastal areas. The bar charts illustrate that Puget Sound resident Chinook salmon had the highest contaminant body burden of PCBs and PBDEs compared to other Pacific west coast areas. PCBs and PBDEs in whole body samples of individual summer/fall Chinook salmon from Puget Sound were 2 to 6 times more contaminated with PCBs and 5 to 17 times more contaminated with PBDEs than other populations of Chinook salmon from the Pacific west coast areas (Puget Sound Action Team, 2007, p. 157, Figure 4-19; O’Neill et al., 2006).





C.6 Chemical contaminant transport in and around Puget Sound

Puget Sound has unique geologic qualities among North American estuaries. These unique features confer a greater residence time for contaminants and trap them within the Sound, thereby increasing the potential for exposure.

The transport and fate of site-specific contaminants

Site-specific chemical contaminants in sediments may be relocated throughout Puget Sound by mechanical or biological transport mechanisms. Based on their life cycle, salmon play a unique role in the biological transport of contaminants in and through Puget Sound and contribute to the chemical contamination of the food web.

Hydrodynamic conditions of Puget Sound

Puget Sound is unique among North American estuaries. Shallow sills at the northern and southern ends of central Puget Sound, where water is rapidly transported across the sills by tidal currents, influence circulation patterns. “The sills alter the normal pattern of estuarine circulation by causing mixing and by restricting the exchange of water with adjacent basins” (Ecology, 2007b).

Contaminant residence times

The residence times for contaminants in Puget Sound are extended because the circulation conditions of the Sound, including the shallow sills associated with different inlets, freshwater/marine water gradients, and highly variable flow velocities in different areas of the Sound, all facilitate the trapping and mixing of toxic chemical contaminants. Chemical contaminants spend longer in the Sound increasing exposures to aquatic organisms, humans, and the environment.

Mechanical transport

Plastic debris may be transporting hydrophobic contaminants to sediments and sediment-dwelling (benthic infaunal communities) organisms (Teuten et al., 2007). Representative plastics (polyethylene, polypropylene, and polyvinyl chloride) were used to evaluate the preferential sorption of PAHs in plastics compared to sediments in marine environments. The addition of small amounts of PAH-contaminated plastics to sediments significantly increased the bioaccumulation of PAHs (phenanthrene) in sediment dwelling organisms. In addition, sorption of hydrophobic chemicals to plastics facilitates the transport of the contaminants to other areas in marine environments and to marine aquatic life.

Contaminant dispersal, re-suspension, and transport

Chemical contaminants can be transported and dispersed throughout Puget Sound by a variety of processes. Chemical contaminants within different estuaries and marine water bodies can be transported and dispersed through different watersheds, bay and harbor areas, and inlets. The implications for the transport and dispersion of chemical contaminants throughout these water bodies is an increased potential for exposure to these contaminants by aquatic life and humans, regardless of where the contaminants originated from.

Dispersal

Sediment reservoirs of historically discharged contaminants (metals, PAHs, PCBs, selected pesticides) may be disturbed and distributed by bioadvection, biodiffusion, and physical processes. The sediment-bound contaminants may be moved from the subsurface to upper sediments where the contaminants may undergo further resuspension and redistribution. Benthic infaunal communities (annelids, mollusks, crustaceans), storm events, and tidal influences contribute to the redistribution and dispersion of contaminated sediments (Niedoroda et al., 1996; Stull et al., 1996; Swift et al., 1996).

Resuspension and transport

Historically deposited chemical contaminants buried in sediments may be resuspended in the water column and then transported and redeposited into coastal areas distant from the bay areas where the contaminants originated. Hydrodynamic processes include diffusion, tidal dispersion and transport of chemicals, sediment-water interactions, and adsorption-desorption of chemicals to and from suspended particulate matter. Models evaluate the transport and fate of chemical contaminants from tidal estuaries and bay areas to other proximate marine environments. Empirical data support modeled outputs related to the remobilization of sediment contaminants, resuspension of the contaminants into the water column, and the subsequent redeposition of the contaminants to distant areas (Zeng and Venkatesan, 1999; Zeng et al., 2005).

Biological transport

All seven Pacific salmon species are biotranporters of pollutants to and from the Pacific Ocean and their spawning sites in freshwater (Ewald, 1998). During river ascent, salmonids use their muscle lipid and triacyglycerol deposits for energy and gonadal development. Particularly in female salmonids, the organic pollutant body burden redistributes and accumulates in the lipid rich gonads and salmon roe. Furthermore, the lipid depletions and redistribution during the river ascent are not coupled with a simultaneous elimination of the organic pollutant body burden in the salmonids. The pollutants in the salmonids are readily available for bioaccumulation because the migrating salmonids, the salmon roe, and salmon carcasses are a direct food source for predators (birds, mammals, and other fish). Hence, salmonids redistribute their pollutant body burdens back to their spawning grounds, to the open-ocean predators, or bioaccumulate in the food web. The redistribution, biotransportation, and bioaccumulation of the salmonid pollutant body burden contribute to food web contamination.

Chemical contaminants are exhibited through the salmon life cycle, which contributes to the transport and distribution of contaminants in Puget Sound:

- Depletion of lipid reserves during upstream migration can cause significant biomagnifications of contaminant body burdens in eggs and gonadal tissues (Kelly et al., 2007).
- Post spawning decay of Chinook salmon carcasses are sources of persistent organic pollutants (POPs), such as PCBs, and dichlorodiphenyltrichloroethanes (DDTs), where body burden contaminants are released into river sediments and, furthermore, are released into the water column of tributary streams (O’Toole et al., 2006).
- Areas in the Pacific Northwest where Chinook salmon are harvested may account for the variations in their PCB body burden concentrations. Although some contamination of the Chinook salmon occurs in the Pacific Ocean, a larger source of the salmon body burden occurs within Puget Sound or along the migratory route within Puget Sound for Chinook salmon (Missildine et al., 2005).
- Chemical contaminants (selected pesticides and POPs) have been documented in outmigrant juvenile Chinook salmon (Johnson et al., 2007).

Life histories and biological variability in life histories of Pacific coast salmonids

The following tables present detailed information on the life histories and biological variability of Pacific coast salmonids.

Additional information on biological transport of contaminants is provided in the following publications:

Table C-6. Life Histories of Pacific Coast Salmonids

Species	Spawning Migration	Spawning Period	Spawning Area	Life History	Most Common Age at Maturity (Years)
Anadromous Salmon					
Chum salmon	Summer to Winter	Summer to Winter	Usually near tidewater	Fry go directly to sea; 2–5 years ocean	4
Pink salmon	Late summer to early Fall	Late summer to early Fall	Usually near tidewater	Fry go directly to sea; 2 years ocean	2
Sockeye salmon	Spring to fall	Late summer to fall	Tributaries of lakes	1–3 years lake 2–3 years ocean	4–5
Coho salmon	Summer to fall	Fall to early winter	Small headwater streams	1–3 years freshwater 6 months Jack ocean 18 month adult ocean	3
Chinook salmon	Spring to fall	Summer to early winter	Large rivers	3 months to 2 years freshwater 2–5 years ocean	4–5
Anadromous Trout and Char					
Steelhead trout	Summer to winter	Late winter to spring	Small headwater streams	2–3 years freshwater 1–3 years ocean *Repeat spawners*	4–5
Searun cutthroat trout	Fall to winter	Late winter to early spring	Small headwater streams	2–4 years freshwater 2–5 months ocean *Repeat spawners*	3–4
Dolly Varden [a]	Late summer to fall	Fall	Main channels on rivers	2–4 years freshwater 2–4 years ocean *Repeat spawners*	Mature 5–6 Die 6–7
Resident Species					
Kokanee salmon	Late summer to fall	Late summer to fall	Tributaries of lakes, lakeshores	Juveniles migrate to lakes to reside	3–4
Rainbow trout	Spring	Spring	Small headwater streams	Variable residence in natal, streams, rivers, & lakes	2–3
Cutthroat trout	Spring	Spring to early summer	Small headwater streams	Variable residence in natal, streams, rivers, & lakes	3–4
Bull trout [a]	Fall	Fall	Large streams with groundwater infiltration	Juveniles migrate from tributaries to lakes or large streams at about 2 years, highly variable	4–9
Mountain white fish	Fall	Fall	Mid-sized streams, lakes	Reside in streams and lakes	3–4

Source: Spence et al., 1996.

a. On occasion WDFW lumps bull trout and Dolly Varden together because both are listed under the Endangered Species Act and it is hard to differentiate the two species in the field; genetic studies have found bull trout throughout Puget Sound and the Strait (Duncan, 2008, personal communication).

Table C-13. Salmonid Stock Inventory for The Port Angeles Harbor and Adjacent Areas

Anadromous Fish		Total Escapement Estimates		WDFW Designated Status		Comments
Species	Stock	From Year: Est. #	To Year: Est. #	1992	2002	
Coho	Dungeness Coho	1992: Depressed	2002: Unknown	Unknown	Unknown	No abundance trend data available; Limited recent-year estimates of smolt production suggest significant natural production Dungeness R. watershed.
	Morse Creek Coho	1998: 488 adults and 511 smolts	2002: 676 adults and 2, 966 smolts	Depressed	Depressed	Spawning distribution: McDonald, Siebert, Morse, Ennis, Valley and Tumwater Creeks; Depressed because of chronically low “redd” counts; mixture of wild and farm-raised stock.
	Elwha Coho	Unknown	Unknown	Healthy	Unknown	No abundance trend data available; Healthy rating based on escapement estimates from Strait of Juan de Fuca tributaries.
Pink	Lower Dungeness Pink	1985: 966	2001: 11,072; 2003: 3,540	Critical	Critical	Estimates based on counts from mainstem of Dungeness R., Gold Creek, and Gray Wolf River; Critical designation due to chronically low escapements.
	Upper Dungeness Pink	1985: 3,764 1989: 10,579	2001: 69,272 2003: 11,576	Depressed	Depressed	Prior to 1981 escapements usually in excess of 20,000; stock status depressed because of chronically low escapements.
	Elwha Pink	1985: 30 1991: 0	2001: 605 2003: 32	Critical	Critical	In early 1970s instantaneous counts over a thousand pinks were made; since 1981 not more than 30 pinks have been seen on any one day; stock status depressed because of chronically low escapements.

Table C-14. Salmonid Stock Inventory for the Port Angeles Harbor and Adjacent Areas

Anadromous Fish		Total Escapement Estimates		WDFW Designated Status		Comments
Species	Stock	From Year: Est. #	To Year: Est. #	1992	2002	
Steelhead	Dungeness Summer Steelhead	Unknown	Unknown	Depressed	Unknown	No abundance trend data available. Due to fisheries closures and low harvest numbers sport harvest is no longer adequate to assess stock status.
	Dungeness Winter Steelhead	1988: 438 1993: 338	2000: 165 2001 183	Depressed	Depressed	Depressed status because of long term negative trends.
	Morse Creek Winter Steelhead	1986: 105 1988: 138	1997: 183 2003: 84	Depressed	Depressed	Escapement estimates based on redd counts; depressed due to chronically low escapements.
	Elwha Summer Steelhead	Depressed	Unknown	Depressed	Unknown	No abundance trend data available.
	Elwha Winter Steelhead	1986: 834 1989: 416	1992: 560 1997: 153	Depressed	Unknown	Access to historic spawning areas blocked by Elwha Dam; Average of 50 redds/year; Lack of systematic abundance trend data.

Appendix D
Glossary

Anadromous fish: fish that hatch in freshwater, spend a portion of their life maturing in saltwater, then return to freshwater habitats to spawn.

Angler: one who fishes with hook and line, sometimes used to denote “fishers.”

Aquatic: from or living in a water body, including both marine and freshwater.

Bottomfish: fish that include Pacific cod, Pacific tomcod, Pacific hake, walleye Pollock, all species of dabs, sole and founders (except Pacific halibut), lingcod and all other species of greenling, ratfish, sablefish, cabezon, buffalo sculpin, great sculpin, red Irish lord, brown Irish lord, Pacific staghorn sculpin, wolf-eel, giant wry mouth, plainfin midshipman, spiny dogfish, six gill shark, soupfin shark and all other species of shark, and all species of skate, rockfish, rattails and surfperches except shiner perch.

Coastal waters: a term that refers to waters having a coastline that forms the boundary between land and freshwaters and marine and/or estuarine waters. This term encompasses all freshwaters of statewide significance (lakes, rivers, streams, etc.) and those marine and/or estuarine waters extending from the landward edge of a barrier beach or shoreline of coastal bay to the outer extent of the Continental Shelf.

Commercial fishers: those individuals who harvest finfish and/or shellfish by any method from Washington State waters (marine, estuarine, and freshwaters) for economic gain as a livelihood.

Creel survey: on-site interview with fishers to obtain information such as species caught; number, length, and weight of catch; location; etc.; typically for use by fisheries managers; may or may not include information on consumption.

Demersal fish: fish that dwell at or near the bottom of a body of water.

Estuarine: from an estuary, i.e., a partly enclosed water body, such as an inlet of the ocean or the mouth of a river where it meets the ocean that contains brackish water (a mixture of salty and freshwater) such as Elliott Bay in Seattle, Washington.

Finfish: fish; a term that is usually applied to the consumption of true fish as opposed to shellfish.

Fish: any of various aquatic animals (belonging to the subphylum Vertebrata) having gills, commonly fins, and bodies usually but not always covered by scales, including those having bony skeletons (bony fishes) and more primitive forms with cartilaginous skeletons (lampreys; hagfishes; and sharks, skates, and rays).

Fish consumers: those individuals who consume finfish and/or shellfish; synonymous with Washington State fish-consuming populations.

Fisher: one who fishes for any type of seafood by any method, inclusive of hook and line and other methods of catching seafood.

Freshwater: water bodies including lakes, ponds, rivers, and streams that contain water with relatively low salinity, i.e., less that 0.5 parts per trillion; species inhabiting freshwater bodies.

Game fish: sport fish that are caught for food.

Indian (Native American) Reservation: land set aside by the federal government for the use, possession, and benefit of a Native American tribe or group of Indians; created by some formal legal directive such as a treaty, statute passed by Congress or an executive Presidential order.

Marine: from, or living in, the ocean; saltwater, with a salinity of approximately 35 parts per trillion.

Native American: a member of the indigenous peoples of the Western Hemisphere. In this technical support document the term “Indian” is used only with reference to the name of a specific Native American tribe.

Noncommercial fisher: one who fishes for recreation and/or home consumption; synonymous with recreational fisher, sport fisher.

Pelagic fish: fish that live near the surface or in the water column of coastal, oceanic, and lake waters.

Reasonable maximum exposure (RME):

The **MTCA definition** of RME (WAC 173-340-200) is as follows:

> *Reasonable maximum exposure means the highest exposure that can be reasonably expected to occur for a human or other living organisms at a site under current and potential future site use.*

The **EPA definition** of RME is as follows:

> *Actions at Superfund sites should be based on an estimate of the* ***reasonable maximum exposure (RME)*** *expected to occur under both* ***current*** *and* ***future*** *land-use conditions. The reasonable maximum exposure is defined here as the highest exposure that is reasonably expected to occur at a site. RMEs are estimated for individual pathways* (U.S. EPA, 1989b, page 6-4 to 6-5).

The worst-case exposure represents an extreme set of exposure conditions, usually not observed in an actual population, which is the maximum possible exposure where everything that can plausibly happen to maximize exposure happens (U.S. EPA Guidelines for Exposure Assessment, Federal Register Notice, Vol. 57, No. 104, May 1992, pages 22888-22938).

The preamble to the **National Contingency Plan** further indicates that the RME will:

> *…result in an overall exposure estimate that is conservative but within a realistic range of exposure. Under this policy, EPA defines "reasonable maximum" such that only potential exposures that are likely to occur will be included in the assessment of exposures. The Superfund program has always designed its remedies to be protective of all individuals and environmental receptors that may be exposed at a site; consequently, EPA believes it is important to include all reasonably expected exposures in its risk assessments…*

Recall bias: Dietary recall surveys may cover specific periods of time or seasons; short term recall surveys may cover a 24-hour food recall to obtain information on the diet of an individual in the prior 24 hours. Dietary surveys that rely on an individual's recall of their diet may undergo some recall errors that introduce an element of bias in the dietary estimates. These recall errors may result in either overestimation or underestimation of fish consumption. Factors that contribute to recall error and bias include how commonly or frequently the food (fish) is consumed, time frames covered by the survey that contribute to seasonal variation in food consumption, survey methods used including provisions to enhance dietary memory or recall (food models), and the desirability or cultural influences on the food consumed. Generally, recall error increases as the length of the recall period increases, with recall periods of 1 year likely to result in the least reliable estimates of consumption. The optimal recall period will be long enough to accurately portray typical dietary (fish consumption) habits and patterns without impairing the ability of respondents to recall their dietary (fish) consumption (Chu et al., 1992).

Recreational fisher: one who fishes primarily for recreational purposes; recreational catch is used primarily for home consumption; synonymous with noncommercial fisher, sport fisher.

Seafood: aquatic organisms that are consumed, including mainly finfish and shellfish, and less frequently, other invertebrate animals or plants or marine mammals.

Shellfish: aquatic invertebrate animals having a shell or exoskeleton, the term usually used in the context of food, including species belonging to the following taxa (some of which have evolved such that the shell has become internal and/or reduced, or has disappeared entirely): (1) mollusks, including bivalves (e.g., clams, oysters, mussels, scallops), gastropods (e.g., snails, limpets, abalone), and cephalopods (e.g., squid, octopods); (2) crustaceans (e.g., crabs, shrimps, lobsters); and (3) echinoderms (e.g., sea urchins, sea cucumbers).

Sport fish: fish that are caught by a sport fisher as opposed to purchased or caught commercially, synonymous with sport-caught, recreationally caught, and noncommercial fish.

Sport fishers: those individuals who harvest finfish and/or shellfish by any method from Washington State waters (marine, estuarine, and freshwaters) for recreation; synonymous with recreational fisher or noncommercial fisher.

Subsistence: Although no single universally accepted definition is available to define what is meant by subsistence or subsistence-based populations, several definitions of subsistence fishers may apply to Washington State ethnic groups and/or fish-consuming populations. It is difficult to define and to quantify subsistence fishers. Definitions and perceptions of what constitute subsistence fishers and fishing may vary among regions and cultures. The 1994 Presidential Executive Order 12898, Section 4-4. Subsistence Consumption of Fish and Wildlife noted differential patterns of subsistence consumption of fish and wildlife for populations who principally rely on fish and/or wildlife for subsistence.[56] Differential patterns of subsistence consumption of fish and wildlife relates to subsistence and differential patterns of subsistence, and means differences in rates and/or patterns of fish, water, vegetation and/or wildlife consumption among minority populations, low-income populations, or Native American tribes, as compared to the general populations. As a response to Executive Order 12898, the 1999 National Academy of Sciences publication noted the following (Institute of Medicine, 1999, p. 17):

> *… differences in behavior, employment, and lifestyles among subgroups in the population may result in differences in exposure. For example, among the Alutiiq, Yup'ik, and Inupiat Alaskan Native peoples, the yearly intake of wild foods per person is between 171 and 272 kilograms (375 and 600 pounds). Increasing evidence of certain contaminants such as mercury in the wild food supply of these Alaskan Natives has been exhibited by methyl mercury levels that exceed those provisionally established as safe by the World Health Organization.*

---

[56] Presidential Executive Order 12898: Federal Actions To Address Environmental Justice In Minority Populations and Low-Income Populations. Signed by President William J. Clinton, February 11, 1994 web location: http://www.epa.gov/region2/ej/exec_order_12898.pdf

Tribal subsistence exposure scenario and fishers: “Subsistence” refers to the hunting, fishing, and gathering activities that are fundamental to the way of life of many indigenous peoples (Confederated Tribes of the Umatilla Indian Reservation, 2004, p. 4). Subsistence utilizes traditional, small-scale technologies for harvesting and preserving foods as well as for distributing the produce through communal networks of sharing and bartering. Because it often misinterpreted, an explanation of “subsistence” is taken from the National Park Service (Confederated Tribes of the Umatilla Indian Reservation, 2004):

> *While non-natives tend to define subsistence in terms of poverty or the minimum amount of food necessary to support life, native people equate subsistence with their culture. Among many tribes, maintaining a subsistence lifestyle has become the symbol of their survival in the face of mounting political and economic pressures. It defines who they are as a people. To Native Americans who continue to depend on natural resources, subsistence is more than eking out a living. While it is important to the economic well-being of their communities, the subsistence lifestyle is also the basis of cultural existence and survival. It is a communal activity. It unifies communities as cohesive functional units through collective production and distribution of the harvest. Some groups have formalized patterns of sharing, while others do so in more informal ways. Entire families participate, including elders, who assist with less physically demanding tasks. Parents teach the young to hunt, fish, and farm. Food and goods are also distributed through native cultural institutions. Most require young hunters to distribute their first catch throughout the community. Subsistence embodies cultural values that recognize both the social obligation to share as well as the special spiritual relationship to the land and resources. This relationship is portrayed in native art and in many ceremonies held throughout the year.*[57]

The average subsistence adult fish consumption rate is 620 g/day (500 pounds/year) for the Confederated Tribes of the Umatilla Indian Reservation.[58]

Usual and Accustomed Fishing Areas: also referred to as U & A areas or U & A fishing areas. The term refers to the 1854 and 1855 negotiated treaties with the Pacific Northwest Native Americans in Washington state: “The right of taking fish at usual and accustomed grounds and stations is further secured to said Indian in common with all citizens of the Territory…”

Abstract

Stormwater and storm sediment discharge data were collected by NPDES Phase I Municipal Stormwater permittees, under Special Condition S8.D, between 2007 and 2013. This report is a summary of the data results. The Phase 1 permittees, all located in western Washington, collected highly representative storm-event data under a prescribed monitoring program that represented multiple land uses, storm characteristics, and seasons. The main goals of this study were to (1) compile and summarize the permittees' data using appropriate statistical techniques and (2) provide a western Washington regional baseline characterization of stormwater quality.

These findings are based on the analysis of 44,800 data records representing 597 storm events. Up to 85 parameters were analyzed in stormwater samples, and 67 parameters were analyzed in stormwater sediments. Metals, hydrocarbons, phthalates, total nitrogen and phosphorus, pentachlorophenol, and PCBs were detected more frequently and at higher concentrations from commercial and industrial areas than from residential areas. Residential areas exported stormwater with the highest dissolved nutrient concentrations.

For context, data were compared to previous stormwater studies and the Washington State water quality criteria. Stormwater pollutant concentrations were lower than those reported by EPA in the mid-1980s, but higher than stream and river concentrations draining to Puget Sound during storms. Across all land uses, copper, zinc, and lead were found more often than not to exceed (not meet) water quality criteria. Mercury and total PCBs exceeded criteria in 17% and 41% of the samples, respectively. For most parameters measured in both stormwater and stormwater sediments, concentrations in stormwater sediments paralleled the trends found in water samples across all four land uses.

The statistical analyses used in this study have produced reliable statistical summaries and allowed for robust comparisons of the impacts of land use and seasons on contaminant concentrations and mass loads. The statistical summaries form a baseline for contaminant concentrations in stormwater that will allow for future comparisons.

Executive Summary

Introduction

In 1995, when the Washington State Department of Ecology (Ecology) issued its first National Pollutant Discharge Elimination System (NPDES) Municipal Stormwater Permit, limited national stormwater data were available. The permit relied on data from the mid-1980s and a few local Superfund sites to provide a reasonable picture of pollutant types and ranges of concentrations in stormwater runoff. In developing the Phase I Municipal Stormwater Permit conditions, Ecology intended to help fill this data gap.

The 2007-2012 Phase I Municipal Stormwater Permit (permit) included stormwater discharge monitoring requirements in Section D of Special Condition 8 (S8.D) to gain local stormwater quality data. These monitoring requirements enabled uniform data collection and similar laboratory methods to represent runoff from local land uses. The Phase I permittees were four counties (Clark, King, Pierce, and Snohomish), two cities (Seattle and Tacoma), and two ports (Seattle and Tacoma). The monitored sample locations and land uses are detailed in Figure ES-1. Phase I permittees spent a tremendous amount of time and effort to collect the data compiled for this report. Some permittees continue to conduct outfall monitoring at some of the same sites under the current 2013-2018 permit, but this report only evaluates data collected under the 2007 permit.

The extensive multi-year effort to characterize sources and reduce toxics from riverine inputs to Puget Sound (*Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates*; herein called *PS Toxics Study*) took place concurrently with the permittees monitoring of outfalls. Results of the *PS Toxic Study* identified stormwater discharge data as a data gap (Herrera, 2011), while S8.D monitoring by permittees was underway. The *PS Toxics Study* reported that concentrations and loadings of toxic pollutants in monitored rivers and streams were higher during storm events than during baseflow, for all land uses.

Purpose

The primary purpose of this report is to summarize the S8.D stormwater discharge characterization monitoring data collected by the Phase I permittees under the 2007 permit.

What were the goals?

The primary goal for monitoring under the permit was to gather data directly from stormwater discharges and establish a regional (western Washington) baseline of data representing municipal stormwater quality. Such data were to be representative of stormwater discharge quality over the course of individual storm events.

The secondary goal in data analysis was to explore variability in stormwater concentrations across different land uses and seasons and to identify chemicals of interest in stormwater.

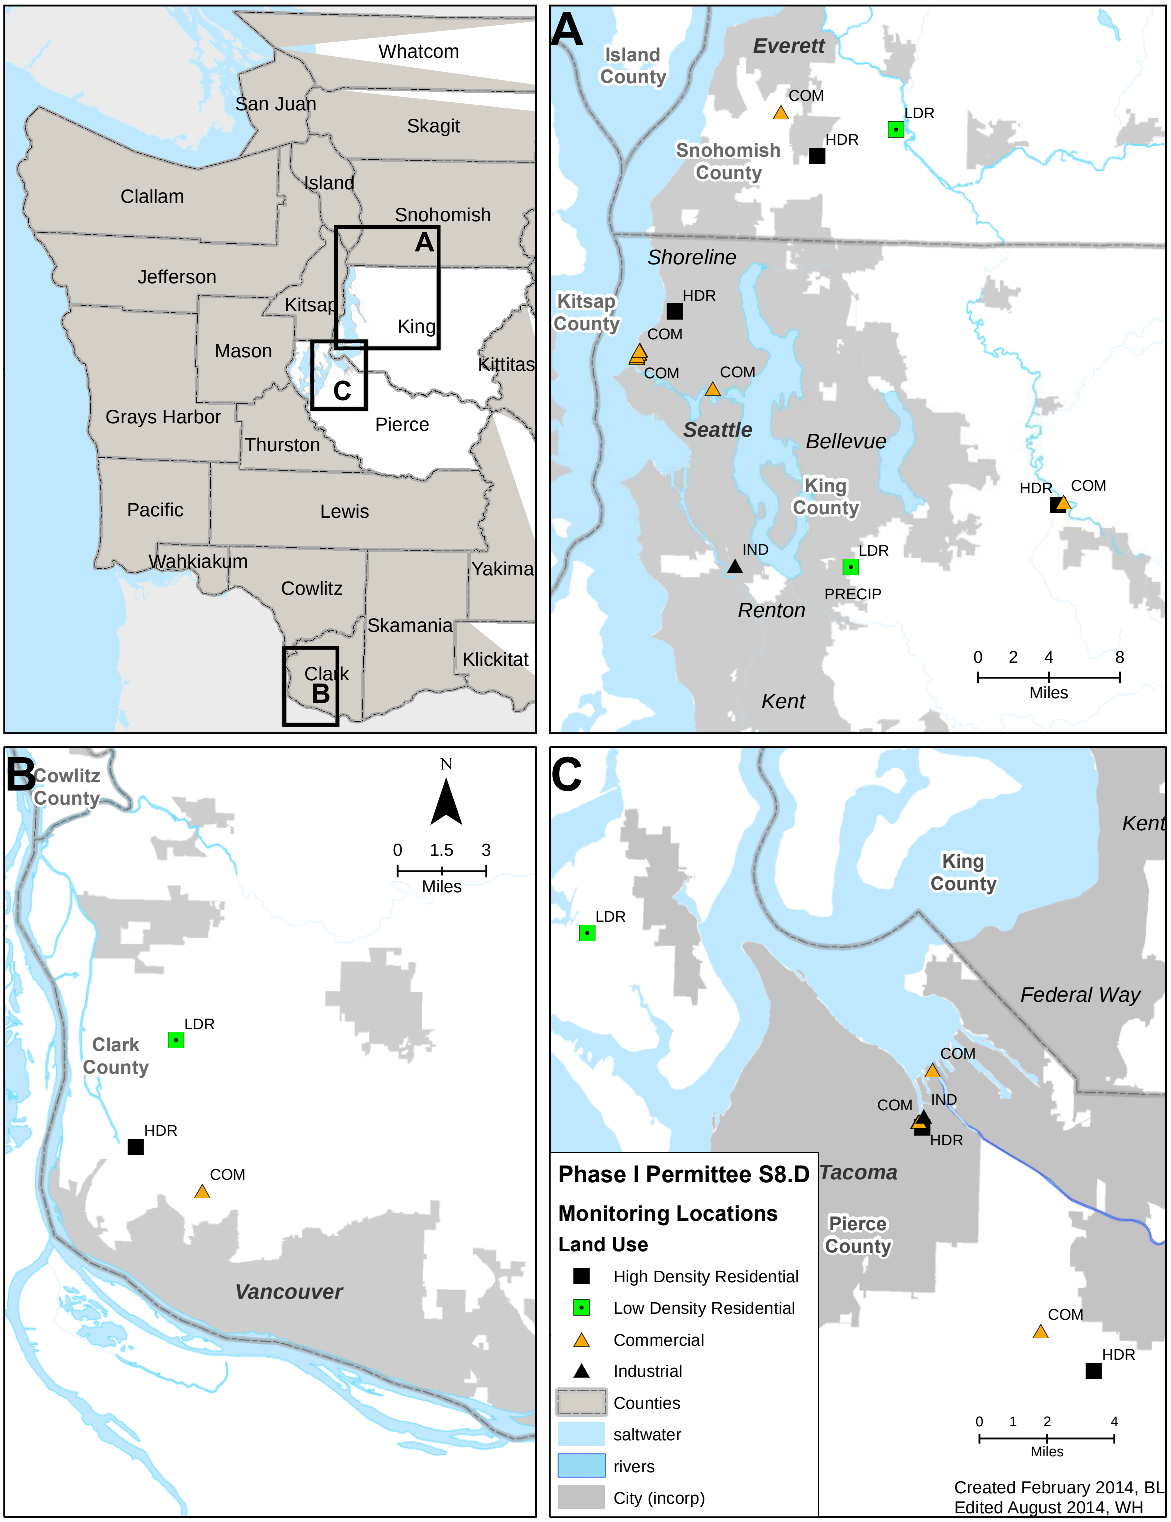

Figure ES-1. Site locations of monitored stormwater catchments and corresponding land use.

Land use types: LDR = low-density residential; HDR = high-density residential; COM = commercial; IND = industrial

What was achieved?

This report provides statistical summaries for municipal storm-event concentrations for 172 parameters across four land uses and wet and dry seasons in western Washington. Ecology recognizes the substantial contribution made by the permittees to our collective understanding of stormwater chemistry in western Washington.

Methods

For this final report, Ecology downloaded, compiled, and analyzed the complete permit monitoring data from Ecology's Environmental Information Management (EIM) database. Stormwater was monitored from 2009 through 2013, and samples were collected using flow-weighted automatic composite samplers for most parameters. Each location has at least three years of data.

Composite sample volumes were in compliance with the required collection approach of a storm's hydrograph under the permit. Samples generally spanned 75% or more of the first 24 hours of each storm. Permittees submitted rainfall amount, runoff volume, and concentration data for stormwater samples to Ecology's EIM database. Concentration data for stormwater-related sediments are also available in EIM; however, these data were collected less uniformly, using either grab samples or traps in the storm pipe system.

Results

The final data set encompassed 44,800 records submitted to Ecology by Phase 1 permittees, representing an estimated 597 storm events. Up to 85 chemicals were analyzed for any given stormwater sample, and 67 chemicals were analyzed in stormwater sediment samples. The composite stormwater samples were found to be representative of storm length, storm volumes, and frequency of storm events in western Washington. The database is suitable for characterizing stormwater quality in western Washington.

Detection Frequency

The rate of detection varied across land use and by parameter. Overall, metals, nutrients, and conventional parameters were detected in nearly all stormwater and stormwater sediment samples. The following parameters were frequently detected in stormwater:

- Conventional parameters (biochemical oxygen demand, pH, conductivity, chloride, turbidity, total suspended solids) had a 98% detection rate. Surfactants were detected in 60% of the samples.
- Metals except mercury were commonly detected; arsenic, copper, lead, magnesium, and zinc were found in 90% of the samples. Cadmium was detected in just over 60% of the samples.
- Nutrients (nitrogen and phosphorus) were detected in 90% of the samples.
- Polycyclic aromatic hydrocarbon (PAHs) were detected in 73% of the samples.
- Total petroleum hydrocarbons (diesel range fractions) were detected in 73% of the samples.
- bis(2-ethylhexyl)phthalate was found in 62% of the samples.

The detection rate of organic compounds (such as total petroleum hydrocarbons – diesel fractions, PAHs, and phthalates) and certain metals (copper, lead, and zinc) in stormwater sediments was more than 90%. Diesel, motor oil, copper, and zinc were found in all stormwater sediment samples collected.

Chemicals are considered *non-detect* if the concentration was not measured above the method detection limit. The following parameters were either infrequently detected or not detected at all:

- Benzene, toluene, ethylbenzene, and xylenes (BTEX) in stormwater were found in less than 3% of the samples.
- Malathion, prometon, chlorpyrifos, and diazinon in stormwater and stormwater sediments were found in less than 4% of the samples.
- Triclopyr and mecoprop was detected at a rate of 8% in stormwater sediments and approximately 11% in stormwater samples.
- Most phenolics in stormwater sediments were not detected at all, except for pentachlorophenol, o-cresol, and p-cresol (detection rates of 25, 19, and 77% respectively).

Land Use

Metals, hydrocarbons, phthalates, total nitrogen and phosphorus, pentachlorophenol, and PCBs were detected more frequently and at higher concentrations from commercial and industrial lands than from residential lands. Residential lands exported stormwater with the highest dissolved nutrient concentrations.

All parameters with high rates of detection exhibited statistically different concentrations across land uses. Individual parameters showed strong differences among land uses. However, when parameters were grouped or summed (e.g., sum of PAHs), greater overlap in stormwater chemistry among land uses was found.

Chemicals of Interest and Importance

To put the results of this compilation effort into context, Ecology compared these results using two primary sources of information. The first source was a suite of literature including the Nationwide Urban Runoff Program (NURP; EPA, 1983) and analysis of the National Stormwater Quality Database (Maestre et al., 2005). These are discussed in the next section. The second primary source was the Washington State Water Quality Criteria. The national studies and Washington's water quality criteria form the "bookends" for comparing the stormwater discharge results of this compilation. The intent of this report is to characterize data, not to evaluate compliance. The comparison to criteria presents an understanding of parameters and land uses where stormwater improvements and resources can be focused to improve water and sediment quality.

Across all four land uses, copper, zinc, and lead were−more often than not−found to exceed (not meet) water quality criteria (Table ES-1). Dissolved zinc and copper in stormwater samples exceeded acute aquatic life criteria in 36% and 50% of the samples, respectively, over the three years of data. Mercury and total PCBs exceeded chronic aquatic life criteria in 17% and 41% of the samples, respectively. Commercial and industrial lands contributed higher concentrations of these compounds.

Table ES-1. Parameters ranked in order of percent of samples exceeding the aquatic life water quality criteria.

Acute aquatic life criteria			Chronic aquatic life criteria		
Parameter	Exceeds (%)	Samples (total)	Parameter	Exceeds (%)	Samples (total)
Dissolved Copper	50.30	600	Dissolved Copper	57.80	600
Dissolved Zinc	36.00	606	Total PCBs	40.70	27
Dissolved Lead	0.30	627	Dissolved Zinc	39.90	606
Dissolved Cadmium	0.30	635	Dissolved Lead	27.60	627
Diazinon	0.30	644	Total Mercury	17.40	455
Chloride	0.20	551	Chloride	0.70	551
Total PCBs	0.00	27	Dissolved Cadmium	0.50	635
Pentachlorophenol	0.00	473	Diazinon	0.30	644
Chlorpyrifos	0.00	644	Pentachlorophenol	0.00	473
Dissolved Arsenic	0.00	16	Chlorpyrifos	0.00	644
Dissolved Mercury	0.00	444	Dissolved Arsenic	0.00	16

PAHs, a significant component of the stormwater pollutants, do not have promulgated numeric criteria in water for the protection of aquatic life.

For most parameters measured in both stormwater and stormwater sediments, concentrations in the stormwater sediments reliably paralleled the trends found in water samples across land uses. Insoluble parameters had much higher frequencies of detection in stormwater sediments than in water. When concentrations in stormwater sediments were compared to the Washington State Sediment Cleanup Objectives (SCOs) for freshwater sediments under the Sediment Management Standards, the number of samples exceeding the SCOs was found highest for phthalates[1] (82% and 29% of samples) and PAHs (34% of samples). To a lesser extent, concentrations of phenolics (20%) and metals (1-18%) exceeded the SCOs.

---

[1] Bis(2-ethylhexyl) phthalate – 82% of samples; di-n-octyl phthalate – 29% of samples

Seasonality and Loads

Higher contaminant concentrations and mass loads were measured for nutrients and metals during the dry season (May through September). This provides strong evidence for an influence of seasonality (or antecedent dry periods) on stormwater concentrations, particularly in late summer through early fall; it also supports the idea that there is a degree of "buildup" in the dry periods between storms. Metals, diesel hydrocarbons, and total nutrient loads were higher in the dry season and highest from commercial and industrial areas.

PAHs, phthalates, and detected pesticides (dichlobenil and pentachlorophenol) did not exhibit this significant seasonal difference, suggesting a consistent source throughout the year and no buildup in the dry months.

Discussion

This study improves Ecology's understanding of the quality of stormwater discharges to receiving waters. The study provides:

- Local and land use-based stormwater quality data.
- Flow-weighted composite sample data which are superior in quality to grab samples and best represent storm-event concentrations.
- Direct baseline to measure the performance of stormwater management actions at a regional scale.
- Summary statistics from a very large data set that are not biased by substituting for *non-detect* results.

Generally in this stormwater discharge data set, individual storm-event concentrations were within the ranges reported in the National Stormwater Quality Database (NSQD) (Maestre et al., 2004 and 2005), but median values were consistently lower (Figure ES-2). These concentrations are also much lower in some cases (e.g., lead is 23 times lower) than those from the earliest national study on stormwater, NURP (EPA, 1983). This may be due to the age of the early studies, subsequent improvements in stormwater quality and management since the NURP sampling, or possibly our wetter climate that allows for more wash off between monitored storms. Nevertheless, the current study offers many of the same conclusions about land-use patterns as the *PS Toxics Study* (Herrera, 2011) and NURP/NSQD studies of the 1980s and 1990s. For example, concentrations of metals from commercial and industrial land uses have remained high.

For many of the parameters, concentrations were higher in stormwater discharges in the current study than levels found in the recent *PS Toxics Study* (Figure ES-2). This finding is not surprising given the *PS Toxics Study* sampled ambient receiving waters, while these current stormwater data are representative of discharges to receiving waters.

In the current study, metals (total and dissolved) were much lower (2 to 15 times) than in the NURP and NSQD data sets (Figure ES-2). Compared with the *PS Toxics Study*, metals were generally higher in stormwater, with the exception of dissolved arsenic. High background arsenic from the regional geologic setting yields higher dissolved concentrations in receiving waters of rivers and streams. The largest difference in metals concentrations between this study and the *PS Toxics Study* was found in lead and zinc (12 and 8 times, respectively; Figure ES-2).

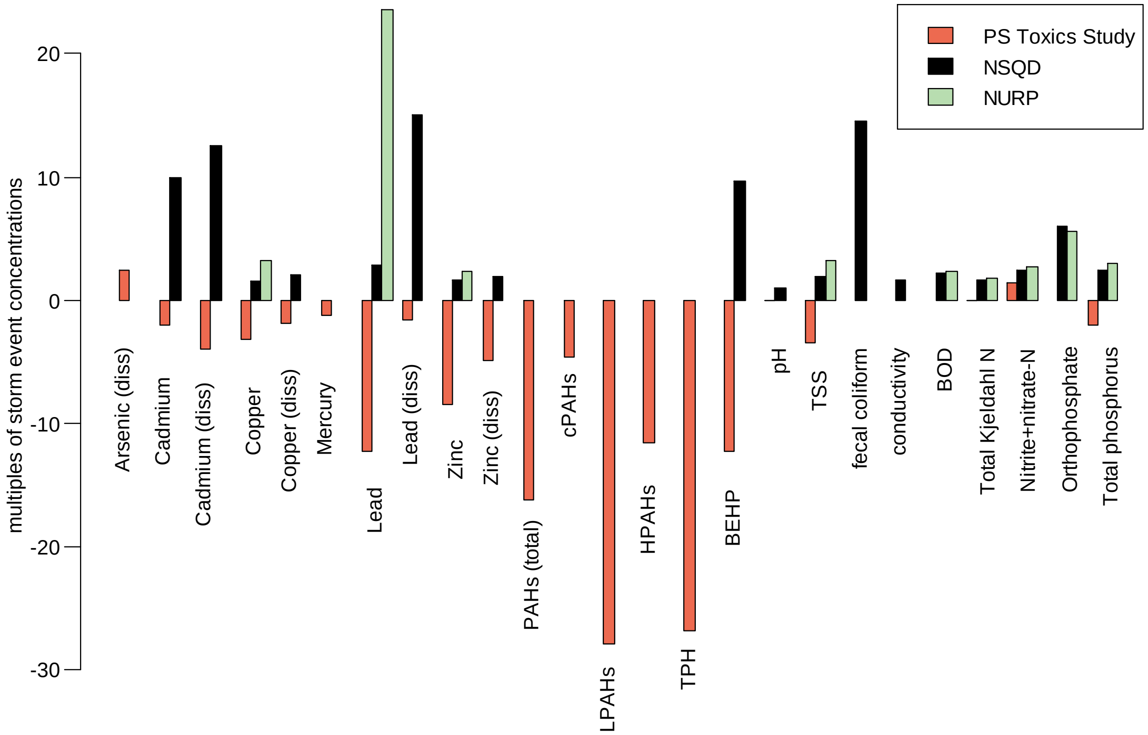

Figure ES-2: Summary of S8.D median stormwater concentrations relative to other studies.

The Y-axis units are the differences (multiples) of the S8.D stormwater median concentrations reported in the other two studies. Bars show the magnitude of difference as less than (negative) or more than (positive) the S8.D results. Many parameters were not measured in the previous studies.

Total nutrients and dissolved nutrients were found to have different land-use patterns. Like many of the metals and organic contaminants, total nutrients were found in higher concentrations and loads from areas of commercial and industrial land use. Total phosphorus concentrations in stormwater discharges were found to be double the receiving water concentrations under storm flows as reported in the *PS Toxics Study* for combined land uses.

Dissolved nutrient concentrations (nitrite+nitrate and orthophosphorus) were higher in stormwater from residential areas. Dissolved nutrients were lower in stormwater discharges than in receiving waters under storm events sampled in the *PS Toxics Study* (Figure ES-2). This suggests the major sources of dissolved nutrients are probably not in piped stormwater systems represented in this data set. This suggests that nonpoint sources for dissolved nutrients may be important delivery mechanisms for dissolved nutrients. Possible sources are shoreline sheet flow drainage, non-urbanized land runoff (such as agriculture and open space), other surface water bodies (such as wetlands), and groundwater.

The permittees analyzed far more parameters than the two older national studies did, particularly organic parameters such as PAHs that were frequently detected in western Washington stormwater. Hydrocarbon median concentrations (PAHs and TPH) were measured at 5 to 26 times higher in this study than those in the *PS Toxics Study* (Figure ES-2). This compilation of stormwater discharge data corroborates the *PS Toxics Study* findings about the dominant source of PAHs. High concentrations of PAHs are observed during storm events, with the greatest contribution of PAHs from areas with commercial and industrial land uses. No seasonal differences in PAH concentrations were found in this study.

Overall, the highest concentrations and the most frequent exceedances of water quality criteria for toxic compounds were found in stormwater and stormwater sediments discharged from basins with a higher percentage of commercial and industrial land uses. Residential lands contributed the highest concentrations of dissolved nutrients and the pesticides dichlobenil and triclopyr. Triclopyr, which had a high frequency of detection in the *PS Toxics Study,* was found in only 10% of the 575 stormwater samples analyzed under the permit in this current study.

Recommendations

Future Monitoring and Stormwater Management

- Continue collecting high quality data representing storm-event concentrations. This is realistic, since all eight permittees met sample frequency and representativeness of the qualifying storm event described in the permit.
- Reduce or eliminate from future stormwater monitoring those parameters which were rarely detected:
  - Benzene, toluene, ethylbenzene, and xylenes (BTEX) in water.
  - Malathion, prometon, chlorpyrifos, and diazinon in water and sediments.
  - Triclopyr and mecoprop in sediments.
- Limit testing of phenolics in sediments to pentachlorophenol, o- cresol, and p-cresol.
- Expand the spatial scale and number of sites for collection of annual stormwater sediment samples to enhance the survey of possible contaminant sources. Stormwater sediment samples effectively reflect the relative contaminant concentrations by land use.
- Apply the findings of this analysis to future stormwater management activities.
  - Stormwater management programs can sweep and conduct other housekeeping best management practices (BMPs) in industrial and commercial areas during the dry season to reduce high stormwater loads of metals, diesel hydrocarbons, and total nutrients during the first-season storms.

Future Puget Sound Monitoring and Modeling

- Use this study's measurements of storm-event concentrations to fill data gaps in Puget Sound models (identified by the *PS Toxics Study)* for areas draining directly to marine or fresh receiving waters. These areas were missed when monitoring the larger drainages in that study (Herrera, 2011).
- Use this stormwater data set in modeling studies for more accurate estimates of toxics loading from stormwater in the Puget Sound basin.
- Conduct future studies of BMP effectiveness in the sampled basins, using a similar suite of stormwater chemistry for comparison to these baseline data. For example, evaluate the best timing for sweeping high traffic areas, ports, and parking lots.

Further Study

- Consider providing the data online in a simple, user-friendly interface that stormwater managers could use to directly compare to future stormwater chemistry results.
- Link this data set with the NSQD to increase the temporal range of the data set.
- Further investigate statistical approaches to define "typical" stormwater chemistry for each land use or other basin characteristics (e.g., total impervious area, effective impervious area, vehicular uses, pollution-generating activities).
- Continue analysis of unusually high runoff coefficients (percent of a storm's rainfall that is directed through the stormwater system) that were calculated for some high-density residential sites. This could show whether the runoff coefficient influences the contaminant contributions from these sites.
- Explicitly test the influence of antecedent dry periods and seasonal first-flush events in stormwater discharges.
- Evaluate the data set for patterns that could help identify and reduce sources of pollution to stormwater. For example, analyze the relationship between the timing of the highest metals concentrations from commercial and industrial areas and whether BMPs can reduce the discharge of copper, zinc, and lead.
- Further investigate the data set for relationships between seasonality and land use (or other basin characteristics) for each parameter (e.g., total phosphorus exhibits strong statistical differences among land uses during the wet season, but no significant differences during the dry season).
- Evaluate more descriptive landscape variables (e.g., vehicle traffic or road density) with the concentration data.

Data Access

This data set is available from Ecology's Environmental Information Management (EIM) database. Inquiries can be made by contacting report authors B. Lubliner or N. Kale.

Introduction

Stormwater transport of pollutants to receiving waters is a local and national concern. The U.S. Environmental Protection Agency (EPA) states, "*Polluted stormwater is the leading cause of impairment to the nearly 40% of surveyed U.S. waterbodies which do not meet water quality standards.*" (EPA Stormwater website). The Washington State Department of Ecology (Ecology) is authorized to administer the Clean Water Act's National Pollutant Discharge Elimination System (NPDES) permits to implement controls designed to prevent stormwater pollutants from impairing local water bodies.

To understand the extent of pollutant loading by stormwater to streams, lakes, rivers, and Puget Sound, Ecology included monitoring requirements in the 2007-2012 Phase I Municipal Stormwater permit (permit)[2] (Ecology, 2006 and 2007). Ecology issued the permit to four counties, two cities, and two ports[3]. Special Condition 8 (S8) of the permit consisted of three main monitoring elements:

- Stormwater discharge characterization monitoring and assessment of seasonal first flush toxicity (S8.D).
- Stormwater treatment and hydrologic best management practices (BMP) evaluation monitoring (S8.E).
- Targeted stormwater management program effectiveness monitoring (S8.F).

This report summarizes the results of stormwater discharge characterization monitoring (S8.D) only. Appendix A provides a summary of the screening level toxicity of the first storms in the dry season. This report of the Phase I Permit's S8.D stormwater monitoring data represents the largest local data set characterizing municipal stormwater discharge quality. Compilation and analysis of stormwater discharges helps fill a data gap identified by a receiving water study: *Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates* by Herrera Environmental Consultants, Inc. (Herrera, 2011), herein called the *PS Toxics Study*. The *PS Toxics Study* stated the major data gap was in regional stormwater quality information from conveyance systems, and that discharge data were needed to improve loading estimates to Puget Sound.

Purpose

Characterization of stormwater pollutant discharges by land use on a regional scale is an Ecology priority. Stormwater management solutions and decisions are based on knowledge gathered from monitoring the types of pollutants in populated industrial, residential, and commercial land-use areas. The National Estuary Program (NEP) also identified stormwater discharge characterization as a priority. In 2012, NEP provided grant funding to Ecology to compile and

---

[2] The 2012-2013 Phase I Municipal Stormwater Permit continued the 2007 permit's monitoring requirements, clarifying endpoints for these monitoring programs and requirements for data submission.

[3] The Phase I Municipal Stormwater Permit also covers Secondary Permittees which were not required to conduct the monitoring discussed in this report.

review the S8.D monitoring data collected from 2007 through 2012. An interim report was published based on results available at the time (Lubliner and Newell, 2013). After the interim report was published, the remaining stormwater monitoring data were submitted to Ecology. This final compilation builds on the interim report and establishes a regional baseline of stormwater discharge quality based on monitoring results from the Phase I Permit.

The information presented herein provides natural resource managers and stormwater managers with actual stormwater discharge data in western Washington, which can decrease reliance on national studies that may not represent western Washington's climate or land uses. Improved confidence in local stormwater event concentrations is useful for stormwater managers, regulators, treatment technology development, and future contaminant studies (e.g., source identification and loading studies). This report provides recommendations for future analysis of this data set and recommendations for separate studies. This report also identifies parameters that provide little information about stormwater quality.

Permit-Defined Stormwater Monitoring

Stormwater Monitoring Design

Monitoring Permittees

The 2007 monitoring requirements applied to eight Phase I permittees:

- Cities of Tacoma and Seattle
- King, Snohomish, Pierce and Clark counties
- Ports of Tacoma and Seattle

To ensure consistency across jurisdictions, monitoring was conducted under Quality Assurance (QA) Project Plans written by the permittees and approved by Ecology. The monitoring program for each permittee is described in detail in each permittees' QA Project Plan (referenced in Appendix B and available from the permittees). A few aspects of the monitoring programs are important for understanding the monitoring results presented here.

Site Selection for Stormwater Characterization

The permit instructed permittees to monitor land uses where, ideally, the drainage area would constitute ≥80% of a particular land use. However, Ecology and the permittees found that stormwater sub-basins tended to contain more variety of land uses and meeting this 80% goal was not possible in all circumstances (Table 1). Permittees monitored one location for each different land-use type. The land-use types monitored by permittees were:

- Counties: commercial, high-density residential, and low-density residential.
- Cities: commercial, high-density residential, and industrial.
- Ports: commercial.

The permit required stormwater monitoring for a total of three years of data collection for each site and each permittee. Table 1 shows the land-use characterization of the drainage areas monitored by each permittee and lists the total impervious area (TIA) estimated in each of the stormwater subbasins monitored. Because estimates of effective impervious area (e.g., impervious surfaces that are connected via sheet flow or discrete conveyance) were not available, the TIA information was intended to provide context for the amount of land area available for dispersion to the ground surface. Not all selected monitoring locations were outfalls to receiving waters; in many cases, the monitoring location was a catch basin or other node in the system that met the project needs. Both ports monitored locations primarily representative of parking lot runoff. The locations of the monitoring sites are shown in Figure 1.

Table 1. Phase I S8.D sites and land-use summary.

Permittee	Land Use			
	Low-Density Residential	High-Density Residential	Commercial	Industrial
Clark County	43 acres 100% residential 7% TIA	239 acres 99% residential 1% open space 52% TIA	27 acres 83% commercial 17% residential 76% TIA	NA
King County	43 acres 100% residential 17% TIA	5 acres 100% residential 50% TIA	5 acres 80% commercial 20% residential 80% TIA	NA
Pierce County	219 acres 43% residential 55% open space 2% other 5% TIA	125 acres 62% residential 16% commercial 14% roadway 8% open space 28% TIA	11 acres 96% commercial 4% open space 96% TIA	NA
Snohomish County	68 acres 85% residential 15% school 26% TIA	20 acres 100 residential 40% TIA	34 acres 100% commercial 77% TIA	NA
City of Seattle	NA	85 acres 95% residential 5% commercial 50% TIA	152 acres 61% commercial 37% residential 2% open space 61% TIA	137 acres 37% industrial 32% residential 18% open space 13% commercial 51% TIA
City of Tacoma	NA	1821 acres 80% residential 19% commercial 5% open space 0.8% industrial 42% TIA	181 acres 97% commercial 3% residential 65% TIA	36 acres 15% commercial 85% residential 90% TIA
Port of Seattle	NA	NA	1.3 acres 100% commercial 95% TIA	NA
Port of Tacoma	NA	NA	1.3 acres 100% commercial 82% TIA	NA

NA: Not applicable
TIA: Total impervious area

Land-use types: LDR = low-density residential; HDR = high-density residential; COM = commercial; IND = industrial

Storm-Event Criteria and Frequency

The permit specified the qualifying rainfall, antecedent dry period, and inter-event dry periods to define a storm event. The permit's criteria were highly specific and necessary to ensure consistent sampling for a regional program, particularly when considering the Pacific Northwest's winter climate with constant and sometimes overlapping wet weather patterns. Qualifying storm events were defined for the wet and dry season as follows:

All Storms

- Rainfall depth: 0.2 inch minimum, no maximum
- Rainfall duration: no fixed minimum or maximum
- Inter-event dry period: 6 hours

Wet Season (October 1 through April 30)

- Antecedent dry period: ≤ 0.02 inch rain in the previous 24 hours

Dry Season (May 1 through September 30)

- Antecedent dry period: ≤0.02 inch rain in the previous 72 hours

Permittees were required to monitor 67% of the forecasted qualifying storm events, up to a maximum of 11 storms per water year. The goal was to distribute sampling across the year with 60-80% of the storms representative of the wet season and 20-40% representative of the dry season. If, for a variety of reasons and despite good faith efforts, 11 "qualifying" storms were not sampled in a given year, a permittee could submit data from three storms that were "non-qualifying" for the 0.2 inch rainfall depth criterion.

Permittee information on timing of sampling or logistics in relation to storms is not evaluated in this report. Non-qualifying storm-event data were included in this project summary and were not differentially treated.

Parameters

Parameters were specified in both S8.D and Appendix 9 of the permit and were prioritized for each land use when the sample volume was limited. Table 2 lists the water quality parameters monitored in stormwater.

Stormwater Sample Collection

Stormwater samples were required to be collected using flow-weighted composite sampling techniques for all but two parameters. Flow-weighted composite samples best represent storm-event concentration. Flow-weighted stormwater samples were collected by automatic samplers (such as ISCO samplers), which were triggered to begin sampling once either the rainfall criteria of 0.02" of rainfall or a presence of flow in the conduit was detected. Permittees used telecommunications and automated equipment to ensure proper sample collection. A qualifying flow-weighted composite sample was required to be collected over 75% of the storm-event hydrograph. The permit defined a composite sample as at least ten aliquots, but as few as seven aliquots were accepted if all other criteria were met. Analytical results from this monitoring program are thus representative of storm-event concentrations, which provide the best indicator of the quality of the discharge over the length of a storm.

Two parameters, fecal coliform bacteria and total petroleum hydrocarbons, were required to be collected as grab samples.

Precipitation and flow volume data for each storm event were also monitored in real-time via electronic sensors.

Stormwater Sediment Monitoring Design

Entrained stormwater solids and sediments (stormwater sediments) were collected once annually. The list of parameters monitored in the stormwater sediment matrix included conventional parameters, PCBs (Aroclors), and phenols (Table 2).

The permit recommended that the sampling protocol use inline traps or other similar collection system, although a single specific sampling technique was not required. As a result, permittees used a variety of stormwater sediment sampling approaches from in-line traps to grab samples. Monitoring in-line stormwater solids using traps can be unpredictable and requires long periods of submersion and/or deployment to adequately trap sediments sufficient for analysis. Other permittees collected grab samples of stormwater sediments that had settled in catch basins. Permittees may also have treated samples differently following collection. Some may have decanted overlying water prior to laboratory analysis, whereas others may not have.

Uncertainty is higher for this stormwater sediment data in general due to the lack of defined protocols for collection and post-collection processing. This variety in collection and processing methods has an unknown impact on the variability of the stormwater sediment concentrations in the data set. For simplicity, Ecology overlooked the method of collection and combined all the stormwater sediment data for analysis, because there are far fewer numbers of samples in the data set due to the monitoring design. For the purposes of this data summary, the annual stormwater sediment samples were presumed to be comparable, and all results were compiled and evaluated. All stormwater sediment results are reported on the basis of dry weight.

Table 2. Permittee-monitored parameters.

Hydrology		
Storm-Event Precipitation Storm-Event Flow Volume Sampling-Event Flow Volume		
Water Quality		
Conventional Parameters	*Bacteria*	*Organics*
Total suspended solids	Fecal coliform	PAHs[a]
Turbidity		Phthalates[b]
Conductivity	*Metals (dissolved and total)*	Pesticides: Nitrogen (Prometon)

Grain Size	Copper	Phenolics[d]
Total Phosphorus	Cadmium	PCB Aroclors
Total Volatile Solids	Mercury	Pentachlorophenol
		Diazinon
		Chlorpyrifos and Malathion
		Petroleum Hydrocarbons
		NWTPH-Dx

(a) PAH compounds include at a minimum but are not limited to: 1-methylnaphthalene, 2-methylnaphthalene, acenaphthene, acenaphthylene, anthracene, benzo(a)anthracene, benzo[b]fluoranthene, benzo(k)fluoranthene, benzo[ghi]perylene, benzo(a)pyrene, chrysene, dibenzo[a,h]anthracene, fluoranthene, fluorene, indeno[1,2,3-cd]pyrene, naphthalene, phenanthrene, and pyrene.

(b) Phthalates include at a minimum but are not limited to: bis(2-ethylhexyl)phthalate, butyl benzyl phthalate, di-N-butyl phthalate, diethyl phthalate, dimethyl phthalate, and di-n-octyl phthalate.

(c) Appendix 9 of the permit mistakenly called for "Total Solids" when it should have said "Percent Solids" in the sediment parameter list. Despite the error in the text, this parameter was correctly analyzed by laboratories as the percent of the sediment sample that is the solid material (as opposed to water).

(d) Phenolics include but are not limited to: 2-methylphenol, 4-methylphenol, 2,4-dimethylphenol, and pentachlorophenol.

Laboratory Analytical Methods

The permit specified analytical methods and reporting limit targets for each parameter to ensure the stormwater data under this monitoring program were analyzed consistently and with comparable rigor among the various laboratories. In some cases, it allowed multiple methods (thought to be comparable) to be used for analysis of a parameter, provided the reporting limit target could be met. For example, conductivity could be analyzed using SM 2510 or EPA Method 120.1. Permittees used 15 laboratories for analysis; no permittee used only a single laboratory for all parameters. All data for a given parameter were pooled for analysis regardless of laboratory and regardless of analytical method.

Laboratory Quality Assurance

Each permittee's QA Project Plan was approved by Ecology and contains sections outlining the QA process and quality control (QC) procedures for its stormwater monitoring program. QA is a decision-making process, based on all available information that determines whether the data are usable for all intended purposes (Lombard and Kirchmer, 2004). QC refers to a set of standard operating procedures for the field and laboratory that are used to evaluate and control the accuracy of measurement data. Determination of laboratory QC and the overall stormwater monitoring program QA was performed by each permittee, per their QA Project Plans.

For this data analysis project, data entered into the EIM database are believed to be usable for the purpose of creating a baseline summary report as stated in the permittees' QA Project Plans.

Methods

Data Qualification

Quantitation and Reporting Limits

Reporting limits lower than those specified in the permit were allowed, provided that permittees' QC procedures were met and their instrumentation allowed resolution at a lower limit. Reporting limit and method detection limit terminology are illustrated in Figure 2. Appendix 9 of the permit listed reporting limit targets for each parameter and stated in the footnote:

> *"All results below reporting limits should be reported and identified as such. These results may be used in the statistical evaluations."*

It is Ecology's expectation that the detected concentrations below the target reporting limit were quantified and flagged as an estimate (e.g., typically a "J" flag).

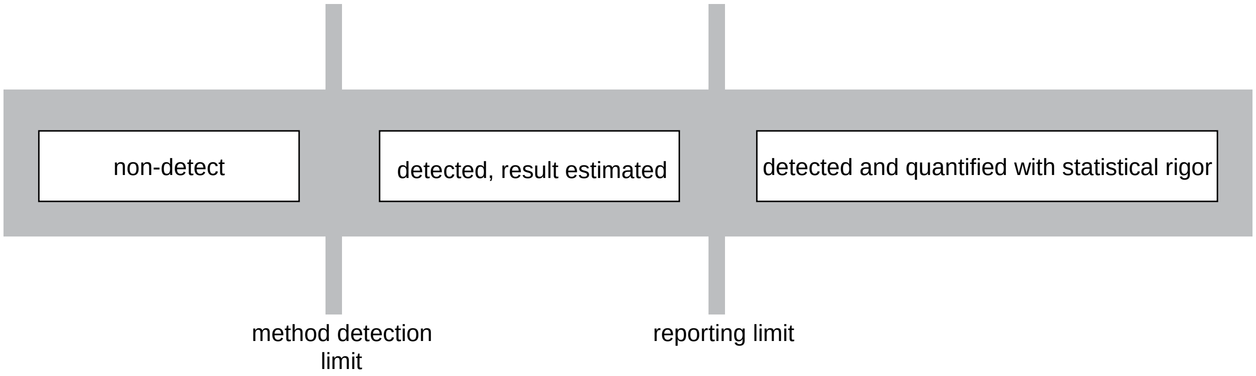

Figure 2. Simplified diagram of laboratory thresholds and data results.

Qualified Data

Data verification is the process of evaluating the completeness, correctness and conformance/ compliance of a specific data set against the laboratory method and study QA objectives. Data verification applies to activities in the field, at the laboratory, and the data user's (permittee's) review. Both the laboratory and the permittee's reviews determine whether the data record is usable as is or requires a corrective action, re-analysis, or flag to indicate qualification as estimate (J flag) or is rejected and is unusable (R or REJ flag). J flags may be given at the laboratory due to a slightly out of range QC sample or by the data QA managers (within the permittees' monitoring programs).

- *Method Detection Limit (MDL)* – The MDL is defined as the minimum concentration of a substance that can be measured and reported with 99% confidence that the analyte concentration is greater than zero and is determined from analysis of a sample in a given matrix containing the analyte. The MDL is determined using the procedure at 40 CFR 136, Appendix C. The permit did not specify MDLs.

- *Reporting Limit (RL)* – The reporting limit has multiple definitions and values, because it is a user-defined value imposed upon the reporting laboratory. RL is the lowest concentration at which an analyte can be detected in a sample and its concentration can be reported with a reasonable degree of accuracy and precision. The reporting limit may vary based on the purpose and use of the data. Reporting limits should always be based on statistical rigor at each laboratory. Analyte detections between the MDL and the reporting limit are reported as having estimated concentrations. Reporting limits are typically three to five times the MDL.

Ultimately, a lack of a signal below the MDL or RL was flagged as "U" meaning the parameter was not detected. In this report Ecology refers to the non-detected data as "non-detect".

Variation in Reporting Limits

Permittees' results had highly variable reporting limits, both between samples and between laboratories. Some variability is common and expected. Generally, the laboratories met the reporting limits listed in Appendix 9 of the permit. In some cases, analyses and/or labs were changed during the three-year data collection period to ensure compliance with permit requirements.

Figure 3 shows an example of the variability in the reporting limits for one of the non-detected compounds. This type of plot was constructed for every parameter with non-detect data. The colored bars represent the non-detect value as extending from "zero" up to the threshold reported for each laboratory. This threshold may have been the MDL or the reporting limit (RL), and this was not determined for this project. Based on the data gathered for this report, there may be differences where laboratories reported the detection threshold. Below Figure 3 is a color key associated with each of the laboratories that contributed data. In this example, dichlobenil (an herbicide) had 611 storm-event concentration records, but 392 of those records were non-detects (64.2% of the records). The non-detects were reported at approximately 20 different reporting limits spanning two orders of magnitude. The Permit gave a target reporting limit of 0.01 – 1.0 ug/L for dichlobenil and other pesticides.

Non-detect data are shown in these plots as line segments extending from zero to the laboratory reporting level. The color of the line segment indicates which laboratory performed the analysis. Laboratory names were removed and represented by a number. The focus of this plot is not to identify permittees or their laboratories, but rather to illustrate the number of laboratories and RLs reported. The information about the non-detect RLs could be used to define a single, realistic RL for each parameter. However, this is outside the scope of this report.

Reporting limits vary for several reasons. Natural variability of concentrations in stormwater samples typically is greater than in surface water or wastewater samples. Natural variability is due to numerous factors such as rainfall intensity, season, air deposition, land use, and potential sampling bias towards seasonal or event-based first flush.

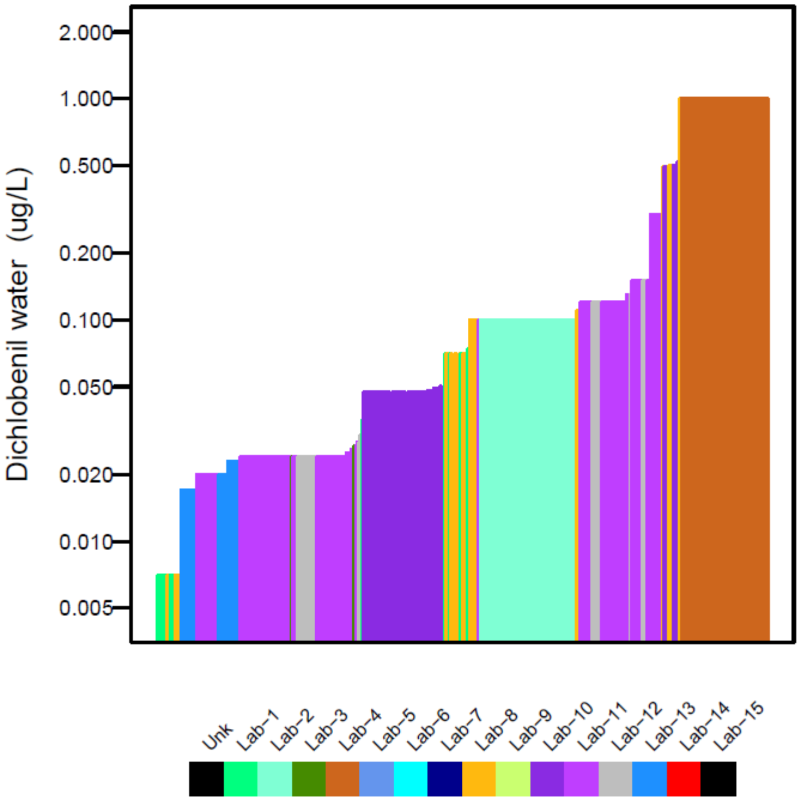

Figure 3. Non-detect reporting limits for dichlobenil by laboratory.

Other reasons for variability come from sampling design or sampling bias (e.g., sample volume collected). The sample volume typically required for an analysis has a predictable error rate associated with the analysis. When a smaller than normal volume is analyzed, the standard error increases, which increases the reporting limit. The anticipated stormwater volume was difficult to predict; it depended on the climatic event and was constrained by the capacity of the compositors. As a result, some samples were likely sent to the laboratory with less than ideal volumes.

Another major stormwater sampling source for variability is interference by compounds present in the stormwater sample (called *interfering matrix).* Stormwater samples can contain debris, sediment, oil, and other compounds that can interfere with sensitive analytical equipment. Laboratories must clean up dirty samples prior to analyzing for the contaminant of interest. This often results in loss of resolution at low levels and, in turn, elevates the reporting limit.

Permittees were required to conduct QC and QA reviews on reported data. Because data verification was performed by the permittees, the data received by Ecology were thought to be usable. For this report, Ecology used the data as reported with few exceptions. Several obvious outliers were verified with permittees and errors resolved. Rejected records were not requested and, if supplied, were not used for summary statistics.

Data Compilation and Management

Data Collection and Accessibility

Permittees were responsible for submitting data collected under the S8.D stormwater monitoring permits, with the exception of the toxicity results, to Ecology for entry into the agency's Environmental Information Management (EIM) system (http://www.ecy.wa.gov/eim/). Toxicity results were submitted to Ecology for review. Ecology prepared a summary of stormwater seasonal first-flush toxicity on trout embryos. This summary is presented in Appendix A.

The S8.D data summarized and presented here are available in EIM. Data may be searched by various characteristics (e.g., parameter, study, geographic area). The study identification codes (IDs) for the S8.D data are detailed in Table 3.

Table 3. Summary of permittee data compiled for this report.

Permittee	EIM Study ID	Period of Record
Clark County	WAR044001_S8D	2009-2012
King County	WAR044501_S8D	2009-2013
Pierce County	WAR044002_S8D	2010-2013
Snohomish County	WAR044502_S8.D	2009-2012
City of Seattle	WAR044503_S8.D	2009-2012
City of Tacoma	WAR044003_S8D	2009-2012
Port of Seattle	WAR044701_S8.D	2009-2012
Port of Tacoma	WAR044200_S8.D	2009-2012

Data Compilation

Ecology downloaded all data associated with the project into a Microsoft Access Database File (.accdb) to query, reorganize, and manage the data into a uniform output file for analysis (Table 4). Reorganization of the data set included such items as renaming a parameter due to variability in nomenclature among the 15 labs. In addition, a number of macros for Microsoft Excel were written in Visual Basic to sum selected parameters. Once the data set was in the final form, it was exported into a comma-separated value (.csv) format, where it could be easily used in a variety of statistical packages.

Table 4. Summary of organizational considerations for stormwater data submitted to the EIM database.

Organizational Steps	Example Issues	Initial Form	Final Form
Removed extra parameters	Laboratory control samples, surrogates, or calculated sums.	Examples of removed parameters include: 1. Maximum conductivity 2. Total PAHs	NA
Parameter names	Different laboratories use slightly different naming conventions; these had to be resolved in the database.	Approximately 25 names were resolved. Example: Triclopyr Trichlopyr Triclopyr (Garlon)	Triclopyr was the chosen parameter name for the database. See Table 2 for list of parameters in the database.
Specific parameter issues (two examples)	NWTPH-Dx Multiple products can be reported.	No guidance was given for reporting.	Sums for several categories created. See description below.
	Percent Solids was erroneously named as Total Solids in permit. Total Solids refers to a water measurement, not solids.	Most of the data were labeled Total Solids	Left as Total Solids, but is thought to be Percent Solids because the sample matrix is sediment for all data points.
Units for parameters	Laboratories and permittees reported using equivalent but different units due to the methods.	Example: 1. Fecal coliform MPN/100 mL or cfu/100 mL 2. ug/L or ng/L or mg/L	Units were preserved as sent in one column, and a lookup table was used to create new columns with data in one unit per parameter for graphing and statistics analysis. Fecal coliform units were assumed to be equivalent.
Sample fraction	Dissolved, total, or total recoverable. Labs used total and total recoverable interchangeably.	There were many blanks in these fields that needed to be populated for the database.	Sample fraction for metals was understood to be totals if blank. The terms *Total* and *Total Recoverable* are interchangeable for NPDES program (EPA, 1998).

Petroleum Hydrocarbon Summations

Petroleum hydrocarbons in stormwater were monitored using an Ecology laboratory method called NWTPH (Northwest Total Petroleum Hydrocarbon; herein called *TPH*) developed in the late 1990s (Ecology, 1997).

TPH-Gx, also called gasoline range hydrocarbon method, is both a qualitative and quantitative method (extended) for assessing volatile ("gasoline") petroleum products in soil and water. Six chromatograms identified by this method include:

- Gasoline
- Weathered gasoline
- Naphtha
- Mineral spirits #1, #2, and #3

TPH-Dx, also called diesel range hydrocarbon method, is also a qualitative and quantitative method (extended) for determining semi-volatile (diesel) petroleum products in soil and water. 24 different chromatograms can be identified by this method, including:

- Jet fuels
- Kerosene
- Diesel fuel
- Diesel oils
- Hydraulic fluids
- Mineral oils
- Lubricating oils
- Fuel oils

According to the method guidance, these NWTPH chromatograms should be summed into a single TPH value. Many of the permittees' results were reported in partial-sum categories typically used at the laboratories. For example, TPH-Dx was reported not as a summed total but as sub-categories, such as "residual range organics" or "heavy fuel oil".

Ecology determined the best path forward for these results was to rename obvious and similar results, preserve the partial-sum designations, and develop a summation plan. The summed TPH-Gx fractions (gasoline, naphtha, and mineral spirits) are called Gasoline Range Hydrocarbons. For TPH-Dx, results are presented in five sub-categories: Diesel Range Hydrocarbons, Heavy Oil Range Hydrocarbons, Heavy Fuel Oil, Lube Oil, and Motor Oil.

PAH and PCB Summation

Polycyclic aromatic hydrocarbons (PAHs) were summed based on functional categories and as a total PAH concentration. Low molecular weight PAHs (LPAH) summed included:

- Acenaphthene
- Acenaphthylene
- Anthracene
- Fluorene
- Naphthalene
- Phenanthrene

High molecular weight PAHs (HPAH) summed included:

- Benzo(g,h,i)perylene
- Total benzofluoranthenes
- Fluoranthene
- Pyrene

Carcinogenic PAHs (cPAH) summed included:

- Benz(a)anthracene
- Benzo(a)pyrene
- Chrysene
- Dibenzo(a,h)anthracene
- Indeno(1,2,3-cd)pyrene

Polychlorinated biphenyls (PCBs) were summed based only on those Aroclors that were detected. All non-detect data were omitted from the sum.

Numerical Analysis

Non-Detect Data

Data sets with non-detect results, particularly with multiple reporting limits, presented complications for data analysis. A considerable amount of complexity accompanied data handling when non-detects made up a large fraction of the data set. However, data were not cast aside or uniformly substituted as a simple approach. Ecology used the approach detailed by Helsel (2012), who describes the nature, analysis, and interpretation of non-detect data.

For the analysis, no substitutions were made for non-detect data, and the data (ranks) were considered. In combining multiple data sets from the permittees, sample sizes increased and statistical power increased with more observations, which improved our confidence in using non-substitution techniques. The statistical approaches used to include the non-detect data are described in the following sections. All statistical analyses were carried out using R (R Core Development Team, 2012) and the NADA package (Helsel, 2012; Lee, 2013).

Data Distributions

Parameters with greater than a 90% detection rate were tested using the distribution hypothesis Shapiro-Wilk Test. The test excludes non-detect data and therefore is not reliable for parameters with a lot of censored data. The Shapiro-Wilk test statistic "W" tests the null hypothesis that the data represent a normally (or log-normally) distributed population. When the p-value is less than the alpha level of 0.05 (in this study), the null hypothesis is rejected.

Probability plots were prepared to assess the log-normal distribution of most parameters, including those with less than 90% detection rates. The plots provide a visual means to estimate the data distribution for any given parameter. Probability plots are described in Appendix C and shown in Appendix F.

In reality the distribution of the data was used largely for descriptive purposes only. Statistical analysis of the data was carried out using Kaplan-Meier (KM) methods which do not rely on transformed data. For those parameters summarized using tools that require data transformation (e.g., regression on statistics [ROS]), the empirical distribution function (EDF) distribution was consulted to define the necessary transformation.

Descriptive Statistics

Categorical Evaluations and Summary Statistics

For statistical analyses, Ecology defined categories within each parameter based on the rate of detection and number of observations. Categories of data are referred to as Case A, B, or C. These categories are based on Helsel's (2012) work and are delineated largely by the reliability of summarizing data using appropriate tools (Table 5). KM and ROS were employed to calculate summary statistics for the reported storm-event concentrations; (mean, median, standard error, and lower and upper confidence levels).

Table 5. Methods for estimating summary statistics.

Adapted from Table 6.11 in Helsel, 2012.

Case	Amount of Data by Parameter		
	Percent non-detect	<50 Observations	> 50 Observations
A	< 50% non-detects	Kaplan-Meier	Kaplan-Meier
B	50-80% non-detects	Kaplan-Meier Robust MLE, robust ROS	Kaplan-Meier MLE
C	> 80% non-detects	Report ranges or % above a meaningful threshold	Report ranges and high percentile concentrations

Case A

Parameters where non-detects make up less than 50% of the data set were summarized using KM statistics. Non-parametric statistics make no assumption about the data's distribution and can also be used on log-normal data to develop summary statistics. The data are ranked, including the non-detect data points, and the statistical analysis (KM) is carried out on the entire ranked data set. The method was not used if more than 50% of the data set was non-detect. For Case A data, the KM method yields robust measures of median, mean, and standard deviation.

Case B

Parameters with 50-80% of the data reported as non-detects were handled according to results from the distribution tests. For the parameters that follow parametric distributions, Helsel (2012) recommends that either substitution methods, robust Maximum Likelihood Estimations (MLE) or robust Regression on Order Statistics (ROS), be followed. However, the majority of the parameters that fell into the Case B situation were not normally distributed.

For these, Ecology calculated summary statistics on the portion of Case B parameters that had more than 50 observations. ROS was used to estimate the summary statistics for this portion of the Case B data.

However, for data sets with fewer than 50 observations, both ROS and MLE provide poor estimates of summary statistics. Thus these data were summarized as a Case C category because Ecology determined that the statistics would be unreliable.

Case C

Case C data were simply summarized as ranges. Calculating other summary statistics would have been unreliable (Helsel, 2012).

Land-Use Significance

To determine if there were significant differences between land uses for a given parameter, Ecology relied on the Peto-Prentice test. The Peto-Prentice score test has been shown to perform well with data sets that have unequal sample sizes and unequal censoring (i.e., detection limits) (Helsel, 2012). The Peto-Prentice is a modified generalized Wilcoxon test, where scores are weighted by the EDF. The Peto-Prentice test identifies when at least one land use among the four has significantly different concentrations. To visualize any significant differences among land uses for each parameter, a plot of the EDF can be produced.

Summary Plots

Ecology relied on six types of plots as visual tools to describe the concentration data (Appendix C). Each set of plots for each parameter consists of:

- Jitter Plot
- Probability Plot
- Non-Detects
- Empirical Distribution Function (EDF)
- Box Plot by Land Use
- Box Plot by Season

Appendix C contains a description of how to read each of these six plots (reproduced from Lubliner and Newell, 2013). Appendix F contains a page for each parameter with all six plots and matrix combination. Ecology also used box plots, cumulative density functions, and jitter plots to describe the contaminant loads (Appendix H).

Multivariate Statistics

In order to summarize multiple parameters for each stormwater catchment together with land use and observe any relevant similarities or associations among them, Ecology relied on principal components analysis (PCA). PCA is a statistical tool that describes the relative similarities among environmental variables (stormwater parameters) and study sites. Multiple axes or components are computed in decreasing order of strength or importance. Each axis represents a synthetic gradient across the sample sites, some more important than others. Visually, a plot of the two most dominant axes (an ordination diagram) can provide an effective means to describe large complex data sets. Points or sites on the plot that cluster together are more similar than those that are more distant. Ecology selected those variables that appeared to be statistically relevant from the prior Peto-Prentice test. The PCA was run on the median concentration values as described above using the statistical techniques for non-detect data. Only parameters which were complete across all study sites were included in the analysis. Data were log transformed, centered, and standardized prior to the analysis. PCAs were run using the R framework and the Vegan package (Oksanen et al., 2013).

Additional tools used to detect similarities among the parameters across the land uses included a hierarchical cluster analysis and an analysis of similarities. The same data set used for the PCA analysis was used for the cluster analysis. Ecology calculated the Euclidean distance (measure of dissimilarity) between sample sites and computed the cluster analysis using Ward's minimum variance method (Hartigan, 1975). This technique is a way of identifying groups of data (sites) that are similar. Visually, a cluster diagram or dendrogram shows the groups of sites starting with the most dissimilar and then continues to separate the sites into groups until each site is on its own branch of the tree (dendrogram). We used the first two major separations of sites in the cluster dendrogram to describe similar 'groups' of sites based on their stormwater chemistry.

Analysis of similarities is a tool to statistically test whether there are significant differences between two or more groups of sampling units based on a dissimilarity matrix. We used the same dissimilarity matrix as the cluster analysis. Ecology employed this test to help determine whether there is a significant difference among land uses based on all sites and all relevant parameters. This differs from the previously described Peto-Prentice test for land-use significance, which tests a single parameter for significant differences.

Comparison to Stormwater Studies and Water Quality Criteria

To put the results of this compilation effort into context, Ecology used three primary sources of information for comparison of these results:

- A suite of literature including the Nationwide Urban Runoff Program (NURP) (EPA, 1983) and analysis of the National Stormwater Quality Database (Maestre et al., 2005).
- Washington State Water Quality Criteria. The national studies and the WA state water quality criteria form the "bookends" for comparison of the stormwater discharge results of this compilation effort.
- A local study to characterize stormwater concentrations and load to Puget Sound from the receiving water during storm events, *Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates* (Herrera, 2011) (called *PS Toxics Study* in this document).

Relevant Stormwater Studies Explored

The median concentrations from this study are compared to the median concentrations of a few other stormwater studies where data exist. Comparisons made to these other studies are informative for this database and are included to give context to the results of this study.

- The Nationwide Urban Runoff Program (NURP) (EPA, 1983).

- Nonparametric Statistical Tests Comparing First Flush and Composite Samples from the National Stormwater Quality Database (NSQD) (Maestre et al., 2004).
- The National Stormwater Quality Database, Version 1.1; A Compilation and Analysis of NPDES Stormwater Monitoring Information (Maestre et al., 2005) http://rpitt.eng.ua.edu/Publications/Stormwater%20Characteristics/NSQD%20EPA.pdf
- Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates (Herrera, 2011) (called *PS Toxics Study* in this document).

NURP and NSQD

The NURP study was a research project conducted by the U.S. Environmental Protection Agency (EPA) between 1979 and 1983. NURP was the first comprehensive study of urban stormwater pollution across the United States and established the national stormwater quality benchmark. NURP samples were also collected to represent the storm-event concentration, which allows us to compare results from the permittees directly. The study evaluated the stormwater data distributions and concluded that 90% of their study parameters followed a log-normal distribution.

The NSQD was created in the mid-1980s to store stormwater data collected by the NURP study and other Phase I MS4 data. Over time, the database gained some specialized U.S. Geological Survey stormwater studies and more recently selected outfall data from the International BMP Database. Several reports have been published by Alex Maestre and Robert Pitt, summarizing the stormwater monitoring data contained in versions of the database over the last 20 years (Version 1.0, 1.1 and 2). Version 3 of the NSQD is available online at: http://unix.eng.ua.edu/~rpitt/Research/ms4/mainms4.shtml.

PS Toxics Study

The *PS Toxics Study*, the largest local study of receiving waters to date, was initiated to assess the relative loading and identify sources of toxic contaminants to Puget Sound. River and streams were sampled in 2009-2010 in multiple watersheds during baseflow and storm-event flows. Stormwater discharges were not directly sampled. Contaminant concentrations were measured and annual mass loads and annual loading rates were calculated.

In this report Ecology compares the stormwater discharge concentrations to the *PS Toxics Study* ambient data, and acknowledges this as an "apples to oranges" comparison. The permittees collected flow-weighted composites from stormwater discharges across 75% of the storm event's hydrograph. The *PS Toxics Study* samples were collected as grab samples from the receiving waters during storm events. The instream concentrations as captured by the *PS Toxics Study* were anticipated to be lower than stormwater discharge concentrations, particularly in urban areas. Nevertheless, it does give us a sense of the scale of differences and an understanding of where patterns in the results are similar.

Loads calculated for this stormwater discharge data compilation are event loads and not annual loads like those calculated in the *PS Toxics Study*. Thus, loading results are too dissimilar and are not comparable. Ecology can compare the trends across land uses for both concentrations and loads.

Water Quality Criteria

Promulgated water quality standards as well as non-promulgated criteria exist for a number of parameters measured in these stormwater discharges. The authors of this report used the Washington State acute and chronic freshwater standards (WAC[4] 173-201A), for comparison to provide context for the stormwater discharge results. For stormwater sediments, the authors made a comparison to freshwater sediment chemical criteria (Chapter 173-204 WAC). The comparisons do not include any consideration of the receiving water. These comparisons are not intended to, and are not appropriate for, determining compliance with regulatory requirements, such as water quality standards and permit conditions.

Water

The criteria for the protection of aquatic life in surface waters of the State of Washington are promulgated under Chapter 173-201A WAC. As defined by EPA (1994), the exposure periods assigned to the acute criteria are expressed as: (1) an instantaneous concentration not to be exceeded at any time or (2) a 1-hour average concentration not to be exceeded more than once every three years on the average. The exposure periods for the chronic criteria are either: (1) a 24-hour average not to be exceeded at any time or (2) a 4-day average concentration not to be exceeded more than once every three years on the average.

Each individual stormwater sample (recall that each sample is a composite across a storm event) was compared to the criteria value. For pH and hardness dependent criteria, Ecology wrote scripts in R to use each stormwater sample's pH and hardness result. If the concentration for a sample was non-detect, then it was excluded from the comparison. See Table ES-1 for results of the criteria comparisons.

Sediment

Sediment criteria are found in Washington State's Sediment Management Standards (SMS) (Chapter 173-204 WAC). The marine Sediment Quality Standards (SQS) found in Part III of the SMS are approved by EPA as water quality standards for the protection of the benthic community. Because these promulgated water quality standards values are for marine sediments only, the authors compared the stormwater sediment data to the freshwater sediment chemical criteria established as Sediment Cleanup Objectives (SCOs) in WAC 173-204-563. These SCO criteria are based on a "no adverse effects level" to the freshwater benthic community. At the time of this publication, EPA has neither approved nor disapproved the numeric freshwater sediment criteria as water quality standards.

Stormwater sediment concentrations are expressed as dry weight and not normalized to organic carbon content, which is suitable for the purposes of this contextual comparison (Michelson, 1992).

[4] Washington Administrative Code

Approaches to Non-Detected Data in the Stormwater Literature

In the NSQD Version 1.1 review, Maestre et al. (2005; Chapter 3) provide a review of how non-detects have been handled in stormwater studies. More recent environmental, and particularly stormwater, studies have used substitution techniques to substitute either one-half or full value of the method detection limit (MDL) for the value of the non-detect. This has been a common practice for data sets with relatively few non-detect data points. Antweiler and Taylor (2008) indicate that using substitutions for non-detects produces comparable summary statistics.

In the NURP study, non-detected data were summarized using substitution of the value of the reported detection limit. In the NSQD version 1.1 data summary, non-detected values were estimated using the Cohen's maximum likelihood method. This is a method that randomly generates the missing data based on the known probability distributions of the data (Maestre et al., 2005). The *PS Toxics Study* estimated the non-detect values by substituting one-half the value of the detection limit (Herrera, 2011). Comparisons of the permittee's data results to NURP, NSQD, and the *PS Toxics Study* are considered approximate because the methods for sample collection and data analysis differed among the studies.

Despite different methods for handling non-detects, comparisons of median values were retained in this report because the NURP and NSQD represent the earliest and largest national stormwater quality characterization efforts in the United States. Most of the parameters monitored in the NURP and NSQD were limited to the conventional parameters, nutrients, and metals where non-detections are infrequent and typically have less influence on summary statistics. The *PS Toxics Study* is the most recent regional publication with wet weather surface water concentrations for toxic pollutants.

Results and Discussion

Database Description

The final stormwater discharge characterization data set comprises 44,800 records across 172 parameters, where each record is a single value for a particular parameter. Table 6 summarizes this database by permittee, period of record, land use, and data type. Permittees achieved three years of data collection in different ways. In some cases, partial years were summed to achieve the permit requirements. In other cases, more than three years of data were collected in part to accommodate individual permittee objectives for evaluating loading on a water year basis.

Table 6. Number of records by permittee, land use, and year.

Permittee	Land-Use Type	Number of Records					
		2009	2010	2011	2012	2013	Totals

Data Quality

Suitability for All of Western Washington

Concentrations monitored under the Permit reflect a range of results by land uses that can be applied to urban and suburban stormwater discharges in western Washington. The permittees monitored both large and small drainages. Ecology determined that both the range of concentrations and median values were useable and represented stormwater quality in western Washington. By summarizing multiple years of data, Ecology also accounted for inter-annual variability.

Pollutant concentrations overlapped between the land uses, and this variability increased confidence in the representativeness of the monitored basins. Table 1 illustrates the mix of land uses for each monitored basin.

Laboratory and Field Quality Control

The data entered into EIM has already undergone external quality control methods (e.g., field replicates, laboratory and field blanks) as defined by the permit. Laboratory assigned data qualifiers were relied upon to define detection rates and the degree to which a parameter is censored. No further quality assessment of the data quality was carried out during this analysis. The number of samples with data qualifiers (flags) for each parameter is presented by matrix in Appendix D, Table D-2, and by land use in Table D-3.

Data Distribution and Case Summary

The distribution defined by the Shapiro-Wilk test for each parameter is described in Table D-1. Parameters are divided into three categories: normal, log-normal, and distribution-free.

Water samples were found to have the following distributions:

- log-normal (18 parameters)
- distribution-free (59 parameters)

Sediment samples were distributed as follows:

- normally (3 parameters)
- log-normally (15 parameters)
- distribution-free (32 parameters).

Ecology restricted distribution testing to the parameters with the highest rates of detection and found that many of the parameter's probability plots (Appendix F) appeared nearly linear, indicating log-normal distribution.

Data Case Summary

The reliability of the data summaries depends on the level of detection for each parameter and is defined by the "case" category for each parameter as indicated in Table 5. Table D-4 describes, by land use, the case category for each parameter. Overall, 88 parameters were classified as Case A, 31 parameters as Case B and 53 parameters as Case C.

These results largely agree with the National Urban Runoff Program (NURP) results. NURP, a large national stormwater study, found that stormwater event mean concentrations (EMCs) for most parameters followed either log-normal distributions or were distribution-free (non-parametric) (EPA, 1983).

High Frequency Non-Detected Parameters

This monitoring program provided a suitable sample number and range of conditions to determine whether certain parameters could be reduced in sampling frequency or excluded from future stormwater monitoring studies. Note however that site-specific or study-specific circumstances may still necessitate the collection of these parameters.

With the exception of dissolved mercury (91.2% non-detect), the inorganic parameters were largely detected. Mercury was analyzed using a different method from other metals (SW7470). Reduction in frequency of dissolved mercury analysis using this method is justified; another method with a lower reporting limit may be more suitable in future studies.

The parameters detailed in Table 7 for stormwater and stormwater sediments were almost completely (>90%) undetected.

Insoluble Organics

The parameters in Table 7 were largely insoluble organic pollutants such as volatile and semi-volatiles; PCBs, phthalates, pesticides, or PAHs. Many organic compounds tend to adsorb to solids, making them easier to detect in the sediments. More volatile or more easily degraded (low molecular weight) chemicals may not have been found in stormwater samples, because they may have been older and weathered.

However, monitoring costs would not likely be reduced by removing a limited number of organics from the monitoring list, since the non-detected parameters from the EPA Method 8270D analytical list are often measured at no additional fee. However, for parameters that require a separate sample or a different extraction method, elimination of those parameters would reduce costs. For example, several pesticides were not found in stormwater or stormwater sediments. In particular, malathion, diazinon, prometon and chlorpyrifos were infrequently detected in both water and sediment. Furthermore, many of the phenols analyzed in sediment samples were detected in only 1 or 2 samples, although the sediment data set has fewer sample number. Pentachlorophenol and phenol degradation products (e.g., p-cresol) may be the most worthwhile parameters to monitor on a consistent basis.

Soluble Organics

The BTEX compounds were all listed in Table 7. This indicates that these four parameters are not found in stormwater, either because they are infrequent contaminants or because they volatilize prior to sampling.

Table 7. Stormwater and stormwater sediment parameters with >90% non-detect data.

Parameter in stormwater	% non-detect	Number of samples	Parameter in stormwater sediment	% non-detect	Number of samples
Insoluble organics			***Organics***		
Chlorpyrifos	99.8	644	2-Nitrophenol	100.0	23
Diazinon	99.1	644	2,4-Dichlorophenol	100.0	24

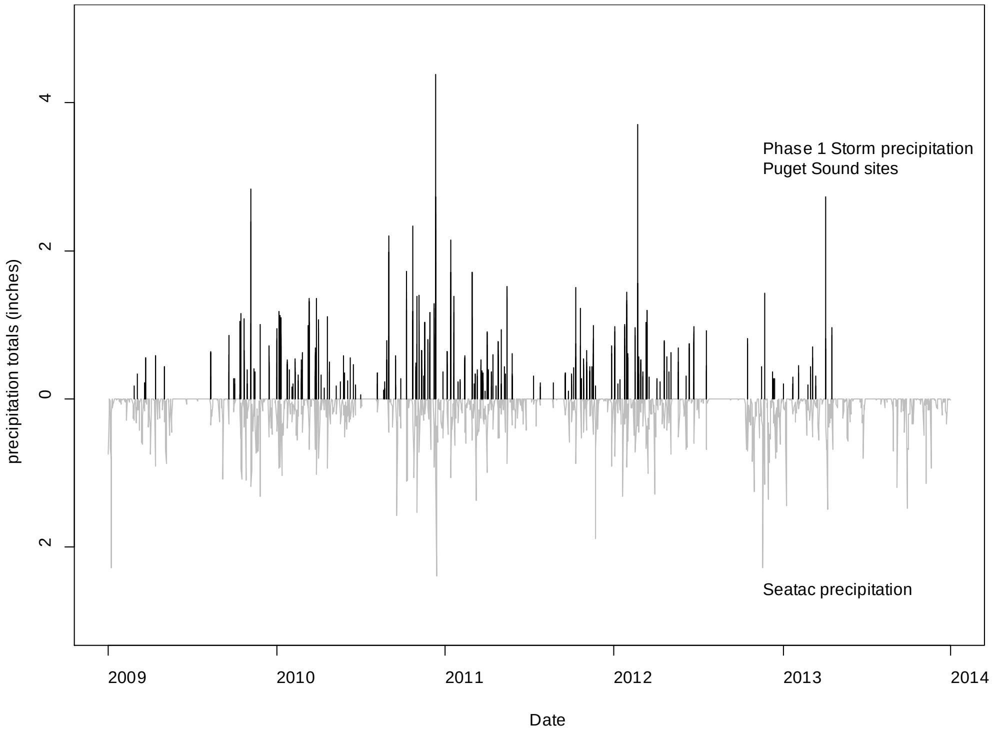
Total Xylenes	99.2	120			

Hydrology

Storm Events

Storm events were described by the permittees as *sample volume* and *storm volume*. Sample volume represents the volume that flowed between the first and last automated sample. Storm volume represents the total volume that flowed during the storm. Permittees also measured the total precipitation amount during the storm.

Ecology assessed how the precipitation amounts of the sampled storms compared to the complete record of precipitation from SeaTac International Airport and Vancouver, Washington as a way of showing how representative the storms were (Figure 4). Ecology recognizes that comparing only to SeaTac precipitation records for the Puget Sound region does not acknowledge the regional variability. Data were accessed from the National Climatic Data Center (administered by NOAA) and are daily precipitation totals, while permittee data are median storm-event precipitation totals. From Figure 4 it is clear that the sampling by permittees did an excellent job of capturing the general timing of major storm events for the regions.



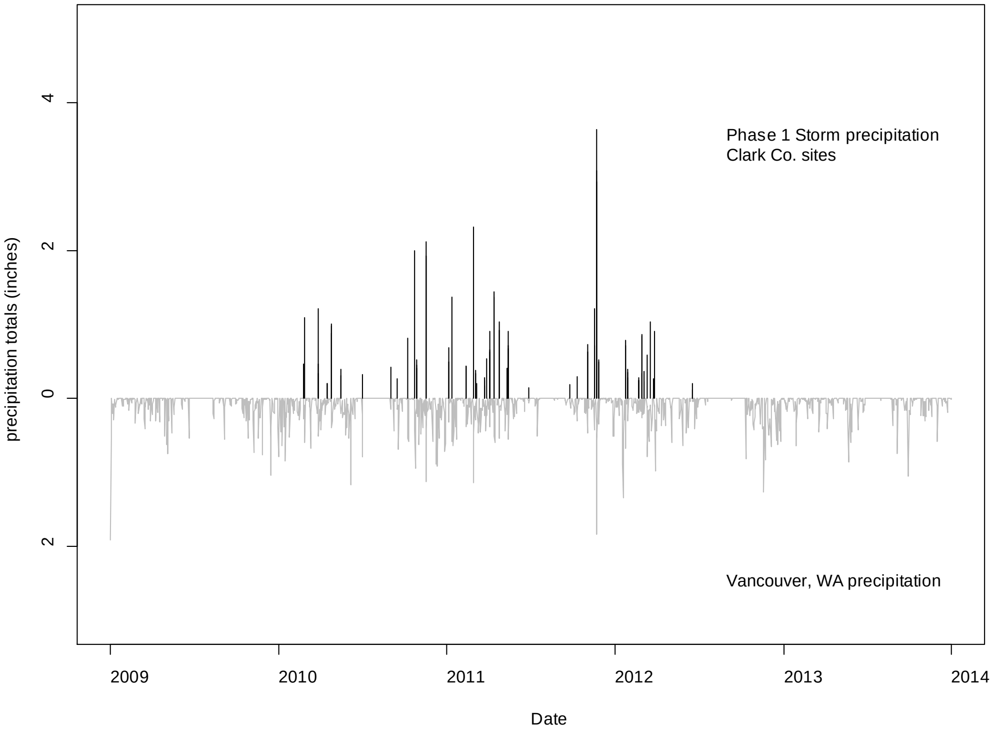


Figure 4. Median measured event precipitation totals for sample locations in the Puget Sound region and Clark County (upper sections of the graphs), combined with daily precipitation totals from SeaTac International Airport and Vancouver, Washington (lower sections of the graphs).

The total number of successfully sampled storm events is estimated in Table 8 by counting the unique start date at each location sampled. Some parameters were collected as discrete grab samples and could possibly be double-counted if two grab samples were collected over two storm-event days. However, given the small number of grab samples (< 1% of samples), it is unlikely this impacts the summary in Table 8. Each permittee was required to sample 67% of the forecasted qualifying storms, up to a maximum of 11 actual events per year. The Port of Seattle and Tacoma had low total numbers of samples, but this reflected a single sample point. In general, these two ports sampled storm events that were well distributed throughout the year. Pierce County collected the fewest number of samples distributed over each year, particularly for the high- and low-density residential land use. The lack of samples in Pierce County residential sites did not appear to bias the overall sample totals for these land-use types.

Table 8. Number of unique sampling dates for each permittee and land use.

Permittee	Count of Unique Sample Events	Land Use	Count of Unique Sample Events
City of Seattle	102	Commercial	262
City of Tacoma	110	High-density Residential	164
Clark County	79	Industrial	66
King County	80	Low-density Residential	105
Pierce County	44		
Port of Seattle	40		
Port of Tacoma	29		
Snohomish County	113		
Total	597	Total	597

Sample Representativeness

As detailed in the *Introduction* section, water samples were collected using flow-weighted automated samplers that allow for a sample that is representative of storm-event concentrations. The permit required the collection of at least 75% of the hydrograph for storms lasting less than 24 hours. For those storms greater than 24 hours, samples were collected for at least 75% of the storm during the first 24 hours. The remaining 25% of the event was typically sampled no more than 48 hours. Permittees reported both the volume of the sampled event and the whole storm event to Ecology. The representativeness of each storm by the respective sample was calculated from the data set by comparing these two reported volumes (Table E-1).

The vast majority of the sites showed that the collected and analyzed composite sample represented approximately 80-90% of the whole storm (Figure 5). The permit required the collection of at least 75% of the hydrograph, which appears to have been achieved. Visually comparing the percent of the storm sampled to the size of the storm, site location, wet or dry season, or the sample year, there appears to be no bias by these parameters on the percent of the storm sampled (Appendix E).

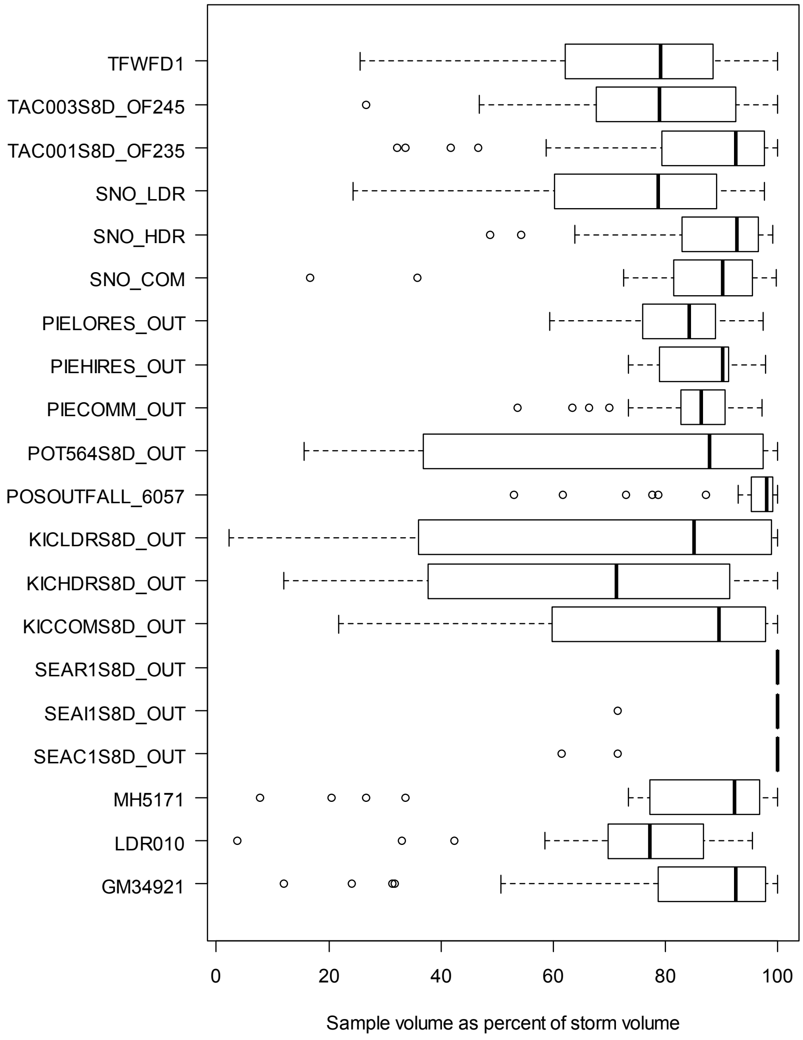

Figure 5. Percent of each storm captured by sampling for each sample site.

The permit required that the permittee collect grab samples for total petroleum hydrocarbons (TPH) and bacteria at the beginning of the storm. Permittees also sometimes collected grab samples for other parameters when the stormwater flow was insufficient for a composite or when attempting to sample the first flush. Overall, 535 records of samples collected using grab methods for parameters other than TPH and bacteria were found in the final data set. This represented only ~ 1% of the records, and these samples were not removed from the data set.

Runoff Coefficients

Ecology calculated the runoff coefficient for each stormwater catchment. The runoff coefficient is the ratio of total stormwater volume that flowed between the first and last automated sample (sample volume) to total rainfall volume across the catchment area. It therefore represents the amount of total rainfall that is captured by the stormwater drainage. Runoff coefficients ranged from 0.05 to 1.00. Typically, Ecology would expect that as the amount of paved surface (percent total impervious surface) increased, more rainfall would have been directed into the storm catchment (yielding a higher ratio). This was true for sample sites with greater than 40% impervious surface (Figure 6). For sample sites with less than 40% impervious surface, the relationship was more variable. Two of the high-density residential catchments with low-percent impervious surface had very high runoff coefficients, suggesting that in these drainage basins the conveyance of precipitation to the stormwater system was greater than in drainage basins with more paved surface. It is unclear why this was the case, and it deserves further inquiry. Ecology can say that it did not appear to be related to catchment size or storm volume. We can speculate that the unusual runoff coefficients may be a result of: (1) incorrect basin delineation or (2) inaccurate flow data.

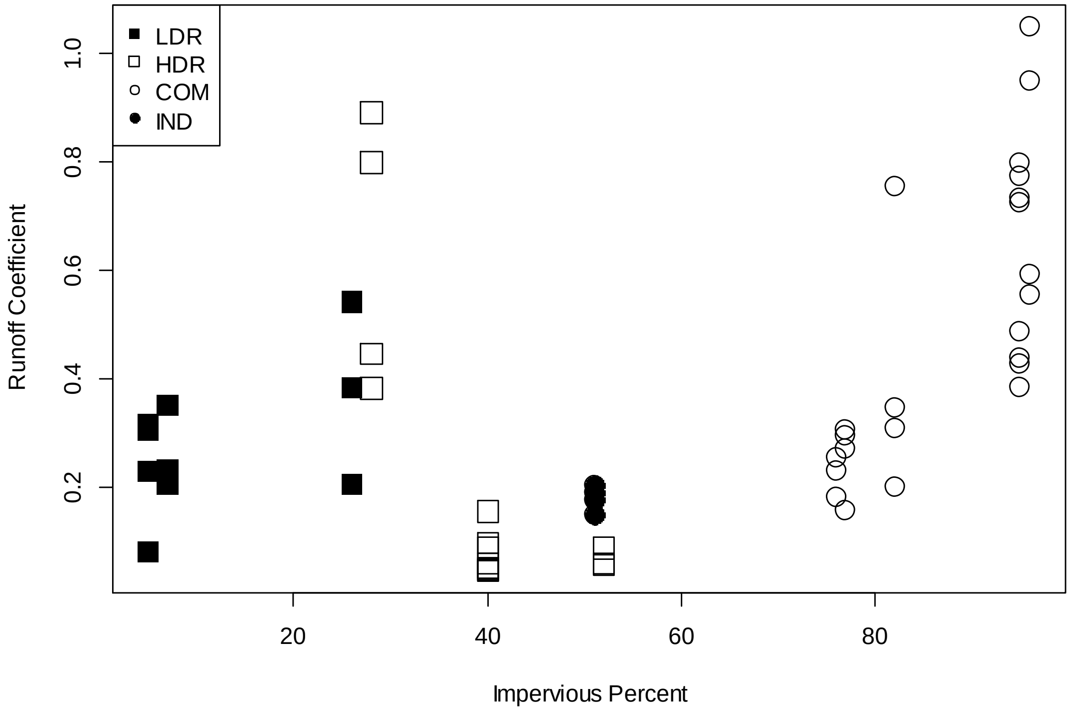

Figure 6. Runoff coefficient for each catchment basin, categorized by land use, relative to the percent impervious surface within each catchment.

Land-use types: LDR = low-density residential; HDR = high-density residential; COM = commercial; IND = industrial

Contaminant Concentrations

In this section, contaminant concentrations are discussed as *median values* (50th percentile) unless otherwise noted; therefore, Ecology is purposely not using the acronym EMC (event *mean* concentration). A summary table of each parameter appears below the parameter headings in each of the subsequent sections. Further detail on parameter summary statistics are calculated and shown as combined land uses in Appendix G, Table G-1, separated by land uses in Table G-2, and by wet and dry seasons in Table G-3.

Where applicable, the contaminant concentrations were compared with water quality criteria as defined in the earlier section, *Water Quality Criteria*. The graphical description of each parameter's concentrations (in alphabetical order) is provided in Appendix F. Summary Figures G-1 through G-3 show graphics of stormwater concentrations ranges in comparison to various water quality criteria.

Conventional Parameters

The conventional parameters (except surfactants) were detected with high frequency (except surfactants) (Table G-1) and were considered as Case A for statistical summaries. All of the conventional water parameters, except pH, were found to have at least one land use for which concentrations were significantly different. Stormwater sediment conventional parameters (TOC and grain size) did not differ between land uses. Figure 7 summarizes the range, median, and 90th percentile for each conventional parameter in stormwater.

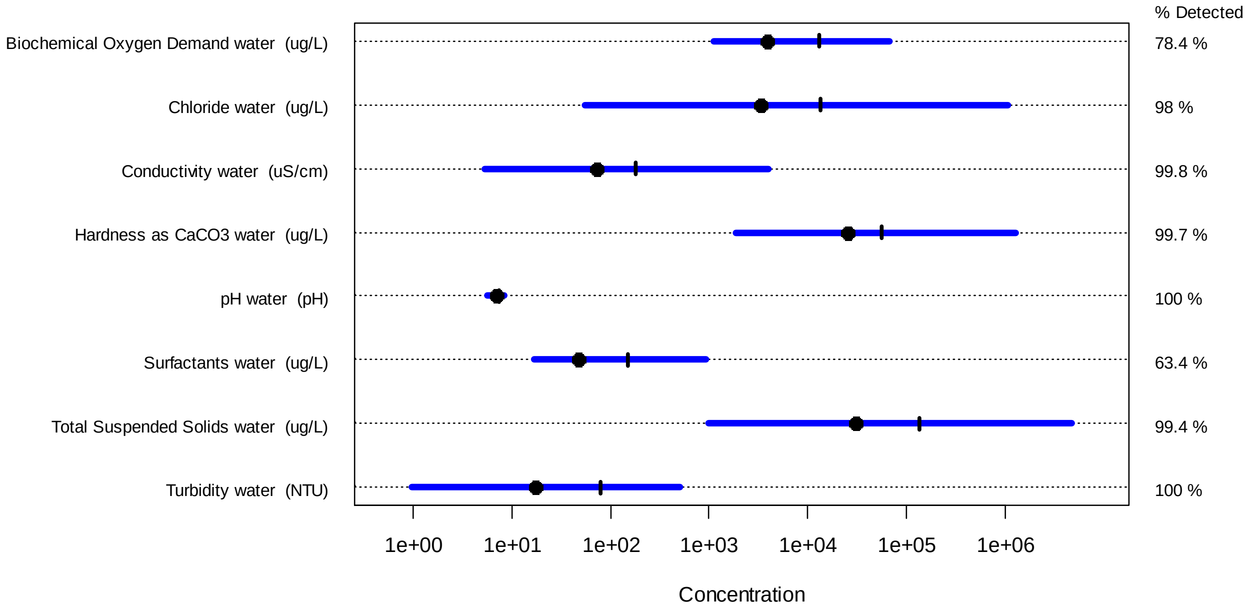

Figure 7. Summary of conventional parameters in water.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Fecal Coliform

Only 6.6% of the fecal coliform samples were below the detection limits, and the majority of these were in areas of low-density residential land use. Significantly lower fecal coliform counts were found in low-density residential land use (47 cfu 100 ml^{-1}), while none of the other land uses showed significant differences (Table 9). Fecal counts were also significantly higher during the dry season (1,220 cfu 100 ml^{-1}) compared with the wet season (300 cfu 100 ml^{-1}).

Table 9. Summary of fecal coliform bacteria data (cfu/100mL).

Land Use	Detected (%)	Count	Min	Max	Geometric mean	Arithmetic mean	SE	Median	90th percentile
Industrial	100	49	2	9.2×10^4	1,062	4,683	1,969	991	12,000
Commercial	96.8	251	1	1.1×10^6	442	7,198	4,392	515	6,900
High-density residential	94.3	157	2	1.6×10^5	260	3,631	1274	350	5,000
Low-density residential	80.6	103	1	1.6×10^4	40	675	209	47	1,600
Overall	93.4	560	1	1.1×10^6	264	4,778	2,009	350	5,400

SE = standard error of the arithmetic mean

The median values for fecal coliform were well below those observed from the NSQD; however, the ranges found in both studies overlapped. Seasonal data from NSQD (Pitt et al., 2004) also suggested that higher concentrations prevail during the summer and fall months. This is similar to the findings of the compiled permittee data set.

Surface water standards for fecal coliform apply to waters with a recreational intended use. For those waters in the secondary contact recreation category, fecal coliform counts cannot exceed a geometric mean of 200 cfu 100 ml^{-1}, with no more than 10% of the samples exceeding 400 cfu 100 ml^{-1}. Each land-use class, except low-density residential, exceeded the criteria (Table 9).

Conductance, Hardness, pH, and Chloride

Table 10. Summary of conductivity, hardness, pH, and chloride concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Conductance (uS cm^{-1})	99.8	5.3	72.3	4,020	yes	yes
Hardness (as ug L^{-1} $CaCO_3$)	99.7	1,900	25,200	1,300,000	yes	yes
pH	100	5.6	7.0	8.26	yes	no
Chloride (ug L^{-1})	98	55	3,300	1,080,000	yes	no

Conductance was significantly higher in discharges from industrial land-use areas (158 uS cm^{-1}; Appendix F). Interestingly, low-density residential land-use areas discharged runoff significantly higher in conductance (99 uS cm^{-1}) than commercial and high-density residential land-use areas. No real differences were found between dry and wet season samples.

Similar trends were found for both hardness (as CaCO3) and chloride concentrations. Chloride is regulated under the water quality standards. For chloride concentrations, 4 out of 551 samples exceeded (did not meet) the chronic water quality criteria for the protection of aquatic life. No samples exceeded the acute criteria.

The pH of the samples varied very little. The range of pH was 5.6 to 8.3 with a mean ± 95% confidence interval (CI) of 6.9 ± 0.03. Areas of high-density residential land use had slightly lower pH values. No significant differences between wet and dry seasons were found (Appendix F).

Surfactants and Biochemical Oxygen Demand (BOD)

Table 11. Summary surfactants and biochemical oxygen demand concentrations.

Parameter (ug L^{-1})	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Surfactants	63.4	17	47	920	yes	yes
BOD	78.4	1,100	3,900	68,000	yes	yes

Stormwater surfactant concentrations were strongly influenced by land use, where industrial and commercial land uses discharged comparable concentrations (63 ug L^{-1} and 64 ug L^{-1}, respectively) compared with significantly lower concentrations from high-density residential (36 ug L^{-1}) and low-density residential (14 ug L^{-1}) land-use areas. In low-density land-use areas, 70% of the samples were below the detection limit. Greater concentrations of surfactants were found during the dry season than the wet season (mean ± 95%CI; 114.5 ± 23.4 ug L^{-1} and 64.7 ± 7.0 ug L^{-1}, respectively).

BOD was detected in 78.4% of all samples. The vast majority of the non-detects occurred in discharges from the low-density residential land use (62.4% of the non-detects). Commercial land-use areas discharged the highest concentrations (5,600 ug L^{-1}). Higher BOD concentrations were found during the dry season (7,200 ug L^{-1}) compared with the wet season (3,600 ug L^{-1}).

BOD measurements in the NSQD were very similar in range to the data in this study, with commercial land uses discharging the highest concentrations. The median values for land-use categories were not as high as those in the NSQD. Surfactants were not quantified in other studies.

Turbidity and Total Suspended Solids (TSS)

Table 12. Summary of turbidity and total suspended solid concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Turbidity (NTU)	100	0.98	17.3	500	yes	no
TSS ($mg L^{-1}$)	99.4	1	31	4,700	yes	no

Significantly higher turbidity was found in industrial areas compared with the other land uses (34.5 NTU). Significantly higher TSS concentrations were also found in industrial land-use discharges (48 $mg L^{-1}$) when compared with low-density residential land-use areas (14 $mg L^{-1}$). No significant differences in turbidity or TSS were found between wet (17.9 NTU and 29.8 $mg L^{-1}$, respectively) and dry (15 NTU and 34.6 $mg L^{-1}$, respectively) seasons (Appendix F).

In comparison to the *PS Toxics Study*, TSS concentrations in this data set were similar for residential land uses but significantly higher for industrial land uses. Overall, across all land uses, the median TSS values were much higher than that reported for the receiving waters sampled in the *PS Toxics Study*. However, median TSS concentrations reported here were much lower than results reported in the NSQD and NURP but within the ranges reported in these databases.

Total Organic Carbon (TOC) and Grain Size in Sediment

Table 13. Summary of total organic carbon concentration in sediments.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
TOC (%)	100	0.002	11	68	yes	no

The TOC of sediment samples ranged from <1% to 68%, and generally varied very little among samples (median was 11; mean of 12.7 ± 1.2% standard error). Slightly higher concentrations of TOC were noted in samples from commercial land-use areas. Overall, stormwater sediment composition was 29.4% fines and 77.3% sand, median values for combined land uses (Table G-1). The sediment composition did not vary among the land uses.

Nutrients

Figure 8 summarizes the range, median, and 90th percentile for each nutrient parameter in stormwater.

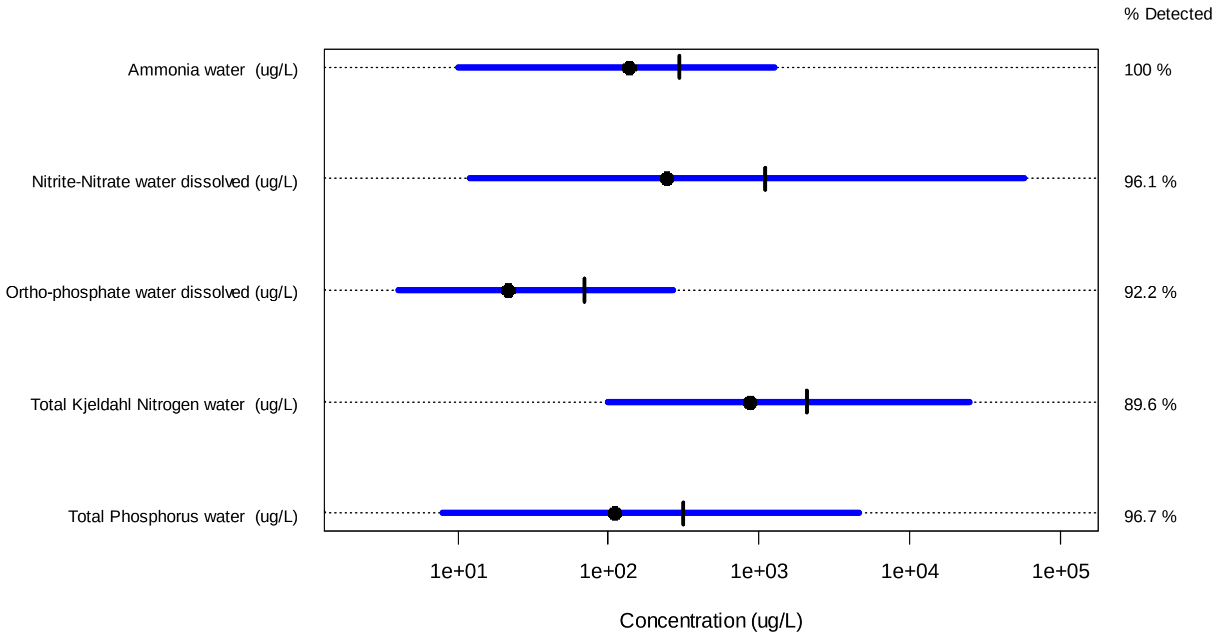

Figure 8. Summary of nutrient concentrations in water.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Phosphorus

Table 14. Summary of phosphorus concentrations.

Parameter (ug L^{-1})	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Orthophosphate	92.0	4	21.6	270	yes	yes
Total phosphorus	96.7	8	110.0	4,600	yes	yes

Phosphorus in water was measured as total phosphorus and orthophosphate, the dissolved, bioavailable fraction. Orthophosphate concentrations were significantly higher in stormwater from the low-density residential land-use areas (Appendix F). Significantly higher concentrations of orthophosphate were present during the dry season (26 ug L^{-1}) compared with the wet (20.7 ug L^{-1}).

Total phosphorus concentrations in the stormwater showed a different trend with the highest concentrations from industrial land-use areas (171 ug L^{-1}) and significantly lower concentrations from low-density residential land-use areas (90 ug L^{-1}). This trend could be related to a particulate form in the industrial discharge, as it follows the same trend as the concentrations for surfactants, turbidity, and TSS results. Total phosphorus had a median value of 110 ug L^{-1} for the combined land use (mean was 155 ug L^{-1}).

Ecology found total phosphorus concentrations in stormwater discharges were greater than the documented median for the *PS Toxics Study* but less than the concentrations in the NSQD and NURP databases. The land-use trends observed were also different from the *PS Toxics Study* where commercial and industrial areas had lower concentrations than residential and agricultural areas.

Nitrogen

Table 15. Summary of nitrogen concentrations.

Parameter (ug L^{-1})	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Kjeldahl N	89.6	100	863	25,000	yes	yes
Nitrite+nitrate N	96.1	12	245	58,000	yes	yes
Ammonia	100	10	136	1260	yes	yes

Nitrogen inputs were measured as total Kjeldahl nitrogen (TKN), nitrite+nitrate as nitrogen (NO_2+NO_3), and ammonia (NH_3). TKN is the sum of organic nitrogen, ammonia, and ammonium (NH_4). TKN was found at significantly lower concentrations in the low-density residential areas (600 ug L^{-1}) compared with other land-use areas (Appendix F). The dry season had higher TKN concentrations (1,300 ug L^{-1}) than the wet (800 ug L^{-1}).

Nitrite+nitrate concentrations were significantly greater in discharges from low-density residential land use, which was similar to the orthophosphate trends (Appendix F). Indeed, the nitrite+nitrate concentrations from both the high- (320 ug L^{-1}) and low-density residential land uses (510 ug L^{-1}) were higher than concentrations from the commercial (200 ug L^{-1}) and industrial (232 ug L^{-1}) land uses. Concentrations during the dry season were significantly higher (462 ug L^{-1}) than the wet season (213 ug L^{-1}) for nitrite+nitrate; however, a great deal of variability was found during the dry season (mean ± 95%CI was 493 ± 262 ug L^{-1}).

Ammonia was not a required parameter under the 2007 permit, but ammonia concentrations were reported by one permittee with 71 observations across three land uses. Significant lower concentrations were observed from industrial (190 ug L^{-1}) compared with commercial (123 ug L^{-1}) and high-density residential (85 ug L^{-1}) land uses. Samples displayed a strong difference between the dry season (163 ug L^{-1}) and the wet season (130 ug L^{-1}) (Appendix F).

Acute and chronic standards for the protection of aquatic life exist for ammonia, and these standards were not exceeded by any samples (Appendix G, Figures G1-G2).

TKN concentrations and ranges were very similar for all land uses to those reported in the NSQD (Pitt et al., 2004). Nitrite+nitrate concentration ranges were also similar to the NSQD, with the exception that residential land uses tended to have higher concentrations in this current study. In the NSQD, discharges from industrial land uses had higher nitrite+nitrate concentrations. Ecology found similar concentration ranges and trends across land uses to the NURP study (EPA, 1983). In comparison with the nitrite+nitrate concentrations observed in the *PS Toxics Study*, Ecology found much lower concentrations in waters discharged from residential land uses (~ 1000 ug L^{-1} in the *PS Toxics Study*). This finding suggests that dissolved nitrogen species were contributed from residential land uses via pathways other than stormwater drainage (e.g., groundwater). In commercial and industrial land-use areas, stormwater discharge and stormflow receiving water median concentrations in the *PS Toxics Study* were roughly similar.

Metals

Metals results in water are given in ug L^{-1}, also referred to as parts per billion (ppb). For stormwater sediments, the units are ug Kg^{-1}, which are also parts per billion (ppb). Figures 9 and 10 summarize the ranges and summary statistics (median and 90th percentile) for each metal parameter in stormwater and stormwater sediments, respectively. Metals concentrations in water and sediments across land uses showed similar trends, suggesting that the sediment serves as a representative sample of metals in the stormwater conveyance systems.

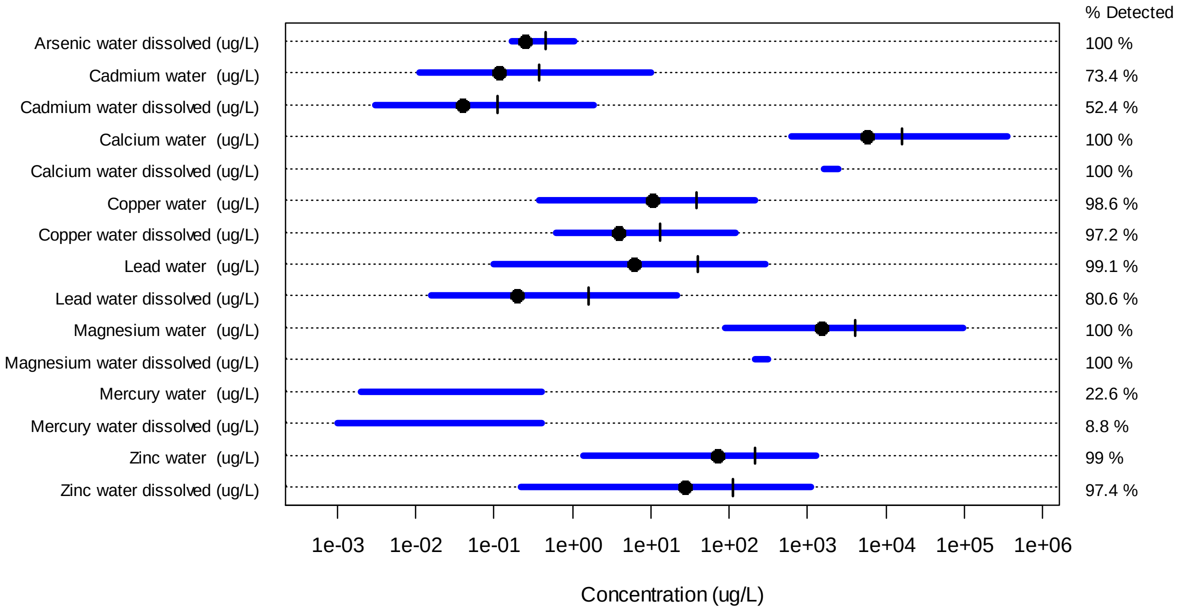

Figure 9. Summary of metals concentrations in water.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Arsenic

Table 16. Summary of dissolved arsenic concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Dissolved As (ug L^{-1})	100	0.17	0.25	1.04	NA	no

Dissolved arsenic was not a parameter required by the permit, but was reported by one permittee. Total arsenic was not measured in water or sediments. Dissolved arsenic (As) was detected in all of the 16 samples analyzed. All but one of these samples was collected from stormwater discharged from low-density residential land-use areas (Appendix F). Dissolved arsenic showed no differences between the wet and dry seasons. None of the measured concentrations exceeded the arsenic water quality criteria for the protection of aquatic life.

Dissolved arsenic concentrations in water from residential land uses sampled during the *PS Toxics Study* (0.60 ug L^{-1}) were twice the median concentrations found by the permittee. Concentrations of dissolved arsenic in the NSQD were considerably higher than observations in this current study (NSQD median = 1.5 ug L^{-1})

Cadmium

Table 17. Summary of cadmium concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Cd (ug L^{-1})	73.4	0.011	0.1	10.1	yes	yes
Dissolved Cd (ug L^{-1})	52.4	0.003	0.04	1.85	yes	yes
Cd in sediment (ug Kg^{-1})	90	0.78	819	4,900	yes	NA

Total cadmium showed clear differences among land uses (Appendix F). Areas of industrial land use discharged the highest median concentrations (0.22 ug L^{-1}) followed by commercial (0.17 ug L^{-1}), high-density residential (0.09 ug L^{-1}), and low-density residential (0.03 ug L^{-1}) land uses. Discharges from low-density residential land use had a 50% non-detect rate and fell into the Case B data classification for statistical analyses. No seasonal differences were found for total cadmium.

Dissolved cadmium showed a similar trend to total cadmium across land uses; however, a high rate of non-detect data made these interpretations more uncertain (Appendix F). Higher rates of non-detect also led to all but the commercial land use data being classified as Case B for statistical analyses. Sufficient sample numbers were attained for reliable summary statistics. No difference was noted between samples from the wet and dry seasons. Of the 635 samples analyzed for dissolved cadmium concentrations, two exceeded (did not meet) the acute water quality criteria and three exceeded the chronic criteria.

The median NSQD concentrations for both total and dissolved cadmium were much greater than concentrations observed in this study. Industrial land uses were also found to discharge the highest concentrations of cadmium in the NSQD. Concentrations found in the *PS Toxics Study* were much lower than those in this study. In fact, total cadmium measured during most storm events in the river systems had low rates of detection.

Cadmium concentrations in the sediment had a high rate of detection. Trends across the different land uses reflected those of the total cadmium in water, with significantly higher concentrations in the industrial and commercial catchments (Appendix F). Cadmium in stormwater sediments exceeded the SCO for 6% of the samples.

Copper

Table 18. Summary of copper concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Cu (ug L^{-1})	98.6	0.38	10.4	218	yes	yes
Dissolved Cu (ug L^{-1})	97.2	0.62	3.9	122	yes	yes
Cu in sediment (ug Kg^{-1})	100	156	81,000	1.26×10^6	yes	NA

Total copper median concentrations were statistically higher in discharges from industrial and commercial land uses (16.0 ug L^{-1} and 19.6 ug L^{-1}, respectively) compared with both high-density (7.7 ug L^{-1}) and low-density (2.8 ug L^{-1}) residential land uses (Table G-2 and Appendix F). Significantly higher concentrations were noted during the dry season (mean ± 95%CI; 25.7 ± 5.6 ug L^{-1}) compared to the wet season (14.7 ± 1.2 ug L^{-1}) (Table G-3).

Dissolved copper median concentrations were significantly different among all land uses; stormwater from commercial land use (6.25 ug L^{-1}) was statistically higher than the other land uses. Industrial (4.4 ug L^{-1}) and high-density residential (3.05 ug L^{-1}) land uses were quite similar, but stormwater discharged from low-density land use was significantly lower (1.84 ug L^{-1}) (Appendix F). Again, the dry season had statistically higher concentrations than the wet season across all land uses. 50% of the dissolved copper results exceeded the acute water quality target. 58% exceeded the chronic target.

Total and dissolved copper concentrations were similar to those reported in the NSQD. The *PS Toxics Study* found lower copper concentrations in waters from industrial and commercial land uses, but roughly similar concentrations in waters from residential land uses. Road systems are often implicated in contributions of copper to stormwater from brake pads and tires (McKenzie et al., 2009). This trend was evident in data from the NSQD. This stormwater data set may provide sufficient resolution to separate parking lots from the combined land uses; however, this was beyond the scope of this study and was not investigated.

Copper concentrations were detectable in all stormwater sediment samples. Similar to copper concentrations in water, significant differences were found in sediment samples between commercial and industrial land uses (157,000 ug Kg^{-1} and 114,000 ug Kg^{-1}, respectively) and between high-density (39,600 ug Kg^{-1}) and low-density residential land uses (15,000 ug Kg^{-1}). Copper in stormwater sediment exceeded the SCO for 9% of the samples (Figure G-3).

Lead

Table 19. Summary of lead concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Pb (ug L^{-1})	99.1	0.1	6.1	294	Yes	no
Dissolved Pb (ug L^{-1})	80.6	0.016	0.2	21.8	Yes	yes
Pb in sediment (ug Kg^{-1})	97.5	360	114,000	1.79×10^6	Yes	NA

Total lead concentrations were statistically different among the land uses: commercial (14.4 ug L^{-1}), industrial (7.94 ug L^{-1}), high-density residential (4.05 ug L^{-1}), and low-density residential 0.72 (ug L^{-1}). Commercial land use had statistically higher concentrations of total lead. Interestingly, the distribution of concentrations from high-density residential was similar to that of industrial land-use areas, above the 70th percentile (approximately 7 ug L^{-1}), but overall the distributions were statistically different ($p=0.003$) (Appendix F). No significant difference in total lead concentrations was found between wet and dry seasons.

Dissolved lead in stormwater had a high non-detect rate, although this varied across land uses. Commercial land use had statistically higher dissolved lead concentrations. High-density residential and industrial land use did not have significantly different dissolved lead concentrations. Industrial, high-density residential, and low-density residential land use had between 25 to 33% non-detects (Appendix F).

Dissolved lead trends across land uses were similar to those observed for total lead. Commercial (0.32 ug L^{-1}) and industrial (0.25 ug L^{-1}) land uses discharged higher concentrations than high-residential (0.17 ug L^{-1}) and low-residential (0.065 ug L^{-1}) land uses. The higher frequency of non-detect data added uncertainty to the trends across land uses. Dissolved lead concentrations appeared to be higher during the dry season. Two samples for dissolved lead exceeded the acute water quality criteria (< 0.5%), but 173 exceeded the chronic criteria (28%).

Lead concentrations in this data set were generally lower than in the NSQD, but much higher than the in-stream concentrations found in the *PS Toxics Study*. Activities in commercial and industrial land uses have been highlighted as the major contributors of lead in all studies.

Lead concentrations in sediment samples followed similar trends as the water samples across land uses (Appendix F). Only two samples had non-detect lead concentrations. Detected concentrations ranged from 360 to 1.79×10^6 ug Kg^{-1} with a median of 114,000 ug Kg^{-1}

(Figure 10). Lead in stormwater samples exceeded the SCO for 18% of the samples (Figure G-3).

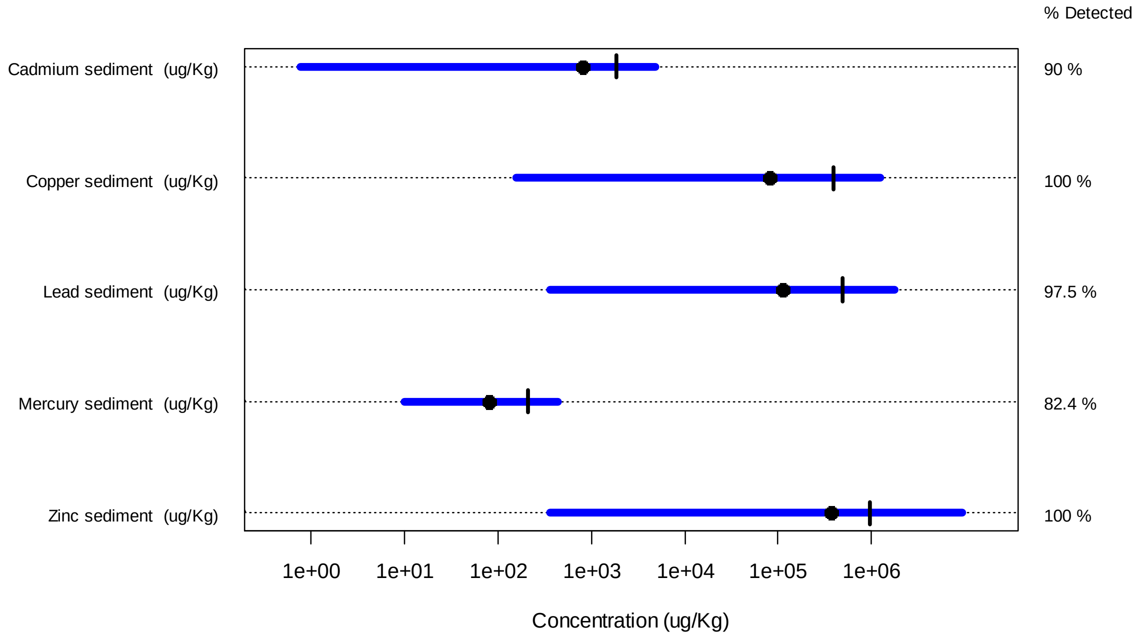

Figure 10. Summary of metals concentrations in stormwater sediment.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Mercury

Table 20. Summary of mercury concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Hg (ug L^{-1})	22.6	0.002	0.01	0.4	NA	no
Dissolved Hg (ug L^{-1})	8.8	0.001	NA	0.4	NA	NA
Hg in sediment (ug Kg^{-1})	82.4	10	80	442	yes	NA

Total and dissolved mercury concentrations in stormwater were not frequently detected. Overall, total mercury was classified as Case B for statistical analyses. When detected in stormwater, total mercury was primarily measured in samples from commercial land-use areas (median 0.01 ug L^{-1}) and, to a lesser extent, in samples from high-density residential land-use areas (0.028 to 0.30 ug L^{-1}). The chronic water criteria, 0.012 ug L^{-1}, was frequently less than the detection limit for total recoverable mercury achieved for these samples (ranging from

0.02 to 0.2 ug L^{-1} depending on the lab). As such, the total mercury results cannot be effectively evaluated against known criteria.

Dissolved mercury results were classified as Case C. No samples exceeded the acute water quality target.

Total mercury concentrations in water from the *PS Toxics Study* were an order of magnitude lower than in this study (median combined land use was 0.008 ug L^{-1}). Total mercury in the NSQD had a median concentration set near the detection limit, which is not an accurate description of environmental concentrations. Therefore, concentrations appeared similar across land uses.

Mercury was detected in sediments at a much higher frequency compared to water. Concentrations of mercury in sediments from commercial (130 ug Kg^{-1}) and industrial (71 ug Kg^{-1}) land uses were significantly higher than concentrations from high-density (31.1 ug Kg^{-1}) and low-density (27 ug Kg^{-1}) residential land uses. The comparisons are less certain due to the greater proportion of non-detects from residential land uses. None of the samples analyzed for mercury in sediments exceeded the SMS levels.

Mercury appears to be found in localized areas and does not appear to be a widespread contaminant in western Washington stormwater.

Zinc

Table 21. Summary of zinc concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total Zn (ug L^{-1})	99.0	1.4	70.6	1,290	yes	yes
Dissolved Zn (ug L^{-1})	97.4	0.22	26.9	1,090	yes	yes
Zn in sediment (ug Kg^{-1})	100.0	366	373,000	9.25×10^6	yes	NA

Total zinc concentrations (median values) in stormwater collected from commercial (102 ug L^{-1}) and industrial (123 ug L^{-1}) land uses were not significantly different (p=0.08). Total zinc concentrations from high-density residential land-use areas (41.2 ug L^{-1}) were significantly lower, as were those from low-density residential land-use areas (13.7 ug L^{-1}) (Appendix F). This was similar to the trend found for copper concentrations. Significantly higher concentrations were detected during the dry season (mean ± 95%CI; 171.4 ± 41.6 ug L^{-1}) than the wet season (86.9 ± 8.0 ug L^{-1}).

Trends for dissolved zinc concentrations were similar across land uses to those found for total zinc (Table 21; Appendix F). Dissolved zinc concentrations were also significantly higher during the dry season than during the wet season. 36% of the samples exceeded the acute water quality criteria and 40% exceeded the chronic criteria.

Zinc concentrations from this study had considerably higher median concentration (5-10 times) than reported by the *PS Toxics Study*. Zinc concentrations were within similar ranges compared with the NSQD. In this study and both the *PS Toxics Study* and the NSQD, the highest concentrations were found in areas of industrial land use.

Zinc concentrations in sediment followed a trend similar to those in water. Zinc in stormwater sediments exceeded the SCO for 1% of the samples.

Hydrocarbons

TPH

Table 22. Summary of total petroleum hydrocarbon concentrations.

Parameter ($\mathrm{ug\ L^{-1}}$)	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
TPH-Dx	72.7	14	433	12,100	yes	yes
TPH-Gx	10.4	11	NA	395	NA	NA
Diesel range organics	57.5	13	130	4,900	yes	yes
Lube oil	41.6	194	207	1,550	NA	no
Motor oil	81.9	200	930	5,800	yes	no

Gasoline range total petroleum hydrocarbons (TPH-Gx) were detected at a low frequency. These data were classified as a Case C for statistical analyses. TPH-Gx is composed of volatile compounds. Insufficient numbers of detections were available to describe any differences among land uses or across seasons.

The diesel range hydrocarbon (TPH-Dx) analysis sums multiple hydrocarbon fractions (lube oil, motor oil, diesel fuel, and diesel range organics). Hydrocarbon fractions have variable rates of detection (Table 22). Significantly higher TPH-Dx concentrations were observed in stormwater from industrial and commercial land uses (890 ug $\mathrm{L^{-1}}$ and 870 ug $\mathrm{L^{-1}}$, respectively) compared with high-density (320 ug $\mathrm{L^{-1}}$) and low-density (113 ug $\mathrm{L^{-1}}$) residential land uses. A greater proportion of non-detects were found in samples collected from residential land uses. TPH-Dx concentrations were significantly greater during the dry season (840 ug $\mathrm{L^{-1}}$) than the wet season (390 ug $\mathrm{L^{-1}}$).

Looking more closely at the components of TPH-Dx, the trends in land use were driven largely by the diesel range organics. Lube oil was not reported separately in industrial samples and was only detected in commercial samples (Appendix F). Motor oil was not reported in low-density residential samples but had a high rate of detection in other land uses. Discharges from industrial land uses were the major contributor of motor oil (1400 ug $\mathrm{L^{-1}}$), followed by those from high-density residential land use (950 ug $\mathrm{L^{-1}}$) and then commercial land uses (620 ug $\mathrm{L^{-1}}$). Each of these differences was significant. Interestingly, the concentrations for each land use at the higher end of the ranges (> 80th percentile) were very similar. No statistical difference was found between contributions of motor oil during the dry season (980 ug L^{-1}) compared with the wet season (910 ug L^{-1}).

TPH-Dx was measured in the *PS Toxics Study,* and concentrations were considerably lower. With the exception of those from commercial and industrial land uses, median concentrations from other land uses were only estimates. Concentrations in commercial and industrial land uses in this study were an order of magnitude greater than those in the *PS Toxics Study*.

It is difficult to comment on any trends for TPH in sediments, as sample numbers were low. Appendix F and Table 22 provide the available data for the parameters. Concentrations of heavy fuel oil and diesel range organics suggested that greater concentrations were prevalent in sediments from commercial and industrial land uses.

BTEX

Table 23. Summary of BTEX concentrations.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
BTEX (ug L^{-1})	2.5	1.1	NA	6.4	NA	NA

Benzene, toluene, ethylbenzene, and xylenes (BTEX) were measured in 120 water samples and detected in only three samples. Benzene was detected once, ethylbenzene was not detected, toluene was detected three times, and total xylenes were sufficiently detected in one sample. The volatile nature of these compounds is the reason for the low detection rates. Continued monitoring for BTEX in stormwater samples does not appear to be cost-effective.

PAHs

Polycyclic Aromatic Hydrocarbons (PAHs) are cyclic compounds with various numbers of six-carbon rings. PAHs vary in volatility and rates of detection in stormwater samples. Half the individual PAHs were classified as Case B for statistical analysis, due to low detection rates but adequate numbers of samples to reliably summarize the data (Table 24). Only three PAH compounds had a high enough detection frequency to be classified as Case A: fluoranthene, phenanthrene, and pyrene. Fluoranthene concentrations were significantly higher in stormwater discharged from commercial land-use areas. No other significant differences were found among the remaining land-use types (Appendix F). Higher concentrations were discharged during the dry season (mean; 0.8 ug L^{-1}) than the wet season (0.4 ug L^{-1}). Phenanthrene and pyrene had very similar trends across the land uses; seasonal differences were weak to non-existent.

Low molecular weight PAH concentrations were summed and reported as LPAH. High molecular weight PAHs were summed and reported as HPAH. Likewise, the carcinogenic PAHs (cPAH) and total PAHs were summed and reported (Table 24; Figure 11). All PAH sums had similar trends across land uses, where commercial land-use discharges had statistically higher concentrations than the other land uses ($p<0.001$). In the case of cPAHs, there was no significant difference between high-density residential and industrial land use ($p=0.17$). No seasonal differences existed for the summed concentrations.

Table 24. Summary of individual PAHs in stormwater (ug L^{-1}).

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
1-Methylnaphthalene	3.8	0.100	-	1.6	NA	NA

PAH Sums						
LPAH	61.4	0.021	0.162	172.5	yes	no
HPAH	67.3	0.012	0.110	154.3	yes	no
cPAH	51.6	0.004	0.044	83.3	yes	no
Total PAH	98.8	0.021	0.162	172.5	yes	no

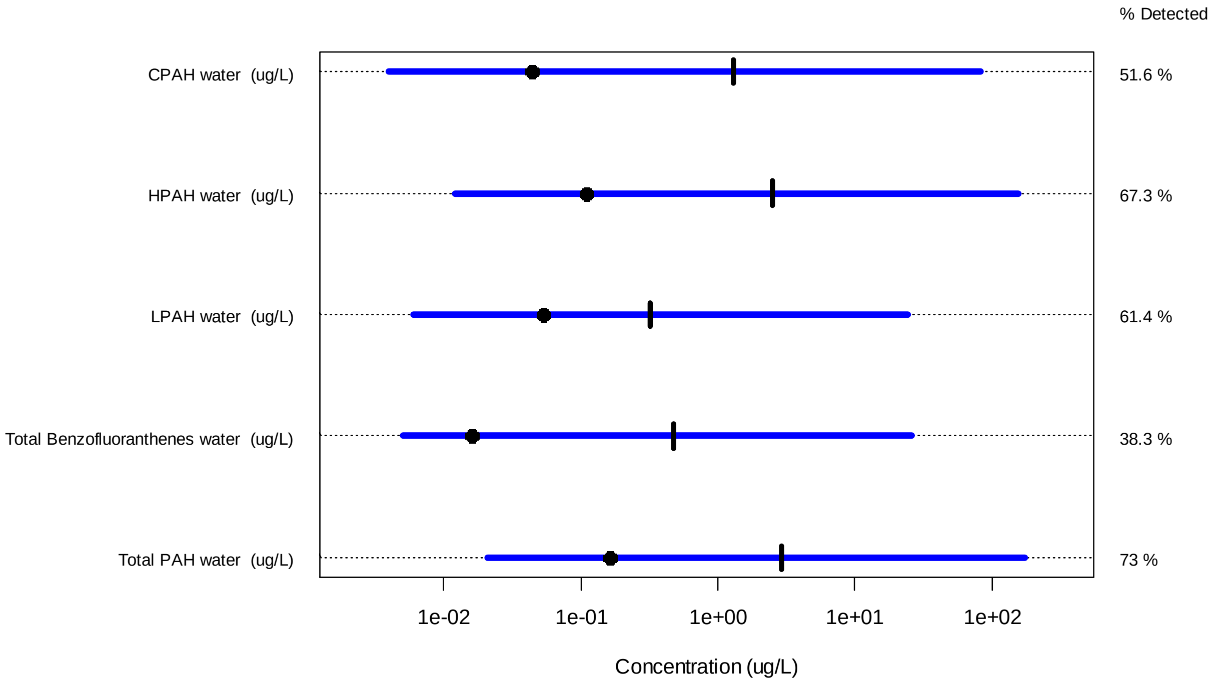

Figure 11. Summary of total PAH concentration sums in water.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Total PAHs all had sufficient levels of detection to be classified Case A data for statistical analyses. Median total PAH concentrations in stormwater discharges from commercial and industrial land uses were found to be 0.53 and 0.11 ug L^{-1}, respectively.

Median concentrations from areas of commercial land use were substantially higher (22 times) than concentrations reported in the *PS Toxics Study* (0.18 ug L^{-1}). Concentrations of individual PAH compounds had low rates of detection in NSQD, similar to this study. However, median concentrations of detected fluoranthene, phenanthrene, and pyrene were two orders of magnitude higher in the NSQD compared with this study.

PAHs were detected much more frequently in stormwater sediments than in stormwater discharges (Table 25; Figure 12). Most individual PAH compounds were classified as Case A data for statistical analyses. Overall, the trends across land-use types followed those observed in the water samples. Runoff from areas of commercial land use had significantly higher concentrations than runoff from the other land uses. Concentrations in discharges from industrial and high-density residential land uses did not differ greatly, while discharges from low-density residential land-use areas were significantly lower (Appendix F). 34% of the stormwater sediment samples exceeded the SCO criteria.

Table 25. Summary of individual PAHs in stormwater sediments (ug Kg^{-1}).

Parameter	% detected	Minimum	Median	Maximum	Land-use differences
1-Methylnaphthalene	40.4	1.07	6	870	yes
2-Methylnaphthalene	47.4	1.12	13	1,500	yes
Acenaphthene	54.4	8.70	34	8,900	yes
Acenaphthylene	32.9	15.80	28	3,600	yes
Anthracene	73.4	17.00	131	33,000	yes
Benz(a)anthracene	88.4	9.40	800	210,000	yes

cPAH	93.9	1.07	3130	1,453,000	yes
Total PAH	98.8	4.10	6728	2,990,960	yes

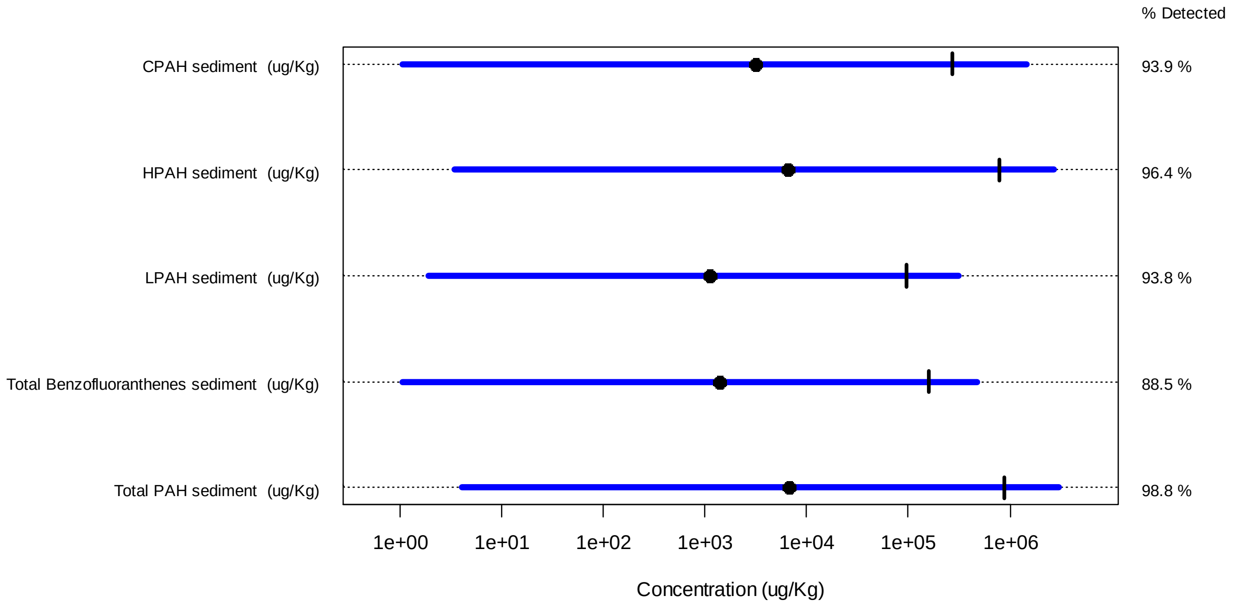

Figure 12. Summary of total PAH concentration sums in stormwater sediment.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis.

Phthalates

Many of the analyzed phthalates had low rates of detection (Table 26), with one exception. Bis(2-ethylhexyl) phthalate had a detection frequency of 61.9%. Bis(2-ethylhexyl) phthalate showed a significant difference across land uses; commercial land-use areas discharged greater concentrations than other areas. Industrial and high-density residential land-use areas discharged similar concentrations, and low-density residential areas discharged significantly lower concentrations. Both residential areas had much lower rates of bis(2-ethylhexyl) phthalate compound detection.

A similar trend across land uses was observed for butyl benzyl phthalate and dibutyl phthalate. Diethyl phthalate did not show differences across land uses, but this was not assessed, given the high rates of non-detection (Appendix F). Diethyl phthalate was more frequently detected in residential samples and had higher concentrations during the wet season, though not significantly higher. No seasonal differences were observed for any of the other phthalates.

Table 26. Summary of phthalates in stormwater (ug L^{-1}).

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Bis(2-ethylhexyl) phthalate	61.9	0.150	0.977	41.4	yes	no
Butyl benzyl phthalate	22.6	0.022	0.0995	2.82	NA	no
Di-N-Octyl Phthalate	11.2	0.018	-	3.19	NA	NA
Dibutyl phthalate	31.8	0.024	0.1128	5.08	NA	no
Diethyl phthalate	30.6	0.026	0.1325	8.9	NA	no
Dimethyl phthalate	14.8	0.025	-	2.8	NA	NA
Sum						
Total phthalates	76.5	0.032	1.1600	41.4	yes	no

This study found much higher rates of detection but lower concentrations for bis(2-ethylhexyl) phthalate than did the NSQD. The *PS Toxics Study* reported rates of detection similar to those found in this study for commercial and industrial land uses. Bis(2-ethylhexyl) phthalate concentrations found in river systems (*PS Toxics Study)* were much lower than concentrations found in stormwater in this study.

The median sediment concentrations were calculated for four of the phthalates (Table 27). Bis(2-ethylhexyl) phthalate and benzyl butyl phthalate (Table 27) were found highest in discharges from industrial land-use areas, followed by commercial, high-density residential, and low-density residential land-use areas. The differences among land uses were significant (Appendix F). This finding is similar to results for water samples. Bis(2-ethylhexyl) phthalate and di-n-octyl phthalate exceeded the SCO in 82% and 29% of samples, respectively.

Table 27. Summary of individual phthalates in stormwater sediments (ug Kg^{-1}).

Parameter	% detected	Minimum	Median	Maximum	Land-use differences
Bis(2-ethylhexyl) phthalate	92.7	22	4,800	34,000	yes
Butyl benzyl phthalate	56.1	22	96	60,000	yes
Di-N-Octyl Phthalate	28.6	116	31	10,000	NA
Dibutyl phthalate	28.1	16	16	2,070	NA
Diethyl phthalate	5.4	81	-	123	NA
Dimethyl phthalate	19.6	28	-	628	NA
Sum					
Total phthalates	88.1	22	3,970	94,000	yes

Pesticides

The pesticides 2,4-D, chlorpyrifos, diazinon, malathion, mecoprop, phenol and p-cresol, prometon, and triclopyr were sampled but infrequently detected in stormwater. Summary statistics were not calculated for these. Only two of the 11 pesticides had rates of detection high enough to justify statistical analysis (Table 28; dichlobenil and pentachlorophenol).

Table 28. Summary of pesticides in stormwater.

Parameter ($ug\ L^{-1}$)	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Dichlobenil	35.8	0.012	0.024	1.3	yes	no
Pentachlorophenol	25.4	0.02	0.06	5.1	yes	no
Diazinon	1.0	0.026	NA	0.53	NA	NA
2,4-D	16.9	0.02	NA	28.4	NA	NA
Triclopyr	11.0	0.02	NA	18.3	NA	NA

For an herbicide, dichlobenil, concentrations were highest in discharges from high-density residential land-use areas followed by concentrations in discharges from commercial and industrial land uses. Samples from low-density residential land uses had very low rates of detection (two of 113 samples). No differences in dichlobenil concentrations were found between wet and dry seasons, suggesting either a year-round application of the herbicide or a year-round runoff from soil residuals.

Pentachlorophenol is used as both an herbicide and insecticide. Most of the pentachlorophenol detections and highest concentrations were in discharges from areas of commercial land use. Similar concentrations of pentachlorophenol were measured throughout the year. None of the analyzed samples exceeded the acute and chronic criteria for the protection of aquatic life (Appendix G, Figures G-1 and G-2).

Concentration ranges are provided in Table G-1. Two sample results for diazinon exceeded the acute and chronic criteria for the protection of aquatic life.

Higher frequencies of detection were found for diazinon and 2,4-D in the NSQD study. Despite poor detection overall, triclopyr detection rate and concentrations were much higher in this study than in storm-event samples collected in the *PS Toxics Study*, which evaluated agricultural land uses.

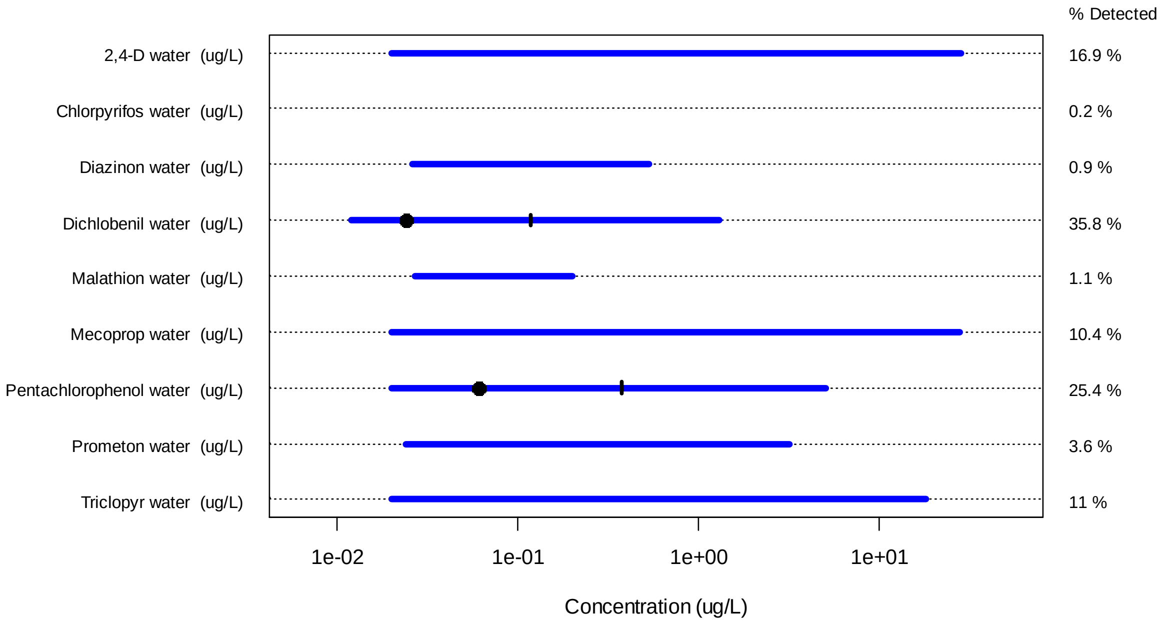

Figure 13. Summary of pesticide concentrations in stormwater.

Blue horizontal segment is the contaminant range, black dot is the median concentration, vertical black segment is the 90th percentile concentration. The x-axis is logarithmic. The rate of detection for each parameter is listed on the secondary y-axis. If no statistical summaries are presented the data are largely non-detect.

Pesticides in sediments also had very low rates of detection. Diazinon, chlorpyrifos, and malathion were detected in only 1 sample out of 53. Phenolics were the only chemical group with a sufficient amount of detected results to provide a summary. Pentachlorophenol and its degradation product, p-cresol, appeared to have higher concentrations in sediments sampled from commercial land-use areas. Concentrations of p-cresol were also high in discharges from high-density residential land-use areas. Other phenolics (2,4-dichlorophenol, 2,4-dimethylphenol, 2,4,5-trichlorophenol, 2,4,6-trichlorophenol, 4-chloro-3-methylphenol, 4-nitrophenol, phenol) and the remaining pesticides (2,4-D, dichlobenil, mecoprop, prometon, and triclopyr) were detected infrequently in most cases (5 - 10% of the samples). Pentachlorophenol in stormwater sediments exceeded the SCO for 1% of the samples. Phenol (Figure G-3) in stormwater sediments exceeded the SCO for 20% of the samples.

Table 29. Summary of pesticides concentrations in stormwater sediments.

Parameter (ug Kg^{-1})	% detected	Minimum	Median	Maximum	Land-use differences
Pentachlorophenol	24.7	7.8	11.2	17,800	NA
p-cresol	76.7	2.46	180	24,100	yes

PCBs

The permit only required monitoring polychlorinated biphenyls (PCBs) once annually in stormwater sediment samples; however, at least one permittee reported PCB monitoring results for stormwater samples across land uses as well. PCBs were measured as Aroclors in water and sediments. Only 27 stormwater samples were analyzed, and no samples were obtained from low-density residential land-use areas. Only 1 of 9 samples from high-density residential sites had a detected concentration, while all 8 samples from areas of commercial land use had detected Aroclor 1254 concentrations. Insufficient samples were collected for total PCBs to assess seasonal differences.

Table 30. Summary of total PCB concentrations in stormwater and stormwater sediments.

Parameter	% detected	Minimum	Median	Maximum	Land-use differences	Seasonal differences
Total PCBs[1] (ug L^{-1})	55.6	0.01	0.011	0.096	NA	NA
Total PCBs[1] (ug Kg^{-1})	51.5	8.5	9.6	770	NA	NA

[1] Sum of detected Aroclors (only 1248, 1254 and 1260)

PCBs in sediments were measured in 33 samples; however, detected concentrations were found only in samples from commercial and industrial land-use sites. One sample from a high-density residential site had detected concentrations. None of the measurements on individual Aroclors had a sufficient number of detected concentrations to summarize.

Contaminant Concentrations - Summary of Findings

Based on contaminant concentrations measured in stormwater discharges across multiple land uses, several major findings are worth highlighting as we move on to discuss land uses and seasonal differences more directly.

- The following parameters had high frequencies of detection and therefore were classified as Case A for statistical analyses:
  - Conventional parameters
  - Metals except mercury
  - Nutrients
  - PAH sums and TPH-Dx
  - PCB Aroclor 1254
  - Bis(2-ethylhexyl) phthalate

- All parameters with high frequencies of detection exhibited statistically different concentrations across land uses. Land use is discussed in detail in the next section of the report.

- Strong evidence exists for discharge of higher contaminant concentrations in stormwater during the dry season (May to September). This suggests the influence of a buildup/wash off relationship, particular to the first dry-season storm events for the following parameters:
    - Conventional parameters: conductivity, hardness, surfactants, BOD
    - Nutrients: all monitored
    - Total and dissolved cadmium, copper, and zinc
    - Dissolved lead
    - TPH-Dx
    - Organics: bis(2-ethylhexyl) phthalate and p-cresol

- For most parameters, stormwater sediment concentrations showed the same trends across land uses as those measured in water samples. Insoluble parameters in sediments had much better detection rates than those in water.

- Nutrients: Ortho-phosphate and nitrite+nitrate were found at higher concentrations in discharges from low-density residential land-use areas. Total nitrogen and phosphorus were highest in discharges from industrial and commercial land-use areas. Significantly higher nutrient concentrations were found during the dry season than the wet season.

- Metals: Commercial and industrial land uses discharged stormwater with comparable concentrations for zinc and copper. These frequently exceeded (did not meet) the water quality criteria. Areas of commercial land use discharged lead and mercury at statistically higher concentrations than other land uses. Areas of industrial land use discharged statistically higher cadmium concentrations. Statistically higher concentrations of zinc and copper were found during the dry season across all land uses.

- PAHs: No seasonal difference in PAH concentrations were found. Stormwater from commercial land-use areas routinely contained the highest concentration of PAHs.

- Total Petroleum Hydrocarbons: Diesel range (TPH-Dx) was discharged at significantly higher concentrations in stormwater from commercial and industrial land uses during the dry season. The motor oil component of TPH-Dx was generally observed at significantly higher concentrations in discharges from industrial land uses (median concentration). However, the higher concentrations (> 80th percentile) did not differ among industrial, commercial, and high-density land use. No seasonal differences were observed. TPH-Gx had very low rates of detection, and BTEX compounds were almost always below detection limits.

- Pesticides: Few samples had detected concentrations of pesticides. Dichlobenil was found at the highest concentrations in stormwater from areas of high-density residential land use throughout the year. Areas of commercial land use contributed stormwater with the highest pentachlorophenol concentrations throughout the year.

Land Use Significance

Peto-Prentice Test

Significant differences among land uses for each of the parameters were tested using the Peto-Prentice test, described in the *Methods* section under *Descriptive Statistics*. We found statistically significant differences among land uses for all parameters detailed in Table 31. The Peto-Prentice test indicates that at least one of the land uses was significantly different from the others, but it does not list exactly which ones differ.

Land uses were separated into two categories for the Peto-Prentice test results: dominant and minor (Table 31). Dominant land use refers to the land use that has the highest concentrations and is the major contributor of the parameter. Minor land use has the lowest concentrations and contributes the least. The determination of major and minor land uses was based subjectively on the Peto-Prentice density functions, as detailed in Appendix F. The reason for defining the major and minor land use for each parameter is to aid in prioritizing the contributions by land use. Reference Table G-3 provides "typical" concentrations for a specific contaminant across land uses.

Table 31. Case A parameters with evidence of differences in water contaminant concentrations by land use.

Parameter	Dominant Land Use	Minor Land Use
Conventionals		
Turbidity	industrial	low-density residential
TSS	industrial	low-density residential
BOD	commercial	low-density residential
Surfactants	industrial and commercial	low-density residential
Fecal Coliform	industrial, commercial, and high-density residential	low-density residential
Conductivity	industrial	commercial/high-density residential
Hardness	industrial	commercial/high-density residential
Chloride	industrial	commercial/high-density residential
Nutrients		
Orthophosphate	low-density residential	commercial/high-density residential
Total Phosphorus	industrial	low-density residential
TKN	industrial, commercial, and high-density residential	low-density residential
Nitrite+nitrate	low-density residential	commercial and industrial
Ammonia	industrial	high-density residential

Table 31 (continued)

Parameter	Dominant Land Use	Minor Land Use
Metals		
Cadmium (total and dissolved)	industrial	low-density residential
Copper (total and dissolved)	industrial and commercial	low-density residential
Lead (total and dissolved)	commercial	low-density residential
Mercury	commercial	low-density residential
Zinc (total and dissolved)	commercial and industrial	low-density residential
Hydrocarbons		
TPH-Dx	commercial and industrial	low-density residential
Diesel range organics	commercial and industrial	low-density residential
Motor oil	industrial	commercial
Fluoranthene	commercial	low-density/ high-density residential
Phenanthrene	commercial	low-density/ high-density residential
Pyrene	commercial	low-density/ high-density residential
CPAH	commercial	low-density/ high-density residential
LPAH	commercial	low-density/ high-density residential
HPAH	commercial	low-density/ high-density residential
Total PAHs	commercial	low-density/ high-density residential
Additional Organics		
Bis(2-ethylhexyl) phthalate	commercial	low-density residential
Dichlobenil	high-density residential	low-density residential
Pentachlorophenol	commercial	low-density residential

The differences among land uses for each parameter have been detailed previously in the discussion of contaminant concentrations. For some parameters, e.g., zinc, the major land-use type is different at low concentrations compared with high concentrations. In other words, at a median zinc concentration, commercial land uses contributed higher concentrations. In contrast, at the 90th percentile of the distribution of concentrations, high-density residential land uses contributed higher concentrations. This finding shows that the relationship of a particular contaminant to land use is not linear. There may be a steady discharge of a contaminant from one land-use type across sites and large variability in discharge across sites for another land-use type.

Principal Components Analysis

The Peto-Prentice test showed significant differences among land uses for individual parameters. We used multivariate statistics to decipher trends among the sample sites and parameters, combined. Using the variables from Table 31 in a principal components analysis (PCA), the distribution of sample sites relative to contaminant parameters can be plotted (Figure 14).
In Figure 14, the arrows represent concentration gradients of the parameters, and the points (circles and squares) represent sample sites. The arrow points to increasing concentration of that parameter, and parameters that had similar concentration trends across the sample sites are close together. Sample sites (points on Figure 14) that had similar stormwater chemistry are grouped together. Sample sites the arrows point to are sites that have high concentrations of these parameters.

The key observation from the PCA (Figure 14) is the general grouping of the sites (points) by land use, suggesting similar stormwater quality. For instance, all the low-density residential sites are grouped in the lower right quadrant of Figure 14. There is also considerable overlap for some sites. In particular, there is overlap between many commercial and high-density residential sites. This observation implies that stormwater chemistry from these land uses can be very similar. In addition, industrial sites do not group together and show more similarities to commercial and high-density residential sites.

The overlap of land uses is likely due to characteristics of the drainage area as described by the permittees (Table 1). For example, Pierce County high-residential site (PIEHIRES_OUT) appeared more similar to a low-density residential site (Figure 14). As shown in Table 1, PIEHIRES_OUT had a very low total impervious surface area, which could explain why the stormwater chemistry resembled the low-density residential sites.

By using multivariate statistics, we gained a greater understanding of how stormwater chemistry can be defined by land use; however, significant overlap or variability exists from site to site within the same land-use category.

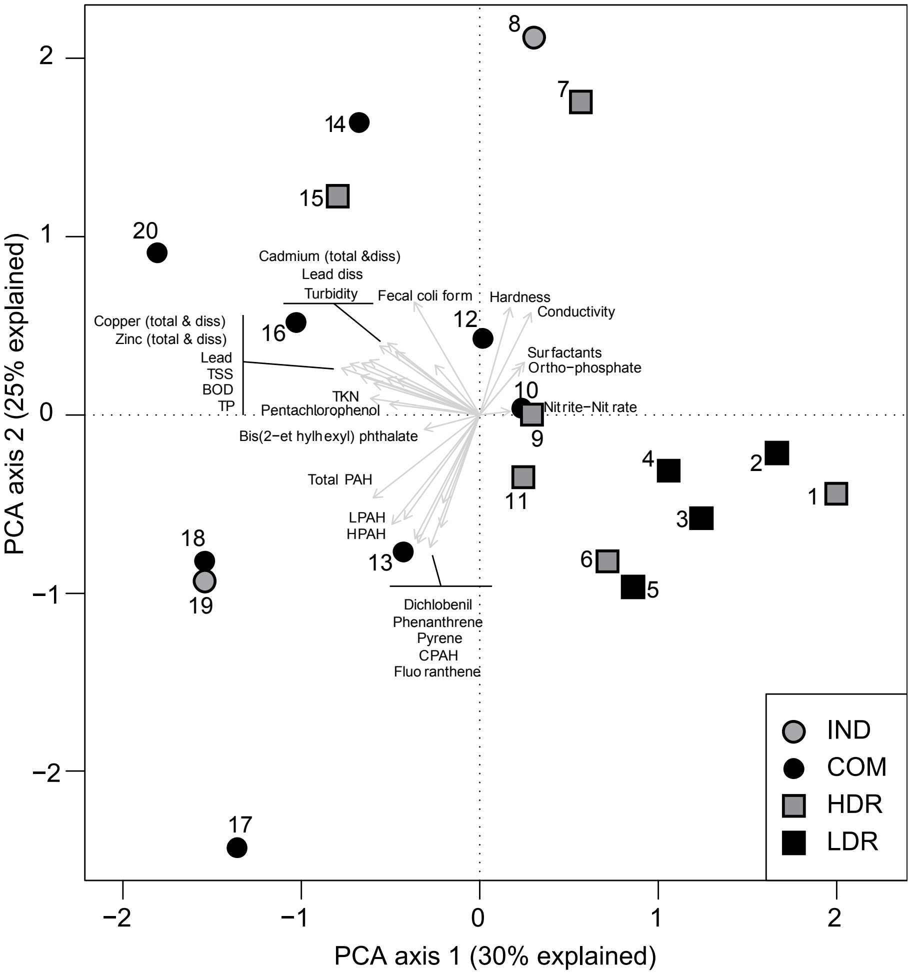

Figure 14. Principal components analysis of stormwater samples.

Biplot shows study sites (points) by land use and contaminant parameters (gray lines) that are statistically relevant across land uses. The amount of variation in the data explained by each axis is detailed in the axis titles.

Sediment concentrations observed in annual sediment samples from the basins strongly paralleled trends in water concentrations across the land uses. For example, those sites with high concentrations of metals in stormwater had high concentrations of metals in catch basin sediments. Similar to water samples, there is an overlap among land uses and variability from site to site within a land use (Figure 15). A significant amount of variation among sites can be explained by the first axis of the PCA (84%; axis 2 explains a further 8% of the variation). Overall, there was a significant difference among the land uses when analyzing all sites and all sediment contaminants (analysis of similarities p=0.004). Note that overall there were fewer parameters available for the sediment PCA compared with the water samples, but similar contaminant groups were represented (metals, phenols, and PAHs).

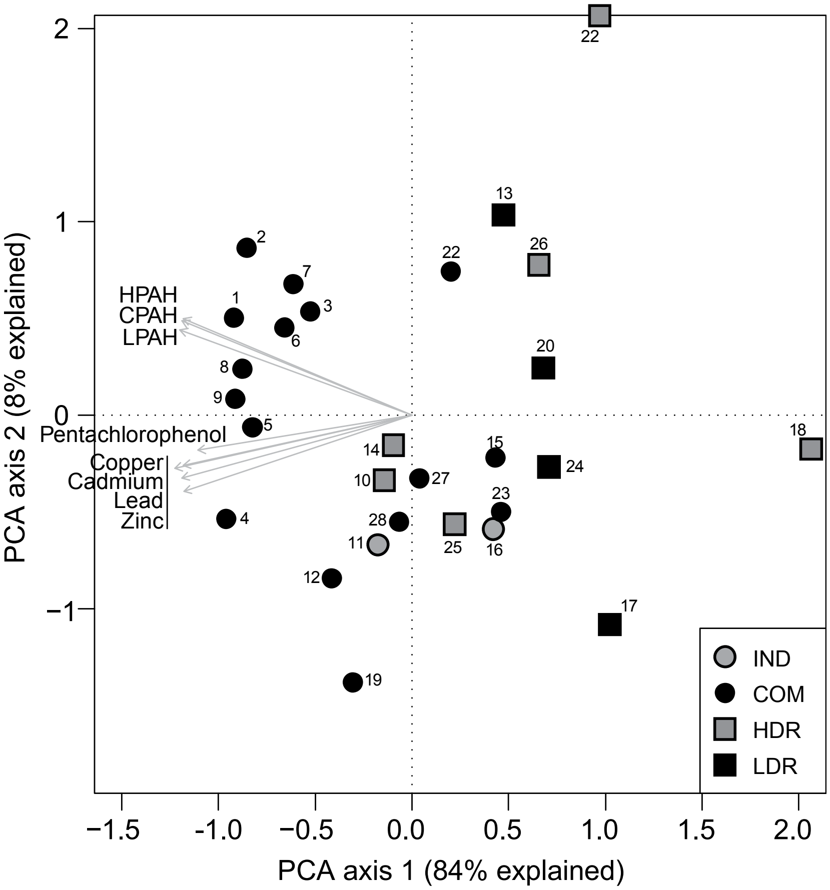

Figure 15. Principal components analysis of stormwater sediment samples

Biplot shows study sites (points) by land use and contaminant parameters (gray lines) that are statistically relevant across land uses. The amount of variation in the data explained by each axis is detailed in the axis titles.

The major difference among the sediment samples was that sediments from the Port of Seattle commercial sites (samples 1 through 9 on Figure 15) were very distinct from the others. Using a cluster analysis (described in the *Methods* section on *Multivariate Statistics*), we were able to define three main groupings of the sites, a "group" of sites having statistically similar sediment chemistry (Figure G-5). Each of these groups was a mixture of land uses, which is the same observation made from the PCA, where many land uses overlap. An example of this overlap is Group 2A in Figure G-5, which had a mixture of industrial (City of Seattle), commercial (City of Seattle, Pierce Co., Clark Co. and the City of Tacoma), and high-density residential sites (King Co. and City of Seattle). Therefore, similar conclusions to those made for the water concentration data can be drawn for sediments: there was considerable overlap in contaminant concentrations among land uses and high variability among sites within a land use.

Overall, the multivariate analysis for water and sediment samples suggests that defining a 'typical' sediment or water contaminant composition for a particular land use is unrealistic. However, this analysis was successful in showing that statistically significant differences exist among land uses over multiple sample sites and parameters.

Parameter Similarities

The grouping of parameters used in the PCA of water concentrations indicated that some parameters were closely related across the sites (Figure 14). This was determined visually by noting which arrows on the PCA plot (Figure 14) were closer together. Parameters that appeared to be positively correlated include:

- PAHs and dichlobenil
- copper, zinc, total lead, TSS, BOD, and total phosphorus
- cadmium, dissolved lead, and turbidity
- TKN and pentachlorophenol
- hardness, conductivity, surfactants, and ortho-phosphate

Nitrite+nitrate and bis(2-ethylhexyl) phthalate are inversely related. Fecal coliform is not strongly related to other parameters.

The apparent similarities among some parameters were related to land-use practices and reflected a common source. For instance, the main group of metals (defined as the second group listed above) was most strongly associated with two commercial sites (KICCOMS8D_OUT and SEAC1S8D_OUT). Also, this group was most weakly associated with residential sites.

The apparent similarities among some parameters could inform stormwater managers whether additional parameters need to be included in a monitoring program. For example, a program that monitors for PAHs may want to consider analyzing for dichlobenil. An additional example is the significant positive relationship between surfactants and ortho-phosphate ($p=0.01$). Further analysis of this relationship suggests that samples from commercial ($p<0.001$) and high-density residential land use ($p<0.001$) are the land uses with strong statistical significance. Surfactants also appear to have a strong relationship with dissolved copper and dissolved zinc in samples from commercial areas ($p<0.001$ in both cases), but not in residential areas. Surfactants do not appear to have any relationship with total suspended solids ($p=0.21$) or turbidity ($p=0.74$). This analysis highlights some of the potential this data set has for exploring relationships between key parameters.

Seasonality

The seasonality and "first flush" storm events are important characteristics for stormwater management. To truly capture first flush events, an instantaneous sample must be taken early in the storm (within approximately 30 minutes). It can then be compared with a composite sample from the same storm event. Few first flush samples from particular storm events were collected by the permittees. Thus, no conclusions can be drawn about the relative load of contaminants discharged during the initial hour of storm events. The dry season in the Pacific Northwest has long antecedent dry periods prior to storms; therefore, Ecology expected the dry-season storm events to exhibit higher contaminant concentrations.

To compare the seasonality of contaminant discharge during storm events, Ecology compared a wet and dry season. In reality, there was considerable overlap between the wet and dry seasons in western Washington (Figure 16). However a statistically significant difference existed between the volume of runoff generated in the two seasons (p = 0.009).

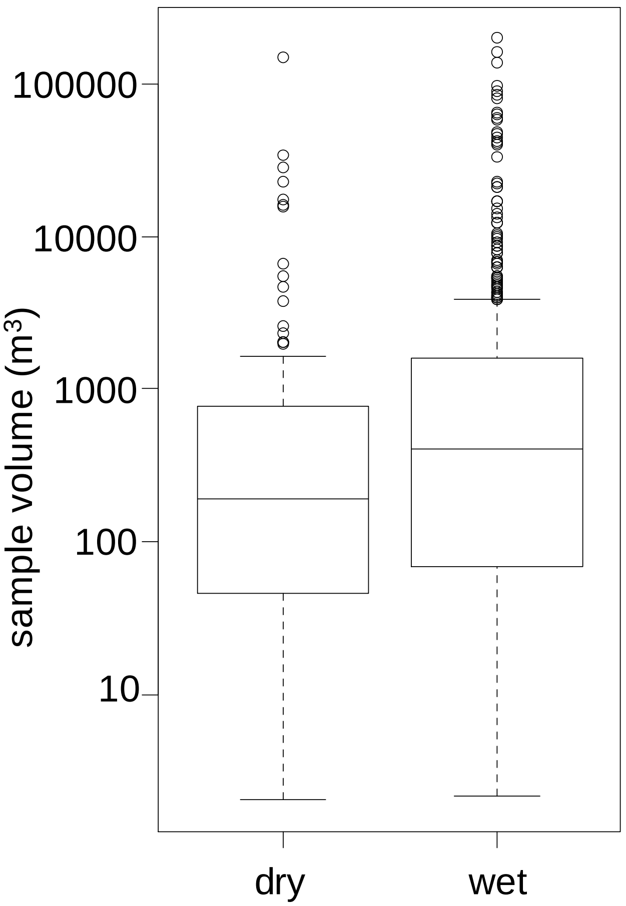

Figure 16. Box plot of measured storm volume (m^3) during the wet and dry season.

Median values is the solid black line within each box. Box extremities from bottom to top are the 10th, 25th, 75th, and 90th percentile.

For some parameters, significantly higher concentrations were measured in the dry season (Table 32). Metals concentration data show particularly strong differences between the seasons, with the exception of total lead (Appendix F). The possible mechanisms for seasonal differences are: (1) a reduction in water volume with a similar contaminant mass throughout the year or (2) greater contaminant contributions during the dry season. Figure 16 suggests that the difference in concentrations between seasons was due to a smaller dry-season storm volume. Yet, when Ecology assessed mass loads of the contaminants per storm event (kg per storm event), which normalized the data, the same group of parameters exhibited seasonal differences. In reality, both of these mechanisms likely contributed to greater contaminant concentrations during the dry season.

A further analysis of concentrations and loads compared to the antecedent dry-period length is a natural next step. Unfortunately, Ecology did not require antecedent dry period data to be submitted to EIM; therefore, the analysis could not be conducted.

Table 32. Seasonality of stormwater concentrations.

Conventional Parameters	Nutrients	Metals	Hydrocarbons	Pesticides	Phthalates	PCBs
Significant seasonal difference						
BOD Surfactants Fecal coliform Conductivity Hardness as CaCO3 Turbidity	Total phosphorus Ortho-phosphate TKN Nitrite+nitrate Ammonia	Cadmium (total and dissolved) Copper (total and dissolved) Lead (dissolved) Zinc (total and dissolved) Mercury	TPH-Dx Diesel Range Organics Fluoranthene Heavy Fuel Oil Pyrene	none	none	none
No seasonal difference						
pH Total suspended solids	none	Lead (total)	Benz(a)anthracene Benzo(a)pyrene Benzo(b)fluoranthene Benzo(k)fluoranthene Benzo(b,k)fluoranthene Benzo(g,h,i)perylene Indeno(1,2,3-cd)pyrene CPAH HPAH LPAH Lube Oil Motor Oil Phenanthrene Total PAH Total TPH-Dx	Dichlobenil Pentachlorophenol Phenol	Bis(2-ethylhexyl) phthalate Dibutyl phthalate Diethyl phthalate Total Phthalate	PCB-Aroclor 1254 PCB-Aroclor 1260 Total PCB

Findings in this study that the dry-season contaminant concentrations were significantly higher for *some* of the parameters was consistent with findings from the NSQD which show that first flush events were detectable for some parameters predominantly in areas of commercial and residential land uses (Maestre et al., 2004). The *PS Toxics Study* also observed greater concentrations during fall storm events when longer antecedent dry periods prevailed.

Contaminant Loads

Data summaries for storm-event contaminant loads were calculated for the Case A parameters. For those contaminants that were classified as Case B and had more than 50 observations (summarized used Robust ROS techniques), contaminant loads should be considered estimates. For all other parameters, a range of contaminant loads was given. Often the ranges were limited by the analytical detection limit, thus ranges were not an accurate assessment of environmental contaminant loads. Event loads were summarized using the same statistical approach as used for the concentration data (i.e., data qualifiers associated with the each concentration were used for the corresponding load). Loads were not calculated for parameters collected by grab samples, as these do not represent the load throughout a storm event.

Ecology calculated both weight-based (mass) loads (kg per storm event) and loads per unit area (kg ha^{-1}) based on the catchment area given in Table 1 for each stormwater basin.

Loads calculated here are reliable, as no bias towards large volume storms was evident across the sample sites, and sample representation of the storms was excellent. Loads are summarized by land use in Table I-2 (mass) and I-5 (per unit area). All data summaries are detailed in Table I-1 through I-6. Graphical summaries for each parameter load are detailed in Appendix H. Peto-Prentice and Kaplan-Meier cumulative density functions were also run on the load by area to describe any significant differences among land uses.

Unfortunately, Ecology could not directly compare to load estimates presented in the *PS Toxics Study*, which were true annual loads; those presented in this study were event loads. However, trends across land uses were compared. In general, mass loads exhibited the same seasonal trends as contaminant concentrations. Contaminant loads per unit area in general followed seasonal trends, but with more exceptions. Contaminant loads per unit area for each parameter are discussed in greater detail below.

Summary of Loads per Unit Area

In this section, contaminant loads (kg per hectare) are discussed as *median values* (50th percentile) unless otherwise noted. Tables I-3 through I-6 detail the data summaries for contaminant loads per unit area (hectares).

Conventional Parameters

Surfactants

Contributions of surfactants were 0.0002 kg per hectare per storm event. Significant differences existed among land uses, but not between wet and dry seasons. Loading data followed trends similar to concentration data across land uses. Commercial and industrial land uses contributed greater loads.

Total Suspended Solids (TSS)

TSS load varied significantly across land uses and showed a significant difference between wet and dry seasons (Table I-3). Loads from industrial and commercial land uses were significantly greater (0.71 kg ha^{-1} and 0.28 kg ha^{-1}, respectively) than loads from high-density residential land use (0.06 kg ha^{-1}) and low-density residential land use (0.04 kg ha^{-1}). TSS load exhibited a clearer difference among land uses than concentration, consistent with findings from the *PS Toxics Study*.

Nutrients

Phosphorus

Total phosphorus loads per unit area had a median value of 0.00045 kg ha^{-1} with 8.46 x 10-5 kg ha^{-1} contributed as ortho-phosphate. Land uses contributed significantly different loads on a per unit area basis. Seasonal loads were not different, in contrast to concentration data where concentrations were significantly higher during the dry season.

As with concentration, total phosphorus loads were significantly greater in stormwater from the commercial and industrial land uses. The residential land uses were significantly lower and quite similar to each other (in kg ha^{-1}; Table I-5).

Dissolved phosphorus load (as ortho-phosphate) from low-density residential land use (1.1 x 10^{-4} kg ha^{-1}) was similar to the load from industrial (1.5 x 10^{-4} kg ha^{-1}) and commercial (1.1 x 10^{-4} kg ha^{-1}) land use. These results are an order magnitude higher than high-density residential land use (3.5 x10^{-5} kg ha^{-1}).

Findings from this study agreed with the *PS Toxics Study* which found that commercial and industrial land uses contributed a higher load of total phosphorus than residential land uses. Dissolved phosphorus was not measured in the *PS Toxics Study*.

Nitrogen

The observed nitrogen loads suggested that 0.0043 kg ha^{-1} of nitrogen was discharged per storm event (sum of total Kjeldahl N and nitrite+nitrate, as nitrogen), with a 90th percentile of 0.026 kg ha^{-1} N. The TKN loads (as kg ha^{-1}) across land uses differed from that observed for concentrations. TKN loads were dominated by contributions from commercial and industrial land-use areas, with residential land-use contributions significantly lower. Nitrite+nitrate loads were also highest in discharges from commercial and industrial land uses. Above the 75th percentile of the distribution, the highest loads observed in the data set were discharged from residential land-use areas. This finding highlights the complexity and variability among land uses and among sites.

There was no difference in nitrogen loads between wet and dry seasons.

The *PS Toxics Study* found that residential land uses contributed the majority of nitrite+nitrate, which was similar to observations of this study. Commercial and industrial land uses were found to contribute the lowest nitrite+nitrate load in the *PS Toxics Study*, which was contrary to the findings of this study in which commercial and industrial land uses contributed the greatest median loads.

Metals

Metals loading (as kg ha^{-1}) generally followed trends similar to concentration data. Commercial and industrial land-use areas discharged the greatest load, followed by discharges from residential land uses. Some deviations from this trend were noted for lead. Similar loading trends during storm events among land uses were noted in the *PS Toxics Study*. All metals showed greater loading during the dry season.

Cadmium

The 90th percentile of the total cadmium load from all land uses was 3.37×10^{-6} kg ha^{-1} per storm event with a median of 4.83×10^{-7} kg ha^{-1}. Approximately 20% of the total cadmium was in dissolved form. The differences among land uses were similar to the cadmium concentration data, where commercial and industrial land uses discharged significantly higher loads than residential land uses. No significant differences were found between the wet and dry seasons for loads per unit area.

Copper

The 90th percentile of copper load discharged during each storm was 3.6×10^{-4} kg ha^{-1} and the median was 5.1×10^{-5} kg ha^{-1}. Approximately 25% of the copper was in dissolved form. Trends across land uses and between seasons were similar to those found for cadmium.

Lead

The 90th percentile of the distribution of total lead load was 3.0×10^{-4} kg ha^{-1} per storm event, and the median was 2.7×10^{-5} kg ha^{-1} per storm event. Land-use trends for loads were similar to those found for concentrations. Commercial land-use areas discharged significantly higher loads; industrial and high-density residential land uses discharged roughly similar loads. Low-density residential land-use areas discharged significantly lower lead loads. No significant differences were found between the wet and dry seasons for loads per unit area.

Mercury

Mercury loads were heavily influenced by the number of non-detect concentrations. Only for areas of commercial land use could the loads be quantified (Appendix I). No seasonal differences were apparent in the loads of mercury from commercial land-use areas.

Zinc

The median zinc load was 3.1×10^{-4} kg ha^{-1} per storm event, while the 90th percentile of the load distribution was 1.5×10^{-3} kg ha^{-1} of zinc per storm event. Land-use trends for loads were very similar to those measured for concentrations, where commercial and industrial land uses showed nearly identical loads. Commercial and industrial lands had significantly higher loads of zinc, than did residential lands. No significant differences were found between the wet and dry seasons for loads per unit area.

Hydrocarbons

TPH

TPH-Dx had significantly higher loads in stormwater (as kg ha^{-1}) from commercial and industrial land uses compared with residential land uses, similar to the concentration trends. The 90th percentile of the distribution of TPH-Dx load was 0.02 kg ha^{-1} per storm event, and the median across all land uses was 2.0×10^{-3} kg ha^{-1}. The motor oil component of TPH-Dx was discharged at a load of 0.02 kg ha^{-1}(90th percentile), with a median of 3.0×10^{-3} kg ha^{-1} per storm event. The TPH-Dx load from high-density residential land use was significantly lower than the load from commercial and industrial land use. No significant differences were found between the wet and dry seasons for loads per unit area.

Polycyclic Aromatic Hydrocarbons (PAHs)

Individual PAH compound concentrations were well-quantified for fluoranthene, phenanthrene, and pyrene. These three compounds displayed trends similar to concentration trends for land uses, where significant differences were present between loads from commercial, industrial, high-density residential, and low-density residential. The 90th percentile of the total PAH mass loads was 2.0 x 10-5 kg $ha^{-1,}$ and the median was 6.7×10^{-7} kg ha^{-1} contributed per storm event. Trends across land uses for loading of total PAHs, CPAHs, LPAHs, and HPAHs were the same as described for the individual PAH compounds.

Significant differences in PAH loads were found between wet and dry seasons, contrary to concentration data. Greater PAH loads were found during the wet season.

Phthalates

Bis(2-ethylhexyl)phthalate was the only well-quantified phthalate in stormwater from all land uses. Ecology estimated the 90th percentile of the load was 3.5 x 10 -5 kg ha^{-1}, and the median was 3.9×10^{-6} kg ha^{-1} discharged per storm. Significant differences in load trended downward from commercial to industrial to high-density residential to low-density residential land uses. A similar pattern was observed for total phthalates across land uses. A significant difference was found between wet and dry seasons.

Pesticides

The load of dichlobenil did not vary across the three land uses (commercial, industrial, and high-density residential) where concentrations were detected. The estimated load per unit area was a median of 4.82×10^{-8} kg ha^{-1} of dichlobenil per storm event. No difference in dichlobenil load was found between wet and dry seasons.

Pentachlorophenol load in stormwater was calculated only for commercial land-use areas, where the estimated median was 6.31×10^{-8} kg ha^{-1} per storm event. No difference in pentachlorophenol load was found between wet and dry seasons.

Contaminant Load Summary

Storm-event mass (kg) and load per unit area (kg ha^{-1}) were calculated for contaminants that were quantified above detection limits in stormwater. Contaminant loads showed trends similar to the contaminant concentrations, with the exception of nutrients. While contaminant mass loads (kg) were not discussed in detail in this report, we observed similar seasonal trends to the contaminant concentration data. On the other hand, loads per unit area were generally constant throughout the year. Contaminant loads per unit area are summarized below:

- *Nutrients*: Total nitrogen and phosphorus loads were highest from commercial and industrial land uses. Low-density residential land uses contributed as much ortho-phosphate load as the commercial and industrial land uses, while ortho-phosphate load from high-density residential land use was significantly lower. Dissolved nitrogen (as nitrite+nitrate) load from high-density residential land use was greater than the 75th percentile of the load from commercial and industrial land uses. Nutrient loads calculated per area were constant throughout the year, although nutrient concentrations were higher in the dry season.

- *Metals*: Commercial and industrial land uses discharged the greatest metal loads, and lower loads were discharged from residential land uses. All metals showed no significant difference in loading between the wet and dry season, contrary to the concentration data and mass loads (kg). A high mass loading observed during the dry season seemed more highly influenced by elevated concentrations rather than by volume.

- *Hydrocarbons:* Commercial and industrial land uses contributed the greatest loads of diesel range total petroleum hydrocarbons (TPH-Dx) and PAHs. Overall, loads per unit area (kg ha^{-1}) showed significant differences between seasons, with greater loads during the wet season.

- *Pesticides*: Commercial, industrial, and high-density residential land uses had comparable dichlobenil loads. No seasonal differences in contaminant loads were noted.

Summary

Stormwater and storm sediment discharge data were collected by NPDES Phase I Municipal Stormwater permittees, under Special Condition S8.D, between 2007 and 2012. This report is a summary of data results contained in Ecology's Environmental Information Management (EIM) System. The eight Phase 1 permittees, all located in western Washington, collected highly representative storm-event data under a prescribed monitoring program that represented multiple land uses, storm characteristics, and seasons. The main goals of this study were to (1) compile and summarize the permittees' data using appropriate statistical techniques and (2) provide a western Washington regional baseline characterization of stormwater quality.

Ecology's analysis provides a comprehensive review of the pollutants in western Washington stormwater from 2007 - 2012. These findings are based on the analysis of 44,800 data records representing 597 different storm events. Up to 85 chemicals were analyzed in stormwater samples, and 67 chemicals were analyzed in stormwater sediment samples. Compiling data from multiple sources was challenging due to differences in parameter names, sample fractions, units, reporting limits, and basin characteristics.

The representativeness of the collected samples across storm events appeared to be of high quality, generally representing above 90% of storm hydrographs. Samples showed no bias of storm volume. The distribution of sampling events over the year was also of high quality with few exceptions.

The statistical analyses used in this study have produced reliable statistical summaries and allowed for robust comparisons of the impacts of land use and seasons on contaminant concentrations and mass loads. The statistical summaries form a baseline for contaminant concentrations in stormwater that will allow for future comparisons. Results can be used to track improvement in stormwater quality as local programs continue to be implemented.

Key Findings

The following key findings are highlighted from this report.

Stormwater Monitoring Program

- Ecology finds the permittees' stormwater monitoring data to be representative of storm events in western Washington. The stormwater discharge data set is large, captured a wide variety of storm events, and does not appear to have biases toward storm size, limb of hydrograph, land use, or season. Results are suitable for creating a baseline understanding of stormwater discharges in western Washington.
- Stormwater monitoring as required in the 2007 permit was met (qualifying storm, sample frequency, and representativeness). The continued collection of high quality data representing storm-event pollutant concentrations seems realistic.
- "Typical" stormwater chemistry for a particular land use was difficult to define.
- This database is a suitable baseline to compare stormwater contaminant concentrations against management actions in future studies.
- Permittees' initial efforts to assess toxicity of stormwater on trout embryos per permit requirements in S8.F were met with considerable logistical and bioassay complexity. Twelve of the 17 samples analyzed using bioassays had no adverse effects. Only samples from larger commercial areas showed toxicity to trout embryos, with the likely toxicants being zinc and copper. Appendix A provides a summary of the bioassay effort and lessons learned.

Stormwater Discharge Quality

- Commercial and industrial areas discharged stormwater with the highest concentrations of metals, hydrocarbons, phthalates, total nutrients, and a few pesticides.
- Residential areas discharged stormwater with the highest dissolved nutrient concentrations.
- Copper, zinc, and lead most frequently exceeded (did not meet) the water quality criteria for protection of aquatic life. Cadmium and mercury also exceeded criteria for protection of aquatic life. Mercury was not a widespread contaminant in western Washington stormwater, although localized areas of concern existed. Comparisons to water quality criteria were made for context in this report.
- Metals concentrations monitored during the dry season (May through September) were statistically higher than concentrations monitored during the wet season. Dissolved zinc, copper, and lead exceeded acute and chronic water quality criteria regularly. Comparisons to water quality criteria were made for context in this report.
- Higher contaminant concentrations and mass loads (kg per storm event) were measured for nutrients and metals during the dry season. This supports the idea that there is a "buildup" during the dry season, when the antecedent dry periods are longer.

- PAHs, phthalates, PCBs, and the few detected pesticides did not exhibit a significant seasonal difference, suggesting these parameters were being discharged from a consistent source throughout the year.
- Bis(2-ethylhexyl) phthalate was frequently found in stormwater and stormwater sediment.
- NWTPH-Dx compounds were persistent stormwater contaminants. Commercial and industrial areas discharged much higher concentrations and loads than did residential areas. When the motor oil fraction was considered separately, the highest load was from residential areas.
- NWTPH-Gx was poorly detected and, if present, was likely volatized before monitoring.
- Individual parameter concentrations showed strong differences between land uses.
- The most volatile organics (some pesticides, lighter weight PCBs, and PAHs) were poorly detected (less than 10% of the samples).
- The most volatile parameters (BTEX) provided less useful information when gathered from composite samples.

Stormwater Sediment Quality

- While the data set for stormwater sediment samples is smaller the data set for stormwater samples, contaminants in stormwater sediments showed trends similar to contaminants in stormwater across land uses.
- The stormwater sediment monitoring design precluded an understanding of sediment pollutants across seasons. A more refined sediment design for both spatial and temporal monitoring would improve our understanding of stormwater sediments.
- Bis(2-ethylhexyl) phthalates in stormwater sediments exceeded the freshwater aquatic life criteria (Sediment Cleanup Objectives) 82% of the time. Di-n-octyl phthalate exceeded the criteria 29% of the time.
- Total PAHs in stormwater sediments exceeded the freshwater aquatic life criteria (SCO) 34% of the time.
- Copper (9%) and lead (18%) were the main metals in stormwater sediments exceeding the SCO. Zinc and mercury were not of concern in stormwater sediments.
- Phenol in stormwater sediment exceeded the SCO 20% of the time.

Comparisons with Relevant National and Local Stormwater Studies

Generally, contaminant concentrations reported in this study were within the ranges reported in the National Stormwater Quality Database (NSQD), but median values were often lower. This is primarily due to the age of the NSQD (early 1980s) and improvements in stormwater quality and management since the National Urban Runoff Program (NURP) sampling. Many of the contaminant concentrations in this study were higher than those found in the *PS Toxics Study*.

This finding is not surprising given that the *PS Toxics Study* sampled receiving waters, not stormwater discharges, during storm events.

- The *PS Toxics Study* found high concentrations of PAHs in receiving waters during storm events. The majority of PAHs were contributed from commercial and industrial areas, which was corroborated by this current study. PAHs in stormwater discharges showed no seasonal differences in concentrations.
- The pesticides, dichlobenil and pentachlorophenol, were reliably detected in this study. Triclopyr, which was detected in the *PS Toxics Study,* was found in only 10% of the 575 samples analyzed in this study.
- The few samples with detected concentrations of PCBs in water showed much lower concentrations in this study than in the *PS Toxics Study*.
- Dissolved nutrients (orthophosphate and nitrite+nitrate-nitrogen) were much lower in stormwater discharges as compared to receiving waters sampled in the PS Toxic Study. This suggests that dissolved nutrient contributions are larger to receiving waters from pathways other than stormwater drainages (e.g., tributary streams and groundwater).
- Higher concentrations and storm-event loads of metals were contributed to receiving waters from commercial and industrial areas than from other land-use areas. The *PS Toxics Study* also found the highest metals concentrations in waters from commercial and industrial areas.

Recommendations

Based on the findings of this study, further actions and data analysis are recommended.

- Implement best management practices (BMPs) and adjust stormwater management programs based on these findings. Use findings to help prioritize activities within stormwater programs.

- Present the data online in a simple, user-friendly interface that stormwater managers could use to directly compare with future stormwater chemistry results.

- Link this database with the National Stormwater Quality Database (NSQD) to increase the temporal range of the data set.

- Further investigate the relationships between seasonality and land use for each parameter. For example, total phosphorus exhibits strong statistical differences between land uses during the wet season but no significant differences during the dry season.

- Conduct further analysis to identify the land use associated with each sample that exceeded (did not meet) water quality criteria.

- Expand the number of sites for annual sediment sample collection to enhance the spatial survey of possible contaminant sources.

- Use results from this study to fill gaps found in the *Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates* (Herrera, 2011; *PS Toxics study*): for example, areas draining directly to marine waters or fresh receiving waters that were missed when monitoring the larger drainages in that study.

- Reduce the sampling frequency of, or eliminate, the following parameters from further stormwater discharge sampling:
    - BTEX in water and sediments.
    - Malathion, prometon, chlorpyrifos, and diazinon in water and sediments.
    - Triclopyr and mecoprop in sediments.
    - Limit phenolics in sediments to pentachlorophenol, o- cresol, and p-cresol.

- Evaluate the data set for patterns among parameters that could help identify sources of pollution to stormwater.
    - Explicitly test the influence of seasonal first flush, or antecedent dry period lengths, on stormwater discharge concentrations.
    - Explore whether the correlations between some parameters and land uses are causative or coincident. For example, surfactants and copper; does the application of surfactants increase the mobilization of copper from the catchment?
    - Investigate dissolved nutrient concentrations in stormwater from low-density residential areas and investigate pollution reduction approaches.

- Track and evaluate any BMPs within each basin using a similar suite of stormwater chemistry (e.g., timing of sweeping or cleaning of Ports or parking lots).
- Explore the high-runoff coefficient calculated for specific high-density residential sites to determine whether the high-runoff coefficients influence the contaminant contributions from these sites.

Appendix A. Municipal Stormwater Trout Embryo Toxicity Testing: Results from First Flush, 2010-2011

By
Randall Marshall
Water Quality Program, Washington State Department of Ecology

Monitoring Strategy

The permittees under the Phase I Municipal Stormwater Permit made attempts to sample seasonal first flush stormwater for toxicity testing in August through October of 2010 and 2011. Each permittee sampled only in one of those years but targeted three of the following four landuse types:

- Commercial.
- Industrial.
- Low density residential.
- High density residential.

Half of the permittees could only sample the discharge from two landuse types because of inadequate discharge volumes during the seasonal first flush timeframe defined in the permit. This monitoring did not provide for results from multiple years or multiple seasons and must be considered no more than a snapshot of any of the discharge locations. In addition, only nine of the seventeen samples were collected in August and represented well a seasonal first flush. Five of the seventeen samples were collected in October.

Metals in water with higher hardness are less toxic and water quality criteria for metals are calculated based upon hardness. The hardness of receiving water is often significantly higher than stormwater. The permit allowed the hardness of stormwater samples to be adjusted to match receiving water hardness to provide some environmental realism.

However, other relevant features of the receiving water environment were not incorporated into test conditions. Features left out include:

- Upstream sources of metals and other pollutants.
- Pulsed pollutant exposures.
- Dilution
- Dissolved organic carbon.
- Suspended solids.
- Variability of stream chemistry during storms.

The monitoring results have limited environmental relevance.

The trout embryo viability test is good for assessing conditions for the first 7 days of a trout or salmon's life. The test measures survival and development during this time. It misses other sensitive lifestage transitions such as hatch or swim-up. Since the toxicity testing did not include other organisms, lifestages, and biological endpoints, the results need to be considered solely within the context of the 7-day trout embryo test.

Test Method and Results

Labs conducted the Environment Canada 7-day trout embryo viability test[5] on the stormwater samples. Tests began with freshly fertilized rainbow trout eggs and continued for a week. At the end of 7 days the labs counted the number of live embryos and the number of normally developed embryos. All tests provided valid results based upon control response. Twelve of the seventeen tests showed no adverse effects to either survival or development.

Only the Port of Tacoma and Port of Seattle samples had EC50s equal to or less than 100% sample[6] and triggered the follow-up actions in the permit. Follow-up actions compare chemical analysis results on split samples to published toxic thresholds. The comparison revealed zinc to be the likely toxicant for the Port of Tacoma sample and copper to be the likely toxicant for the Port of Seattle sample. Ports are especially large and intensive commercial operations.

The dissolved copper and zinc concentrations in the samples from the commercial landuse types were 2 to 10 times higher than the concentrations of the same metals in samples from residential landuse. The Pierce County and Snohomish County commercial samples had higher concentrations of zinc than the one industrial landuse area sampled. The Snohomish County commercial sample also had higher copper than the industrial sample. Parking lots are significant sources of copper and zinc. Galvanized metal roofs can produce runoff with toxic concentrations of zinc. Commercial areas have abundant parking lots and galvanized steel. Table A-1 shows the average concentration of copper and zinc in the same samples from the various landuse types that were tested for toxicity.

Table A-1 – Average Copper and Zinc Concentrations in Samples from Different Land Uses.

	Copper	Zinc
Commercial (n = 6)	17.9	100.8
Residential (n = 8)	5.4	18.4
Industrial (n = 1)	19.2	125.0
Port of Seattle	101.0	171.0
Port of Tacoma	13.7	767.0

Copper and zinc concentrations along with toxicity test results for all samples are listed in Table A-2.

The samples from the commercial landuse types for the City of Seattle, Pierce County, and Snohomish County were moderately toxic. The toxicity test result for the Snohomish County

---

[5] EPS 1/RM/28

[6] This toxicity test used a series of dilutions of the sample (starting at 100% concentration). Therefore if the half maximal effective concentration (EC50) was equivalent to or less than the raw sample, the sample had regulatory significant toxicity.

commercial sample nearly triggered the follow-up actions in the permit, but the results from the other commercial samples were not as close. None of the residential landuse samples showed any toxicity. The one industrial sample did not either. Toxicity test results are given in Table A-2.

Lessons Learned

- Rainbow trout do not naturally spawn in late summer through early fall. The hatchery had to make a special effort at that time to bring fish into spawning condition. Permittees and labs had to predict a qualifying seasonal first flush storm event enough in advance to arrange for the hatchery to have trout gametes available for setting up tests. Scheduling was not always successful and most tests needed variances from sample holding times. Ten out of seventeen samples were past the recommended sample holding time of 36 hours at test startup. Two samples were slightly older at test setup than the EPA maximum allowed holding time of 72 hours.
- Uneven quality of trout gametes due to the time of year may have produced variability in response that led to poor statistical sensitivity. Five out of the seventeen trout embryo tests did not meet the chronic statistical power standard[7] of being able to determine that a reduction in survival or development of 40% or more is statistically significant. The percent minimum significant differences (PMSDs) highlighted in Table A-2 show which tests failed to meet the power standard. These municipal stormwater tests had 50% of the PMSDs ≥ 40% from all ninety-seven trout embryo tests in the toxicity test database even though they are only 18% of the total.
- The seasonal first flush was over by early fall in 2010 and probably most years. It was also more pronounced for commercial (metals 3.5 to 4 times higher than average) rather than residential (metals 1.5 to 2.5 times higher) sites. See Table A-3 for an example.
- The most experienced lab closed at the beginning of the 2011 monitoring season. The replacement labs failed to take advantage of the opportunity to adjust sample hardness to match the receiving water.
  - The Port of Seattle's sample may not have been toxic if its hardness had been adjusted.
  - The Port of Tacoma's sample would likely have still been toxic even if hardness was adjusted.
  - The King County samples were also not adjusted.
- Available information is more than adequate to guide stormwater management for many years. These toxicity test results confirm what Ecology already knows about urban sources of copper and zinc. Commerce depends upon transportation and supporting infrastructure. Transportation and infrastructure are major sources of copper and zinc.
- Toxicity testing of stormwater or urban streams should be reintroduced when stormwater controls are well-implemented in order to see if they are missing pollutants or sources.

Appendix C. Description of the Statistical Plots

This appendix describes each of the six plots created for data analysis. Four parameters are displayed and described for each of the six plot types. The four parameters are fecal coliform bacteria, total phosphorus, total copper, and Dichlobenil (an herbicide). These parameters were selected because they display a variety of discussion elements, considerations for data summaries, and peculiarities encountered in this report. For both the jitter and box plots, the x-axis is categorical and uses the abbreviations defined below:

Land Uses
Ind = Industrial
Com = Commercial
HRes = High-Density Residential
LRes = Low-Density Residential

Sample Result
Det = Count of detected records
ND = Count of non-detected records and the percent non-detected records of the total

Season Type
Winter = Winter Quarter (January, February, March)
Spring = Spring Quarter (April, May, June)
Summer = Summer Quarter (July, August, September)
Fall = Fall Quarter (October, November, December)
DrySeas = Dry Season (May 1 through September 30)
WetSeas = Wet Season (October 1 through April 30)

1. Jitter Plot

Jitter plots offer an excellent visual of the data. The jitter plot (Figure C-1) shows both the detected data as points and the non-detected data as bars extending from zero to provided reporting limit. The bar is useful in conveying the idea that the true value of the non-detect is unknown; only the range for which its true value may occur. The two-toned purple dots are the detected data points, divided into dry and wet seasons.

The jitter plots are divided into four vertical panels. Each panel represents a different land-use type. Within each panel, the x-values are randomized (jittered) to spread the data out and make them easier to view. Land-use types are indicated by abbreviations below the x-axis, along with the number of detects, the number of non-detects, and the percentage of non-detect data.

As seen in the jitter plots, most of the data for fecal coliform, total phosphorus, and dissolved copper were detected values, whereas the majority of the data for Dichlobenil were non-detects as indicated by the gray lines.

The fecal coliform jitter plot shows that the data spans 5 orders of magnitude and includes non-detects.

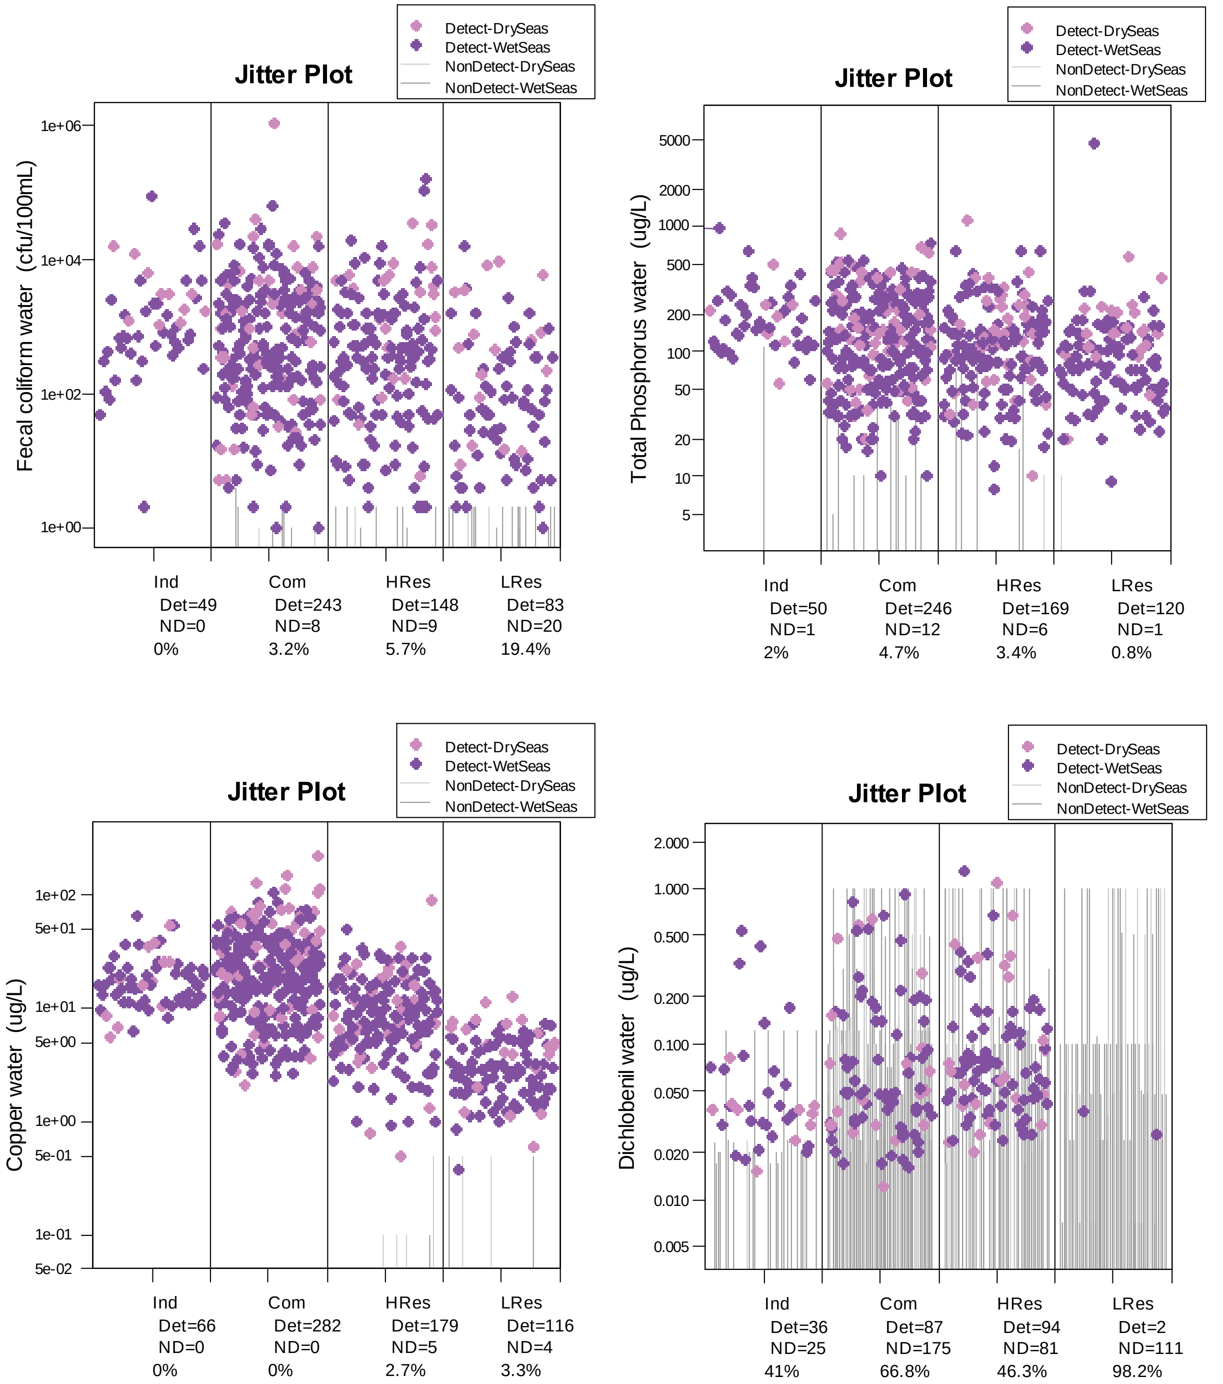

Figure C-1. Jitter plots for four example parameters.

The total phosphorus data range from 0.008 to 4.6 mg/L. There are a number of non-detects at elevated reporting limits. The reason for these elevated non-detects is unknown. This could be due to matrix interference, or this could illustrate a gap in the data QA process (QA) at the laboratory or the data review level. Ecology did not investigate peculiarities such as these for two reasons: (1) The data had already been QA reviewed by the laboratory and the permittees and therefore were useable for summarization into the regional data set, and (2) time was limited under the grant process to investigate a small number of oddities.

The jitter plot for Dichlobenil shows that the bulk of the data were non-detect. Organic contaminants in stormwater were more likely to contain greater percentages of non-detects than conventional parameters, nutrients, or metals. Additionally, non-detects for organics were more likely, as shown for 2,4-D, to have multiple reporting limits for non-detects. The variable reporting limits may be due to the interfering matrices, low sample volumes, or different laboratory QA processes. An inter-laboratory comparison for the analytical methods used under the S8.D monitoring programs in the Puget Sound region has not been investigated, to Ecology's knowledge.

The jitter plot was also used in summarizing the contaminant load data over a gradient of % impervious cover (Figure C-2). Here, Ecology has binned or grouped the results into ranges of % impervious area by 20%. The gray dots are results that are qualified as non-detect, while the blue dots are detected concentrations. The goal of this plot is to show the distribution of contaminant loads across the range of % impervious ground cover. The plot for total copper typifies what one might expect: as the % impervious surface increases, the load of copper increases.

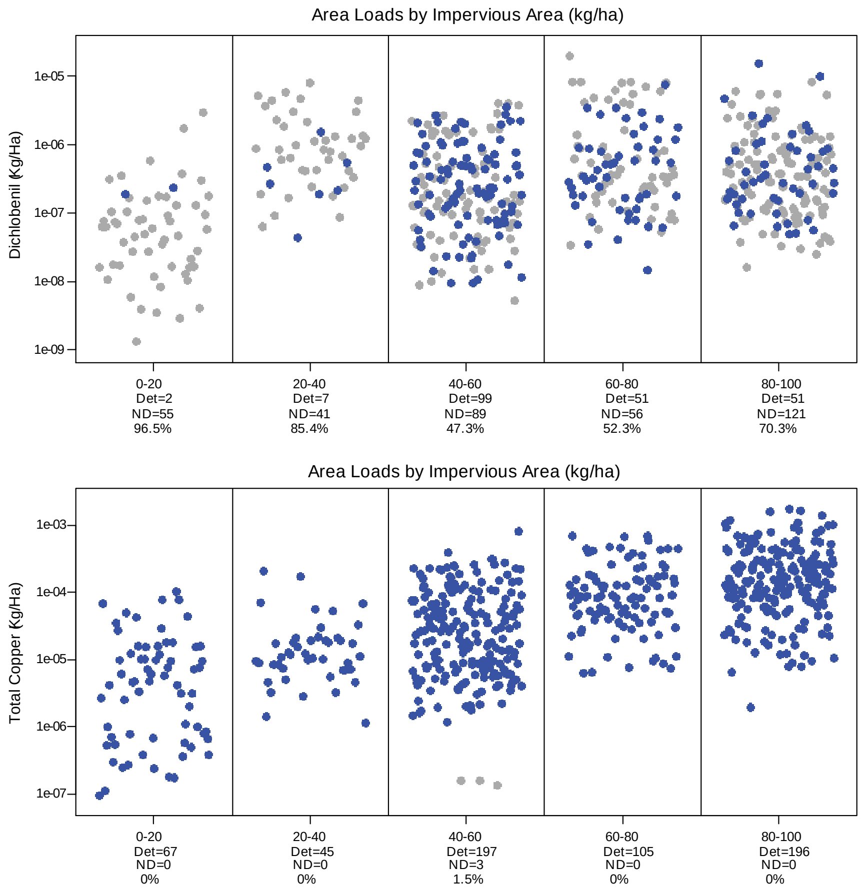

Figure C-2. Jitter plots of contaminant loads for total copper and Dichlobenil.

2. Probability Plots

Some statistical calculations assume that data follow a specific distribution. In these cases, a method is needed to check whether this assumption is valid. For example, stormwater professionals have consistently found that the concentrations of many stormwater parameters follow a log-normal distribution (EPA, 1983; Burton and Pitt, 2002; Maestre et al., 2004, 2005). A log-normal distribution results in a positive bias, meaning the average values are larger than the median values (Pitt, 2011).

Probability plots are used to visually compare a data set to a specified distribution (Helsel, 2012), in this case a log-normal distribution. The distribution is represented on the plot as a straight line, and observed data are plotted as individual points. If the data points fall near the line then they are described as reasonably fitting the log-normal distribution. If the data points show curvature or have a number of points that plot far from the line, then the data are said to differ significantly from the log-normal distribution. Parameters with few or no non-detects were tested for a normal or log-normal distribution using the Shapiro-Wilk test. This was discussed further in the *Methods* section of the report.

For all other parameters, the presence of non-detects must be properly accounted for when creating a probability plot. Although non-detects are not shown on the plot, they affect the placement of the observed data points on a probability plot. A probability plot that ignores non-detected data is invalid according to Helsel (2012). Ecology used the regression on statistic (ROS) approach to generate probability plots for this report. This approach accounts for the proportion of the data below each reporting limit and adjusts the placement of the detected data accordingly.

On these plots, the lower x-axis shows the quantile while the upper x-axis represents the percentiles of the data distribution (Figure C-3). The y-axis shows the concentrations (typically in log scale). The detected data are shown as black dots. The non-detect values are ranked, and the positional range and count of data points associated with the non-detects is taken into consideration, but are not shown on the plot.

These plots use the entire data set and do not divide the data by land use. This is particularly useful in describing stormwater baseline characterization conditions.

In the examples shown in Figure C-3, only total copper appears to “fit” the straight line well over the entire distribution of the data. This is a visual indication that total copper is the only log-normally distributed parameter in this example. The Shapiro-Wilks test indicates the fecal coliform, total phosphorus, and dichlobenil data are distribution-free.

Probability plots accurately present the median, as well as other percentiles presented on the upper x-axis of the entire data set. For example, the median values for fecal coliform, total phosphorus, and total copper appear to fall at the middle point of the detected data. This makes sense, since Figure C-1 showed that the majority of their data were made up of detected records.

On the other hand, the median for Dichlobenil is near the lower limit of much of the detected data. This also is logical, because in Figure C-1 76% of the 2,4-D data points were non-detect. Therefore, in Figure C-3 the median value falls in the area of the plot where there are few to no data points showing.

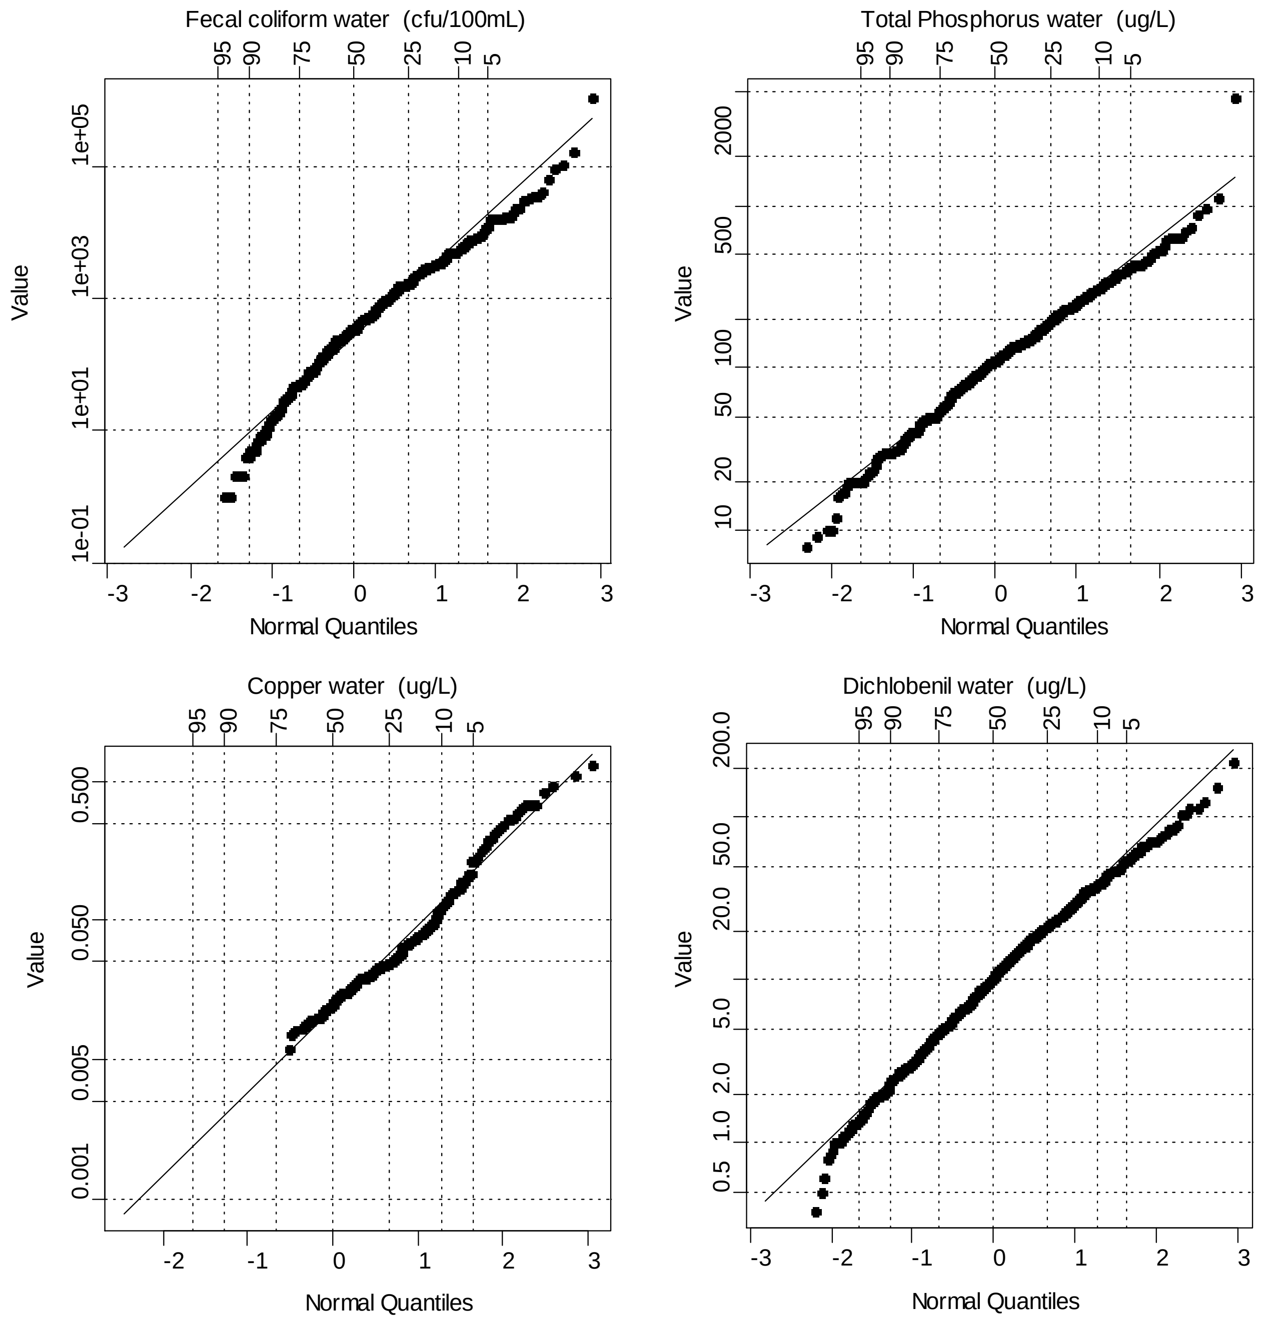

Figure C-3. Probability plots for four example parameters.

3. Plots of Non-Detects

To understand differences in laboratory reporting levels, Ecology plotted non-detect thresholds reported by the permittees. Non-detect data are shown in these plots as line segments extending from zero to the laboratory reporting level. The color of the line segment indicates which laboratory performed the analysis. Laboratory names were removed and represented by a number. The focus of this plot is not to identify permittees or their laboratories, but rather to illustrate the number of laboratories and the numerous reporting limits reported.

Within each plot, the non-detect data are spaced evenly and sorted from lowest to highest reporting level. Plots with few points show the lines distinctly, whereas plots with a large number of data points show no spaces between the lines. Examples are shown in Figure C-4.

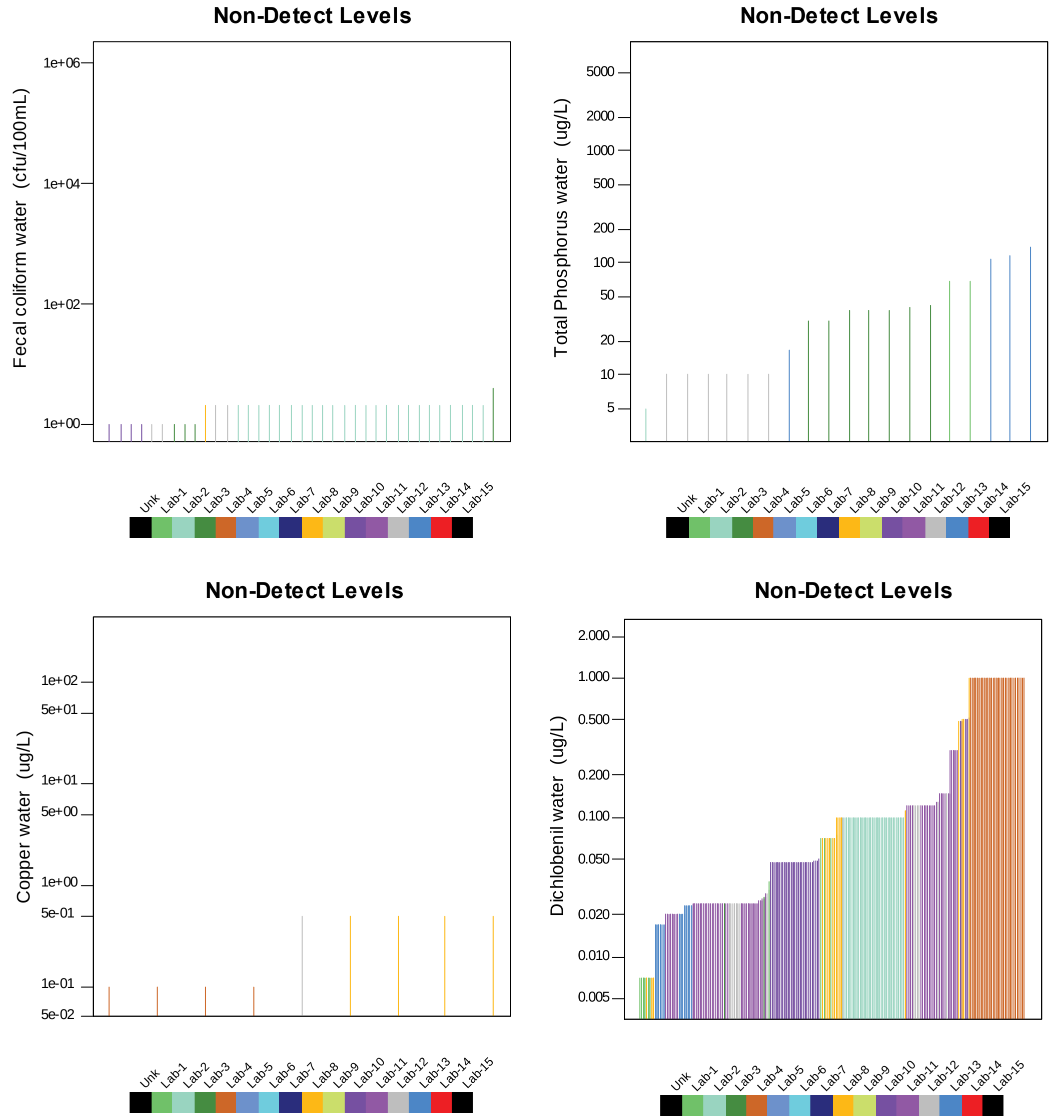

Figure C-4. Non-detect plots for four example parameters.

These examples illustrate both the frequency a parameter was not detected and the variability in the reporting limit threshold for the non-detect data. Recall that variability comes from different samples' matrices, sampling dates, handling techniques, and laboratories. The parameter data in Appendix F did not contain this plot if there were no non-detect data.

4. Empirical Distribution Function (EDF)

These plots (Figure C-5) help identify differences in concentrations among the four land-use types. EDF plots of the observed data are constructed by ranking the data from smallest to largest (Helsel, 2012). EDF plots are also known as the Kaplan-Meier (KM) Curves. The graph shows the likelihood of any given sample concentration to occur in the population of the data set by percentiles. Line type and color indicates land use, as shown in the plot legend.

On these plots, Ecology swapped axes from the usual convention in order to allow comparison with the jitter plots and box plots. Only the detect values are actually plotted, but their positions are influenced by both detections and non-detections. This is a preferred method to display data sets that contain non-detects, as opposed to the traditional box and whisker plots that use only detected values. EDF plots were not shown if there were less than five detected values for any given parameter, and in this case, the data plots (Appendix F) will show the message: "Not Plotted (Less than 5 detections)".

These four example parameters begin to illustrate the impact of the surrounding land use on the water quality of stormwater.

In the case of fecal coliform, the EDF curve for industrial is similar to commercial but quite different from low-density residential. A vertical dashed line was placed on the fecal coliform plot to illustrate where the median value (50%) occurs by land use. A horizontal dashed line was placed to show that fecal concentrations of 100 cfu/100 mL or higher occur approximately >95% of the time for the industrial land use, > 75% for commercial, > 65% for high-density residential, and > 40% of the time for low-density land use.

For total phosphorus, there is less difference observed among the four land-use types.

For Dichlobenil, the EDF for high-density residential shows both a higher proportion of detections and consistently higher concentrations. The data for low-density residential land use reflects the large number of non-detects (98%) and low concentrations in the detected samples. When many non-detects occur at the same reporting level, this shows up in the EDF plot as a long horizontal line segment.

EDF plots were also created for each parameter load as kg ha^{-1}. These are part of the plot summaries for the loading per unit area in Appendix H. Data qualifiers associated with the parameter concentrations were incorporated into the Kaplan-Meier analysis with the load value.

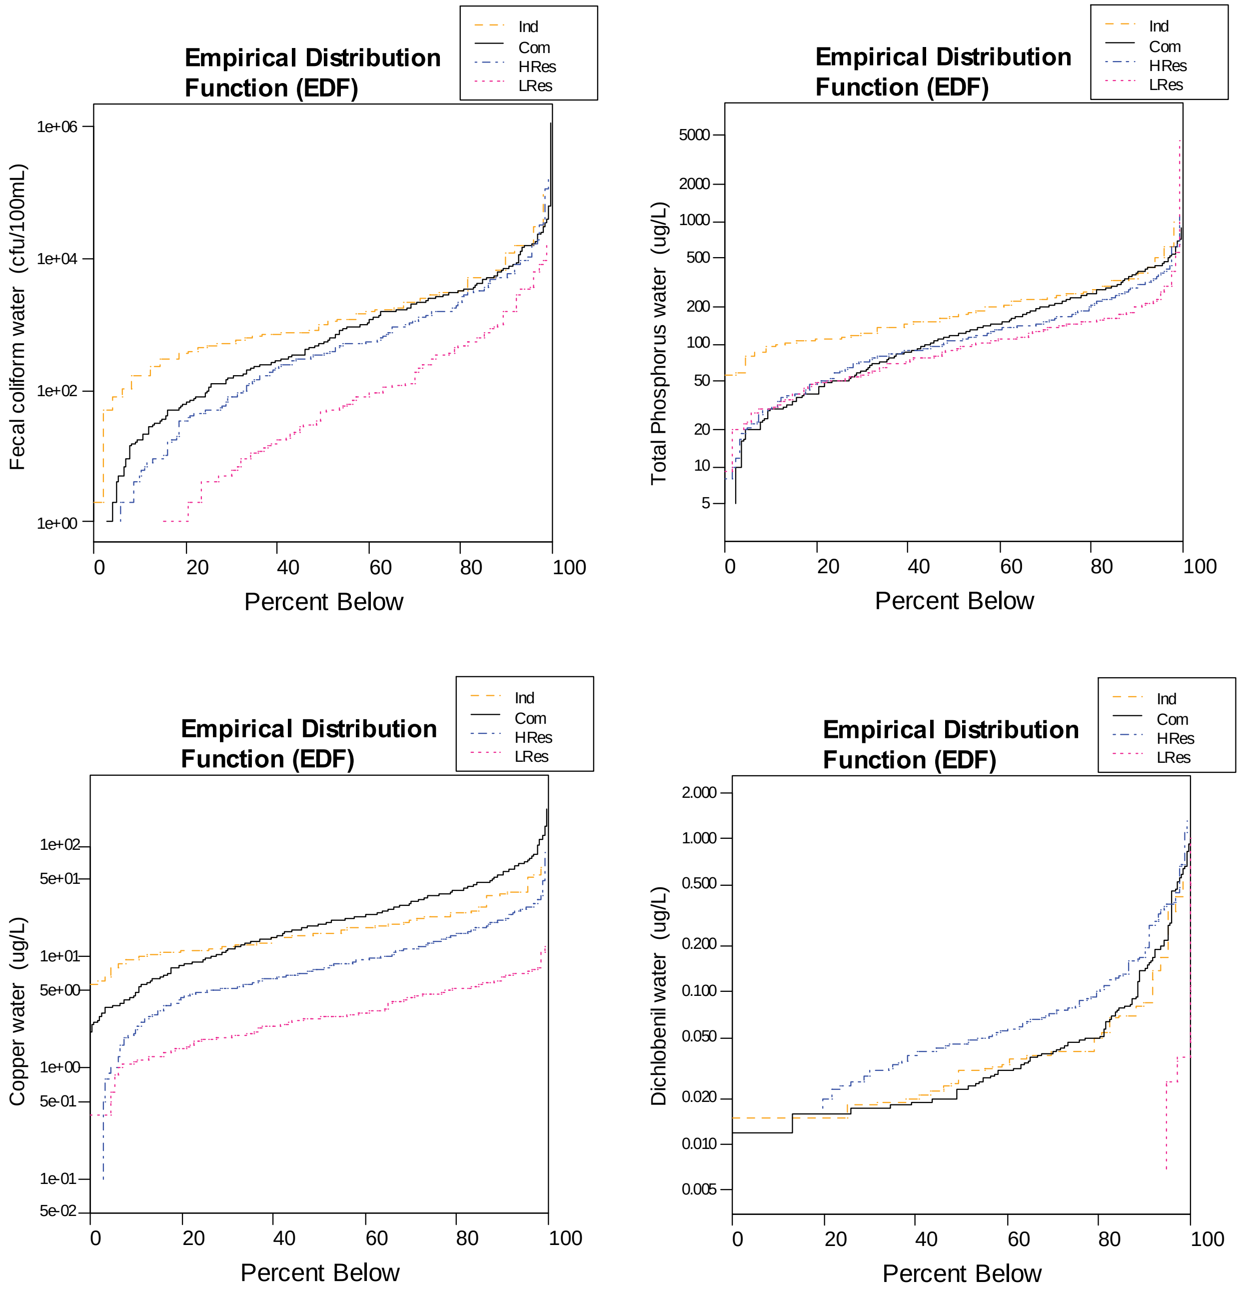

Figure C-5. EDF plots based on KM for four example parameters.

5. Box Plot by Land Use

Standard box and whisker plots were created to compare concentrations between land-use types (Figure C-6). This type of box plot is described in Helsel and Hirsch (2002). The box extends from the 25th to the 75th percentile and is split with a heavy line at the 50th percentile. Whiskers extend to the last observation within 1.5 times of the box height (prior to log transformation). Observations beyond this are shown as individual hollow circles. Thus, half of the data should fall within the box, a quarter of the data should lie above the box, and a quarter of the data should lie below the box. The box plots were created using the entire data set and make no distinction between detected and non-detected values. That is, all data values were included as if they were detections.

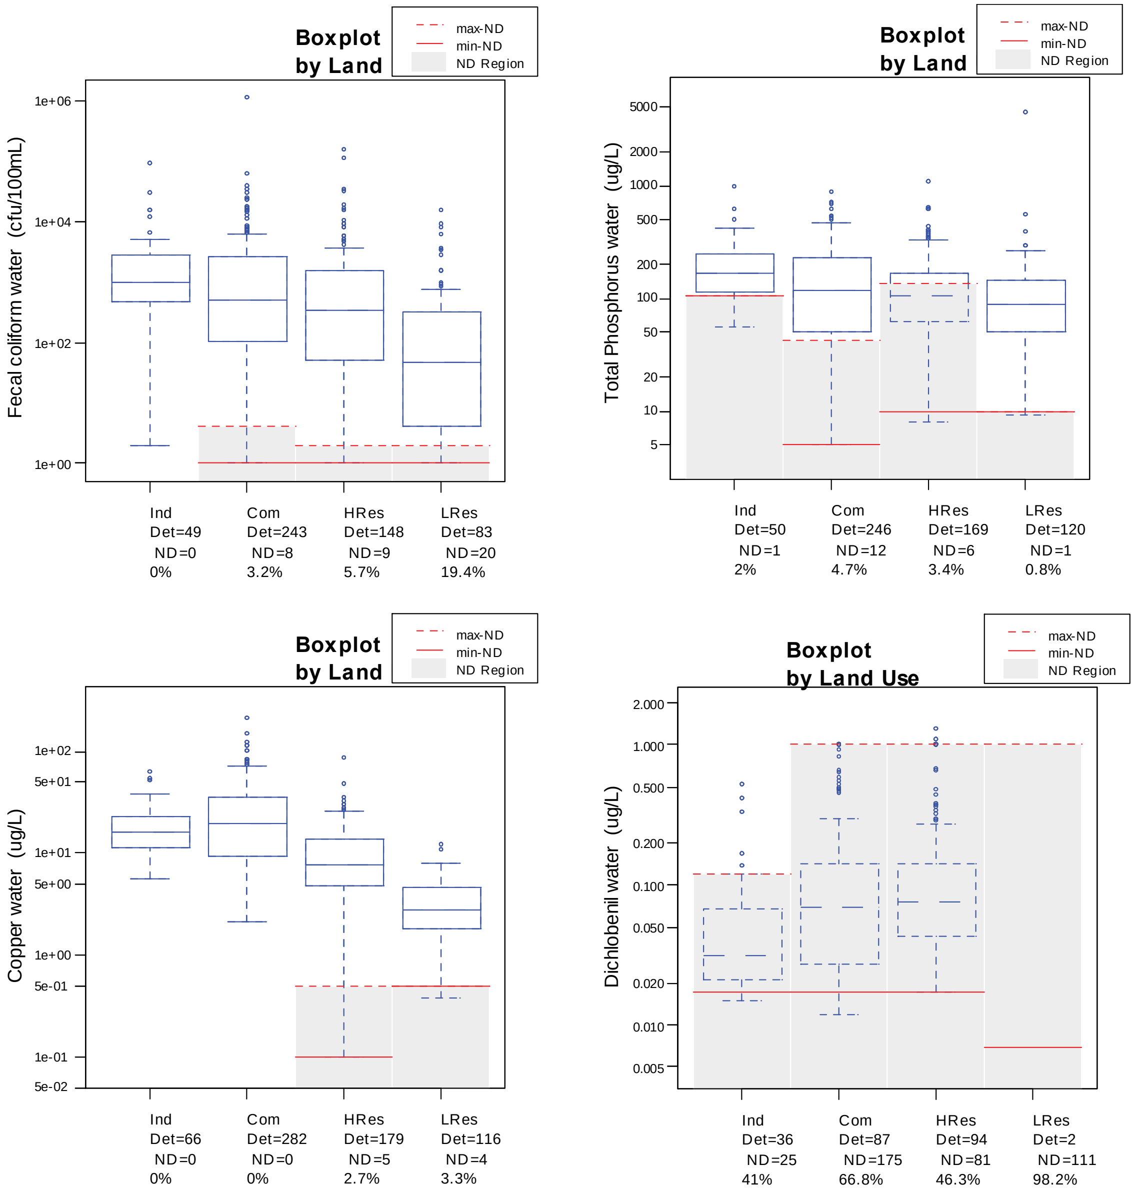

Figure C-6. Box and whisker plots of the detected data by land use for four example parameters.

As discussed in Helsel (2012), only the portions of the box plot which lie above the maximum non-detect limit are known exactly. To illustrate the region where the non-detected thresholds would influence the box plots, the visual of a gray "curtain" is used to represent the range of non-detects, as if it were pulled up over the box plot to illustrate where uncertainty still remains in the data set. The box outline is dashed under the gray curtain to reflect this uncertainty. Red horizontal lines also indicate the maximum and minimum non-detect thresholds.

Helsel (2012) recommends calculating the portion of the box plot using either KM or ROS statistics to estimate the 25th-50th-75th percentiles. This was not done for this report, so very little weight should be given to portions of the box plot in the shaded region. In some cases, the shaded region may be caused by only one or two non-detects. In these cases, the box plot may be only slightly affected. Each case must be assessed individually.

Similar to EDF plots (Figure C-5), box plots (C-6) illustrate how the surrounding land uses impact water quality of stormwater. In the case of fecal coliform, the box (25th and 75th) and median values (line) for industrial is quite different than the box for low-density residential. Visually the reader can see that the open circles range up to almost the same values, despite the land use categories. Box plots by land use were not calculated if there were less than 5 detected values for any given parameter. Data plots (Appendix E) will show the message: "Not Plotted (No land use has 5 or more detections)".

The box plot graphs and the EDF plots show similar patterns for fecal coliform and total phosphorus, with industrial and commercial areas showing higher concentrations than the residential land uses. If a parameter was detected in all samples or had relatively few non-detects, then the EDF and box plots will show the same information. For parameters where non-detects account for a larger percentages of the data set, the box plot is not presenting the same information as the EDFs. This means that the box plots are misleading for data sets that comprise medium to large percentages of non-detect data, as is the case for Dichlobenil and many of the organic parameters monitored.

Box plots were also used to summarize the contaminant loads by mass (kg) and area (kg ha^{-1}) over the land-use categories. The same approach and tools were used to construct the box plots for the load data, including the non-detect "curtain" which was calculated using the data qualifiers from the concentration data.

6. Box Plot by Season

These box and whisker plots (Figure C-7) are identical to the box plots by land use (Figure C-6), except that they are broken up by season. Seasons are as follows: Winter was Jan-Mar, spring was Apr-Jun, summer was July-Sept, and fall was Oct-Dec.

Box plots by season were not calculated if there were less than 5 detected values for any given parameter. Data plots (Appendix D) will show the message: "Not Plotted (No season has 5 or more detections)".

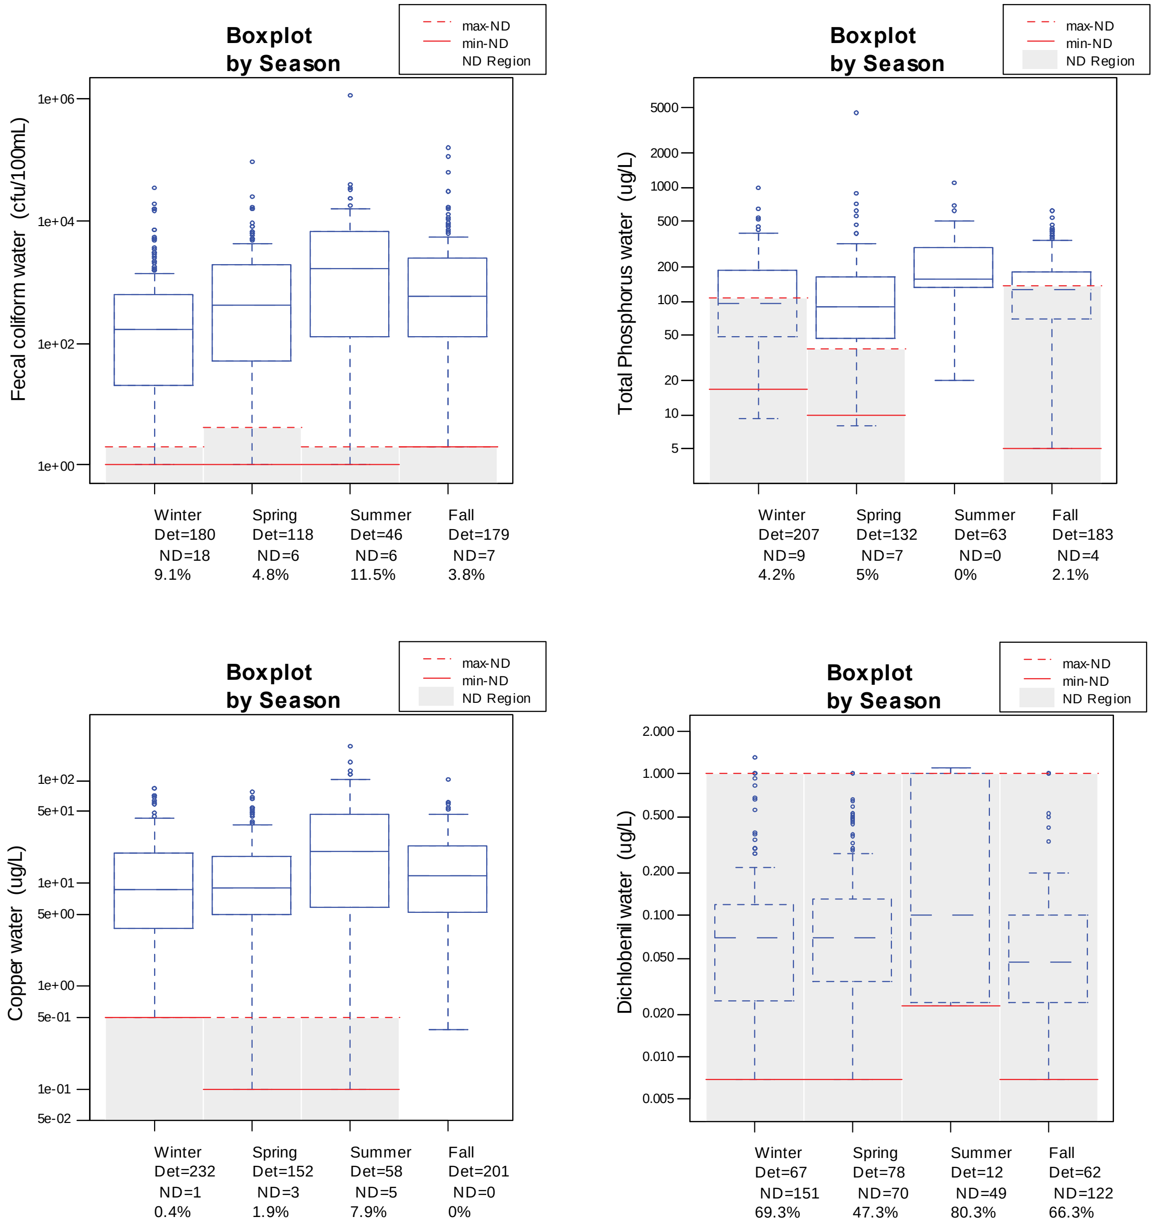

Figure C-7. Box and whisker plots of the detected data by season for four example parameters.

Statistical tests were carried out for the contaminant data on whether there was a significant difference between dry and wet seasons. The *dry* season is the months of May and June and the summer season in the box plot, and the *wet* season is the rest of the year. There is therefore more detailed information on seasonal differences shown in the box plot than described by the simple Wilcoxon test for significant differences. The observation that many of the parameters have higher concentrations during the dry season can be seen by the position of the summer median values for each of the example parameters (Figure C-7). However, this observation becomes more uncertain for the Dichlobenil data. Indeed, the Wilcoxon test describes the wet and dry season as being not significantly different.

Seasonal differences in storm-event contaminant loads (kg ha^{-1}) are also summarized using the box plots (Appendix H).

Case C Parameter – Data Sheet

In the data plots, many of the graphs are not shown, and the message “Not Plotted (Case C)” is given. Figure C-8 gives an example data sheet for a Case C parameter, triclopyr.

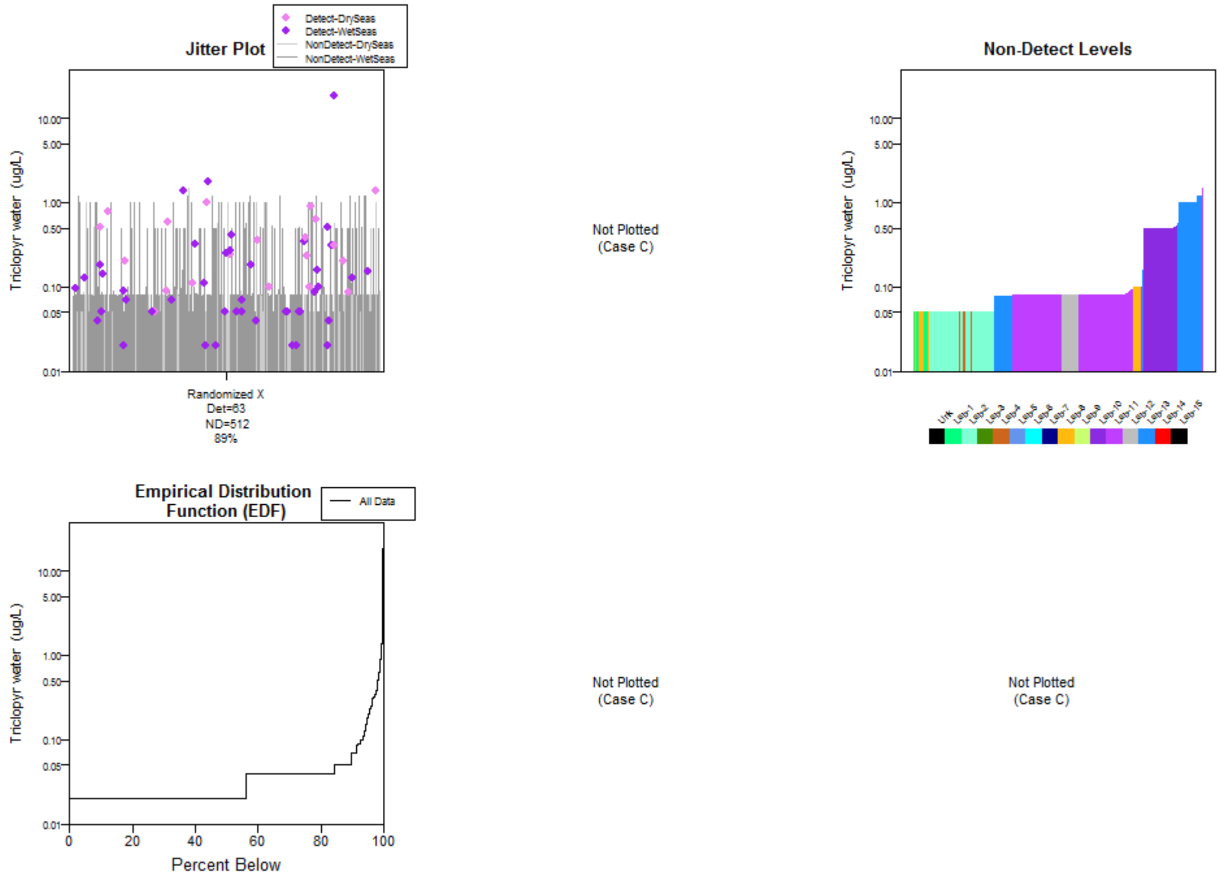

Figure C-8. Six plots for the parameter, triclopyr, in stormwater.

Triclopyr is an herbicide typically used in weed control. The previous *PS Toxics Study* found detectable concentrations in ~ 50% of the samples from commercial, industrial, and residential land uses, which was not the case in this stormwater study. It is soluble in water and breaks down fairly rapidly. Data sets that contain a large frequency of non-detects, such as for triclopyr, do not have enough detected values to warrant further analysis. The three plots that give the most information about the non-detections are retained. The jitter plot shows that there were 63 detected concentrations and that there were 512 non-detects. The plot of non-detect thresholds shows that many reporting limits were reported. The EDF plot shows that >90% of data was non-detect, and when detections were made, they varied from 0.1 to 18.3 ug/L.

Appendix D. Tables for Database Description

Table D-1. Distribution results for parameters with detection rates >95%.

Water	Sediment
Log-normal	***Normal***
1-Methylnaphthalene water (ug/L)	Dimethyl phthalate solid/sediment (ug/Kg)

Benzo(b)fluoranthene water (ug/L)	Benzo(k)fluoranthene solid/sediment (ug/Kg)
Benzo(b,k)fluoranthene water (ug/L)	Benzofluoranthenes, Total solid/sediment (ug/Kg)
Benzo(g,h,i)perylene water (ug/L)	Bis(2-ethylhexyl) phthalate solid/sediment (ug/Kg)
Benzo(k)fluoranthene water (ug/L)	Cadmium solid/sediment (ug/Kg)
Benzofluoranthenes, Total water (ug/L)	Chrysene solid/sediment (ug/Kg)
Biochemical Oxygen Demand water (ug/L)	Copper solid/sediment (ug/Kg)
Bis(2-ethylhexyl) phthalate water (ug/L)	CPAH solid/sediment (ug/Kg)
Cadmium water (ug/L)	Dibenzo(a,h)anthracene solid/sediment (ug/Kg)

Water	Sediment
Cadmium water dissolved (ug/L)	Fluoranthene solid/sediment (ug/Kg)
Calcium water (ug/L)	Fluorene solid/sediment (ug/Kg)
Chloride water (ug/L)	HPAH solid/sediment (ug/Kg)
Chrysene water (ug/L)	Gravel solid/sediment (%)
Conductivity water (uS/cm)	HPAH solid/sediment (ug/Kg)
Copper water dissolved (ug/L)	Indeno(1,2,3-cd)pyrene solid/sediment (ug/Kg)
CPAH water (ug/L)	Lead solid/sediment (ug/Kg)
Dibenzo(a,h)anthracene water (ug/L)	LPAH solid/sediment (ug/Kg)
Dibutyl phthalate water (ug/L)	Mercury solid/sediment (ug/Kg)
Dichlobenil water (ug/L)	Motor Oil solid/sediment (ug/Kg)
Diesel Range Organics water (ug/L)	Naphthalene solid/sediment (ug/Kg)
Diethyl phthalate water (ug/L)	Phenanthrene solid/sediment (ug/Kg)
Dimethyl phthalate water (ug/L)	Pyrene solid/sediment (ug/Kg)
Fecal coliform water (cfu/100mL)	Sand solid/sediment (%)
Fluoranthene water (ug/L)	Solids solid/sediment (%)
Fluorene water (ug/L)	Total Organic Carbon solid/sediment (%)
Gasoline Range Organics water (ug/L)	Total PAH solid/sediment (ug/Kg)
Hardness as CaCO3 water (ug/L)	Zinc solid/sediment (ug/Kg)
HPAH water (ug/L)	
Indeno(1,2,3-cd)pyrene water (ug/L)	
Lead water (ug/L)	
Lead water dissolved (ug/L)	
LPAH water (ug/L)	
Magnesium water (ug/L)	
Mecoprop water (ug/L)	
Mercury water (ug/L)	
Mercury water dissolved (ug/L)	
Naphthalene water (ug/L)	
Nitrite-Nitrate water dissolved (ug/L)	
Ortho-phosphate water dissolved (ug/L)	
pH water (pH)	
Phenanthrene water (ug/L)	
Pyrene water (ug/L)	
Sampled-Event Flow Volume water (m3)	
Storm Event Flow Volume water (m3)	
Surfactants water (ug/L)	
Total Benzofluoranthenes water (ug/L)	
Total Kjeldahl Nitrogen water (ug/L)	
Total PAH water (ug/L)	
Total Phosphorus water (ug/L)	
Total Suspended Solids water (ug/L)	
Triclopyr water (ug/L)	
Zinc water dissolved (ug/L)	

Table D-2. Summary of data qualifiers by parameter and matrix.
Those parameters with < 5% detection are highlighted with a gray-shaded box.

C = This flag applies to pesticide and PCB Aroclor results when the identification has been confirmed by GC/MS.

E = Reported result is an estimate because it exceeds the calibration range.

G = Expected/scheduled analyses could not be performed.

j or J = Analyte was positively identified; the associated numerical value is the approximate concentration of the analyte in the sample.

L = Off-scale high. Actual value is known to be greater than value given. To be used when the concentration of the analyte is above the acceptable level for quantitation (exceeds the linear range or highest calibration standard) and the calibration curve is known to exhibit a negative deflection.

T = Value reported is less than the laboratory method detection limit. The value is reported for informational purposes only and shall not be used in statistical analysis.

U = Analyte was not detected at or above the reported sample quantitation limit.

UJ = Analyte was not detected at or above the reported sample quantitation limit. However, the reported quantitation limit is approximate and may or may not represent the actual limit of quantitation necessary to accurately measure the analyte in the sample.

Multiple qualifiers may apply (e.g. JT).

Table D-3. Summary of data qualifiers by parameter and land use.
Those parameters with < 5% detection are highlighted with a gray-shaded box.

Appendix F. Data Plots for Contaminant Concentrations

Appendix F (172 pages) is available only online.

It is linked to this report at https://fortress.wa.gov/ecy/publications/SummaryPages/1503001.html

Appendix G. Contaminant Concentrations

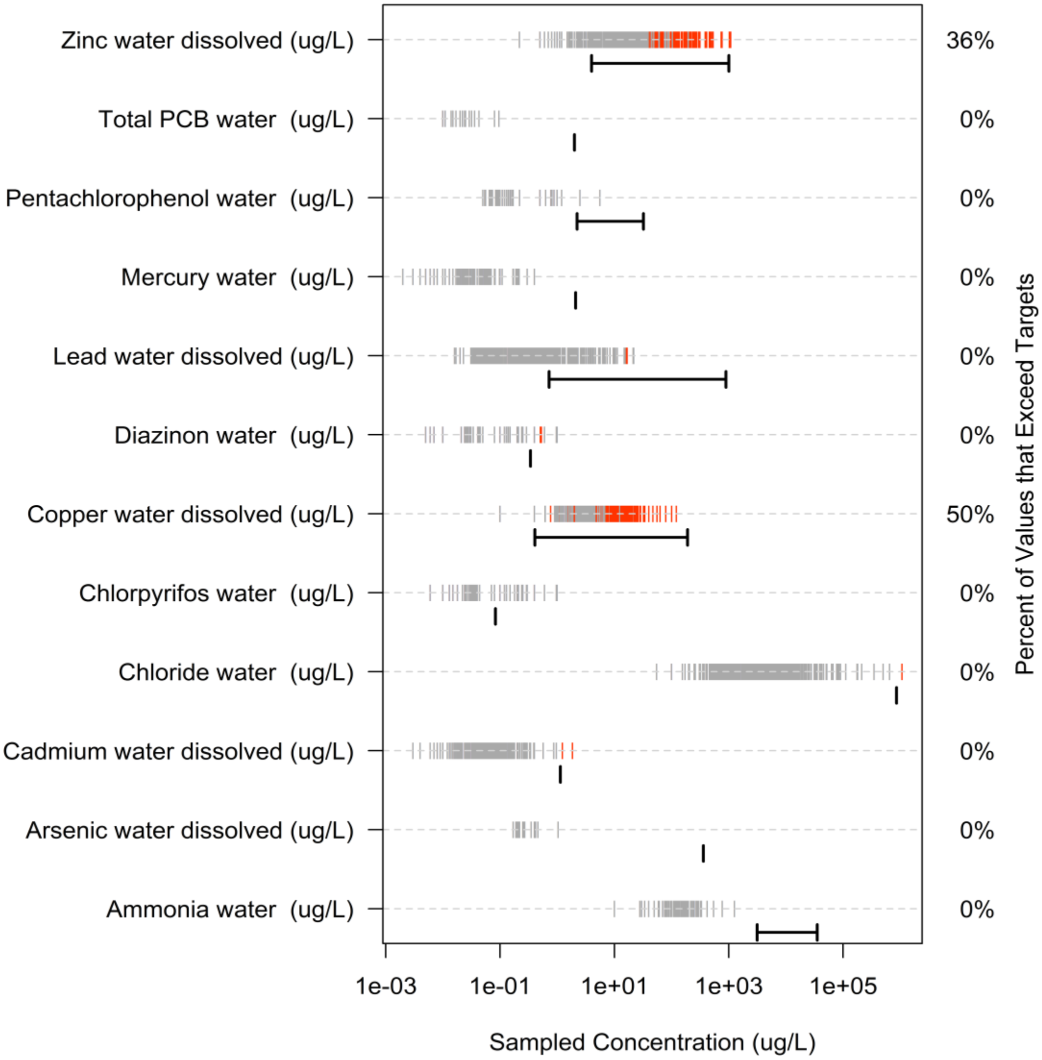

Figure G-1. Range of concentrations compared with water quality standards for the protection of aquatic life (acute criteria).

Vertical gray bars are concentrations that do not exceed criteria, and vertical red bars exceed the target. The range of criteria calculated for parameters with pH or hardness dependent criteria is highlighted by the black bar. The percent of samples which exceed the criteria is documented on the secondary y-axis.

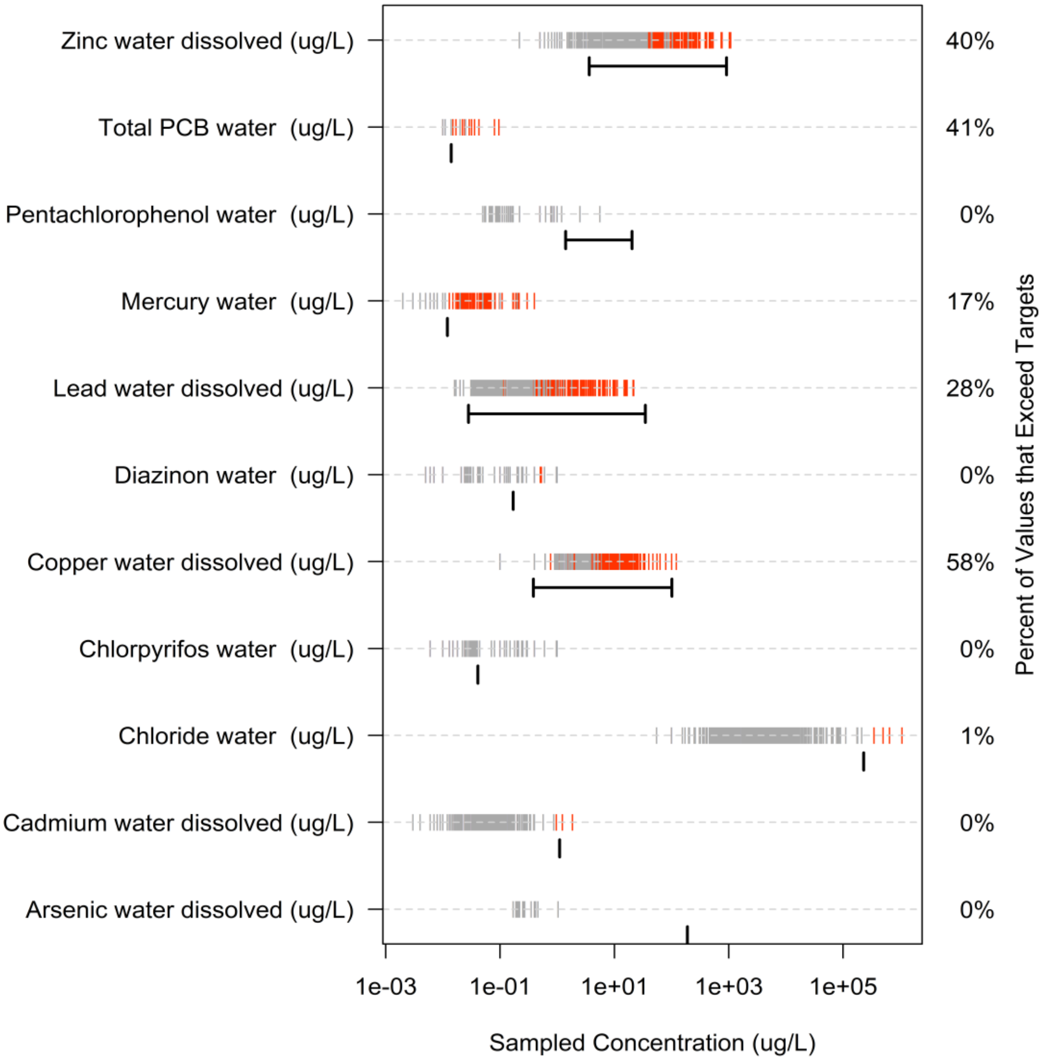

Figure G-2. Range of concentrations compared with water quality criteria for the protection of aquatic life (chronic criteria).

Vertical gray bars are concentrations that do not exceed criteria, and vertical red bars exceed the target. The range of criteria calculated for parameters with pH or hardness dependent criteria is highlighted by the black bar. The percent of samples which exceed the criteria is documented on the secondary y-axis.

Appendix J. Glossary, Acronyms, and Abbreviations

Glossary

Clean Water Act: A federal act passed in 1972 that contains provisions to restore and maintain the quality of the nation's waters. Section 303(d) of the Clean Water Act establishes the total maximum daily load (TMDL) program.

Conductivity: A measure of water's ability to conduct an electrical current. Conductivity is related to the concentration and charge of dissolved ions in water.

Exceed criterion or standard: Did not meet (or violated) the criterion or standard.

Fecal coliform: That portion of the coliform group of bacteria which is present in intestinal tracts and feces of warm-blooded animals as detected by the product of acid or gas from lactose in a suitable culture medium within 24 hours at 44.5 plus or minus 0.2 degrees Celsius. Fecal coliform are "indicator" organisms that suggest the possible presence of disease-causing organisms. Concentrations are measured in colony forming units per 100 milliliters of water (cfu/100 mL).

National Pollutant Discharge Elimination System (NPDES): National program for issuing, modifying, revoking and reissuing, terminating, monitoring, and enforcing permits, and imposing and enforcing pretreatment requirements under the Clean Water Act. The NPDES program regulates discharges from wastewater treatment plants, large factories, and other facilities that use, process, and discharge water back into lakes, streams, rivers, bays, and oceans.

Nutrient: Substance such as carbon, nitrogen, and phosphorus used by organisms to live and grow. Too many nutrients in the water can promote algal blooms and rob the water of oxygen vital to aquatic organisms.

Parameter: A physical, chemical, or biological property whose values determine environmental characteristics or behavior.

Percentile: A statistical number obtained from a distribution of a data set.

pH: A measure of the acidity or alkalinity of water. A low pH value (0 to 7) indicates that an acidic condition is present, while a high pH (7 to 14) indicates a basic or alkaline condition. A pH of 7 is considered to be neutral. Since the pH scale is logarithmic, a water sample with a pH of 8 is ten times more basic than one with a pH of 7.

Pollution: Contamination or other alteration of the physical, chemical, or biological properties of any waters of the state. This includes change in temperature, taste, color, turbidity, or odor of the waters. It also includes discharge of any liquid, gaseous, solid, radioactive, or other substance into any waters of the state. This definition assumes that these changes will, or are likely to, create a nuisance or render such waters harmful, detrimental, or injurious to (1) public health, safety, or welfare, or (2) domestic, commercial, industrial, agricultural, recreational, or other legitimate beneficial uses, or (3) livestock, wild animals, birds, fish, or other aquatic life.

PS Toxics Study: Control of Toxic Chemicals in Puget Sound: Phase 3 Data and Load Estimates (Herrera, 2011).

Stormwater: The portion of precipitation that does not naturally percolate into the ground or evaporate but instead runs off roads, pavement, and roofs during rainfall or snow melt. Stormwater can also come from hard or saturated grass surfaces such as lawns, pastures, playfields, and from gravel roads and parking lots.

Total suspended solids (TSS): Portion of solids retained by a filter.

Turbidity: A measure of water clarity. High levels of turbidity can have a negative impact on aquatic life.

Executive Summary

The project team's purpose was to improve the estimates of toxic chemical loadings to Puget Sound by targeted assessment of National Pollutant Discharge Elimination System (NPDES) permitted publicly owned treatment works (POTWs). Our goals were (1) to screen treated wastewater discharges for toxic chemicals that POTW operators do not routinely monitor, and (2) to improve the loading estimates for certain toxic chemicals by employing more sensitive analytical methods.

The project team identified and collected treated wastewater samples from ten POTWs of varying types of treatment process, size, and source of wastewater, distributed around the Puget Sound Basin. Two of the POTWs discharged to freshwater rivers, and the rest to Puget Sound marine waters. Together, the ten sampled POTWs discharged an average of about 48 percent of the total treated municipal wastewater discharged by all Ecology-permitted POTWs in the Puget Sound Basin. Although we collected samples only twice from each POTW (in February and July 2009), these 20 samples represented the aggregate of all treated wastewater discharged by the 106 permitted POTWs of the Puget Sound Basin.

The project team analyzed the wastewater samples for the following classes of toxic chemicals, using methods that yielded significantly lower than typical reporting limits:

- Polycyclic aromatic hydrocarbons (PAHs)
- Phthalates
- Other base/neutral/acid (BNA) extractable compounds
- Pesticides
- Herbicides
- Polybrominated diphenyl ethers (PBDEs)
- Perfluorinated compounds (PFCs)
- Polychlorinated biphenyls (PCBs)
- Metals (copper, lead, and zinc)

Following data review and validation, this project generated a total of 4,579 valid analytical results that characterized treated wastewater discharged from POTWs into the Puget Sound Basin. Toxic chemicals from each chemical class were detected in at least one sample from each of the ten sampled POTWs. We detected a total of 230 chemicals, not counting PBDE and PCB homologs. In order to evaluate the reasonableness of the results from this study, we compared the total concentrations of phthalates, PFCs, and PCBs discharged from the ten subject POTWs with those reportedly discharged to or from other POTWs in the state. The results of this study were similar to the results of those several other previous studies.

The project team determined individual annual loading rates of each of the chemicals from each of the ten sampled POTWs. Although the small number of samples precluded drawing any conclusions regarding specific POTWs, a few general findings were apparent.

- The majority of the PAHs discharged from most of the POTWs consisted primarily of five chemicals (fluoranthene, fluorene, naphthalene, phenanthrene, and pyrene).

- The majority of the phthalates discharged from each of the ten POTWs consisted of bis(2-ethylhexyl) phthalate.

- The POTWs discharged only relatively small amounts of about a dozen pesticides and herbicides.

- Although the POTWs discharged many PBDEs, only three of them (BDE-047, BDE-099, and BDE-209) comprised almost all of the total loadings from each.

- Similarly, the POTWs discharged most of the PFCs that were analyzed, but only four of the PFCs (perfluorohexanoate, perfluorononanoate, perfluorooctane sulfonate, and perfluorooctanoate) comprised most of the total loadings from each POTW.

- Generally, as the total loadings of PCBs increased from any given POTW, so did the number of different PCB congeners that were discharged. Most of the PCB congeners were distributed among the tri-, tetra-, and penta-chlorobiphenyl homolog groups.

The project team also estimated the total loadings from POTWs to the surface waters of the Puget Sound Basin of 68 chemicals, plus two homolog groups and seven chemical classes. Chemical classifications are useful because they often indicate which chemicals might share a single source, affect environmental receptors in a similar manner, or all be amenable to particular treatments or other control actions. These estimated loadings were divided to represent the input from each of the 14 geographically distinct study areas of the basin. Due to the limited number of sampling events and atypical weather during the sampling period, we did not discern seasonal variations in loadings.

The results from this study greatly extended our understanding of chemical loadings from POTWs and were consistent with the results from Phase 2 and other recent studies conducted by Ecology and others. Future determination of the most effective and efficient actions for controlling or managing toxic threats should include evaluation of the effects of the chemicals, the new loading estimates of those chemicals, and the many other interdependent variables that characterize the pathways that facilitate chemical movement through the environment to Puget Sound.

1. Background and Purpose

1.1 Context of This Project

The Washington State Department of Ecology (Ecology) and several other groups have been working with the U.S. Environmental Protection Agency (EPA) and the Puget Sound Partnership (PSP) to restore the environmental health of Puget Sound by 2020 (PSP, 2010). This multi-year effort has required development of strategies, actions, and performance measures for restoring the Puget Sound ecosystem. Ecology has teamed with several partner organizations to study toxic chemical loadings to Puget Sound to understand the relative contributions from sources of contaminants in the Puget Sound ecosystem (Ecology, 2010). The main objectives of the "Control of Toxic Chemicals in Puget Sound" projects have included:

- Identify toxic chemicals that have harmed or threaten to harm the Puget Sound ecosystem or the beneficial uses which humans obtain from the Sound.

- Estimate the loading rates of key contaminants from their sources through their major pathways to Puget Sound.

- Provide information that will support development of a strategy to identify the actions, practices, and policies necessary to protect and restore the overall health of the Puget Sound ecosystem.

Accomplishing these objectives requires an understanding of the complex inter-relationships among the following three distinct elements of the Puget Sound ecosystem:

- The sources of pollutants.
- The pathways those pollutants take through the environment.
- The effects of those pollutants on the ecosystem.

It is important to clarify the difference between sources and pathways.

The term *source* may apply in a variety of ways with regard to chemicals in the environment. For the purpose of this project, the term source is defined as the location, object, or activity from which a pollutant is released to environmental media or released in a form that can be mobilized and transported through an environmental *pathway*. The term *primary source* identifies the initial release of a pollutant, as distinct from a *secondary source*, such as an old toxic chemical spill site, atmospheric deposition, or a publicly owned wastewater treatment plant (POTW). However, these secondary sources are more accurately described as pathways because they transport and mobilize chemicals from one location to another, or (in the case of POTWs) act as a focal point for chemical collection. Often, as also is the case for POTWs, pollutants moving along a pathway are degraded, destroyed, or permanently rendered harmless through designed or natural treatment processes.

The following examples illustrate the distinction between primary sources and secondary sources:

- Examples of *Primary Sources*:
    - Polycyclic aromatic hydrocarbons released to air from wood or petroleum burning.
    - Copper released to air, stormwater, and roadside ditches from brake pad wear.
    - Unmetabolized pharmaceuticals discharged from homes into sanitary wastewaters.
    - PCBs released to soil from transformer leakage.
    - Triclopyr applied to roadside ditches to control weeds.

- Examples of *Secondary Sources*, which are typically also pathways:
    - Atmospheric deposition of pollutants onto the surface of land or waterbodies.
    - Stormwater discharged from a municipal outfall into a stream.
    - Treated wastewater discharged from a POTW.
    - Contaminated soil leachate entering either groundwater or surface water.
    - Forest fire releasing back into the air the mercury that the growing vegetation had previously absorbed.

The toxic effects of a chemical depend on the dose (or exposure concentration), the duration of exposure, the timing of the exposure (e.g., at what stage of the lifecycle exposure occurs), the synergism and antagonism among multiple toxicants, and the harmful result of the exposure (e.g., temporary functional impairment, reduced reproductive capacity, shortened lifespan, and death). Given the goal of protecting the entire Puget Sound ecosystem, when evaluating relative toxic effects, Ecology must also consider the impacts of chemicals on the dependencies and interactions among species, such as through food chain relationships and altered predator avoidance behaviors.

Thus, while estimates of total loadings are important data, they are not particularly meaningful when considered in isolation. Loadings do not directly translate into threats, such that reducing the loading by half would reduce the threat by half. Determining the most effective and efficient actions for controlling or managing toxic threats must include evaluation of many interdependent variables and options. Management actions may occur at several different points along the pathways that facilitate chemical movement through the environment. For example, a control action may be to eliminate the initial release of the chemical by banning the primary source. Alternately, a more efficient method to reduce the threat from a chemical may be to treat a contaminated medium at a location where the pathways of several chemicals converge. Another approach for managing a toxic threat may be to establish a management zone for a small area, for example by prohibiting shellfish harvest within the vicinity of a POTW outfall. In some cases, targeting some of the available resources on limited goals may be preferable so that the remaining resources will be sufficient to ensure that other critical areas always remain healthy and usable. Final policy decisions for how to control and manage the chemicals that enter the Puget Sound ecosystem must include consideration of all these factors along with the various estimates of chemical loading.

These toxic chemical loading projects have been conducted in three phases, which are described in the following subsections. The Phase 1 study provided initial estimates of toxic chemical loadings to Puget Sound. Phase 2 projects improved those loading estimates. Phase 3 activities, of which this project is one component, target priority sources to collect and analyze environmental samples and improve the numerical model of the Sound (the Puget Sound box model) with the new data. The results of Phase 3 will help to enable Ecology and the PSP to assign the threats from toxic chemicals to specific sources and to select and implement actions to clean up and prevent contamination from those sources posing the greatest risks to Puget Sound.

Phase 1 – Initial Estimate of Toxic Chemical Loadings to Puget Sound

The purpose of this project was to assemble preliminary estimates of loadings of the most important toxic chemicals to Puget Sound via the presumed nine major pathways. These pathways were: surface runoff, aerial deposition onto Puget Sound, wastewater discharge, combined sewer overflows, direct spills to aquatic systems, groundwater discharges to marine surface waters, exchanges with the Pacific Ocean, leaching or biologically-induced movement from contaminated sediments, and migration of contaminated biota into Puget Sound. Based on data already available for the first five of these, the authors estimated the loadings of 17 chemicals (or classes of chemicals) from 14 hydrologically-based study areas that comprised the Puget Sound Basin. Depending on the contaminant, the main pathways were surface runoff and direct deposition from the air to the Sound (Hart Crowser, Inc., et al., 2007).

Phase 2 – Improve Loading Estimates

Two critical informational needs were to better understand and quantify the sources of toxic contaminants that enter Puget Sound and to improve the understanding of how toxics move within the ecosystem once they are there. The seven different projects in Phase 2 built upon the initial Phase 1 study to address these needs, and their results are available (Ecology, 2010a).

One of the Phase 2 projects focused on improving the loading estimates from permitted point source dischargers of wastewater within the Puget Sound Basin (EnviroVision Corporation, et al., 2008). While the available data were limited, the authors found that the contributions of toxic chemicals from wastewater dischargers (both publicly and privately owned) were small relative to the total loadings from all the major loading sources to Puget Sound, ranging from 1.4 to 7.0 percent of the total. The data also suggested that publicly owned treatment works (POTWs) discharged significantly more of some toxic chemicals than did the privately owned industrial point source dischargers.

Phase 3 – Targeting Priority Toxic Sources

In Phase 3, six of the 11 projects included the collection and analysis of environmental samples from within the Puget Sound Basin so that Ecology and its partners could further improve estimates of loadings from specific sources. The other projects focused on improving the Puget Sound box model with the new data and the synthesis and reporting of the results from all three phases to date. Results of the studies completed to date are available (Ecology, 2010a).

Two of the Phase 3 projects focused on POTWs regulated by Ecology through the National Pollution Elimination System (NPDES) permit program. One of these projects consisted of collecting and analyzing samples of wastewater for pharmaceuticals and personal care products

(PPCPs) (Lubliner, et al., 2010). The authors found differences in the removal efficiency of PPCPs among wastewater treatment plant processes, and that advanced nutrient reduction and tertiary filtration may provide additional PPCP removal. The other Phase 3 project that focused on POTWs is the project addressed by this report.

1.2 Purpose of This Project

One of the recommendations from one of the Phase 2 projects was:

> "If better estimates of toxic chemical loadings are necessary, Ecology should collect targeted samples and analyze them using methods that produce smaller MDLs. Also, as Ecology identifies emerging potential threats from other toxic chemicals (for example, polybrominated diphenyl ethers, fluorinated organic compounds, bisphenol A, and pharmaceuticals and personal care products), Ecology should (or should require permittees to) collect and analyze wastewater samples for those newly identified pollutants." (EnviroVision, et al., 2008)

The purpose of this project was to improve the estimates of toxic chemical loadings to Puget Sound by targeting POTWs and collecting and analyzing representative samples of the treated wastewater that they discharge. The goals of this project were (1) to screen treated wastewater discharges for toxic chemicals that POTW operators do not routinely monitor, and (2) to improve loading estimates for certain toxic chemicals by employing more sensitive analytical methods.

2. Methods

The project team consisted of the following organizations:

- Washington State Department of Ecology (Ecology)
- Herrera Environmental Consultants, Inc. (Herrera)
- Ecology and Environment, Inc. (E & E)
- Analytical Resources, Inc. (ARI)
- Axys Analytical Services, Ltd. (Axys)
- Pacific Rim Laboratories, Inc. (Pacific Rim)

Ecology was the project lead. E & E worked under contract to Ecology and was responsible for coordination of field and laboratory activities and quality assurance review of the analytical data. Herrera worked under subcontract to E & E and was responsible for sample collection and loading calculations. ARI worked under subcontract to Herrera and provided clean sample containers. Axys and Pacific Rim worked under subcontract to the Ecology Manchester Environmental Laboratory (MEL) and conducted the analyses of polybrominated diphenyl ethers, perfluorinated compounds, and polychlorinated biphenyls. MEL conducted the analyses of all the other parameters.

2.1 General Approach

The project team expected that variations in the following factors might drive differences in the loading rates of the various toxic chemicals discharged from POTWs:

- Types of treatment processes employed by the POTW.
- Rate of flow through the POTW.
- Activities of the sources in the POTW service area (e.g., residential or industrial).
- Time of day.
- Season of year.

Assessing these factors would have involved collecting samples from several POTWs that represented each type of treatment, at several different flow rates, for a variety of upstream sources located in different areas of the Puget Sound Basin, and collecting many samples from each POTW to establish how the loading rates of toxic chemicals varied at different times of the day and during the seasons of the year. However, due to a limited budget, the project team needed to produce a limited scope of work that balanced all of these factors, while maximizing the amount of usable data that this project would produce.

2.1.1 Selection of Pollutants

Ecology requires NPDES-permitted POTWs to periodically analyze their treated effluents for Priority Pollutant chemicals using standard analytical methodology and to report that data to Ecology. Review of that data in Phase 2 (EnviroVision, et al., 2008) found that most organic analytes were not detected in the effluents discharged from the POTWs using then standard analytical methods. These organic compounds included:

- Polycyclic aromatic hydrocarbons (PAHs)
- Phthalates
- Other base/neutral/acid (BNA) extractable compounds
- Pesticides
- Herbicides
- Polychlorinated biphenyls (PCBs)

In addition, Ecology was aware that several new classes of toxic chemicals were emerging as potentially harmful components of POTW effluent. These chemicals included:

- Polybrominated diphenyl ethers (PBDEs)
- Perfluorinated compounds (PFCs)
- Pharmaceuticals and personal care products (PPCPs)

The project team chose to analyze the wastewater discharges for 390 of the compounds contained within these chemical classes, excluding PPCPs. We did not focus on PPCPs in this study because another toxics loading project was evaluating these chemicals (Lubliner, et al., 2010). The project team also analyzed the treated wastewaters for total copper, lead, and zinc to enable a better comparison of the results from this study with the previous loading estimates derived in Phase 2 (EnviroVision, et al., 2008). We employed analytical methods that were more sensitive than those which POTW operators have been required to use so that we might detect smaller concentrations of the target pollutants (i.e., to decrease the "minimum detection limits" – MDLs). We analyzed for PCBs in only the samples collected in February, and only for six of the POTWs (Bremerton STP, City of Tacoma (Central No. 1), Everett STP (Outfall 100), King County West Point, Pierce County Chambers Creek STP, and Shelton STP).

2.1.2 Selection of POTWs

General POTW Characteristics

POTWs receive the following types of wastewater for treatment:

- Raw sewage from residential toilets, showers, and sinks, including wastes from laundry, dishwashing, and food preparation activities.

- A wide variety of wastes from industrial, commercial, and institutional facilities which may or may not undergo pretreatment prior to discharge to the POTW.

- Unless collected and conveyed separately, stormwater runoff from streets, rooftops, and other impervious surfaces.

Once wastewater reaches a POTW, it undergoes treatment before it is discharged to the environment, typically a surface water body. The treatment process can involve three stages: primary, secondary, and tertiary treatment. Occasionally where stormwater and sanitary lines are combined, large storm events can produce an influx of stormwater in excess of plant capacity that overwhelms the treatment system, resulting in the combined stormwater and sewage bypassing the treatment plant and discharging directly to surface waters untreated. This is a "combined sewer overflow" event and, except for the potentially severely impacted local areas, does not constitute a large part of the total loading of toxic chemicals to Puget Sound (Hart Crowser, et al., 2007).

For treating wastewater, the primary treatment stage employs a mechanical or physical process designed to remove solids and immiscible fats and oils. This may be accomplished in large settling tanks (usually referred to as sedimentation tanks or primary clarifiers) where solids and immiscible materials either float to the top or sink to the bottom. POTWs may also use preliminary screens to separate large objects before wastewater enters the settling tanks. The top product is skimmed off with a raking mechanism and is processed for disposal. The bottom product (or sludge) is scraped into a hopper where it is further dewatered before disposal to a landfill, biosludge composter, or waste fuel incinerator. Sludge can also be processed along with other compostable waste (grass clippings, leaves, food waste, and some cardboard products) and be sold as a biosolid fertilizer.

The purpose of secondary treatment is to meet federal and state secondary effluent standards by substantially degrading the biological or organic content of the liquid sewage effluent. These standards target biological oxygen demand and total suspended solids, typically using aerobic biological processes. The essential elements that drive the secondary treatment process are oxygen and biota, consisting of bacteria and protozoa that are capable of consuming the soluble organic contaminants (e.g., sugars, fats, and other hydrocarbons). The biota require a substrate in which they can thrive and bind much of the less soluble fractions into flocculent. Flocculation is a process of contact and adhesion whereby the particles of dispersion form larger-size clusters. Secondary clarifiers separate the flocculated solids from the wastewater stream, producing an additional sludge product that is processed in similar ways as the primary sludge product.

Some POTWs use treatment processes with the intent to address specific pollutants (e.g., organic nitrogen and phosphorus) beyond those specified in secondary water quality standards (biological oxygen demand, total suspended solids, and fecal coliform). They may employ multiple treatment processes for removing specific target pollutants. Sometimes this is called "tertiary treatment."

Prior to discharge to the environment, treated wastewater requires disinfection to inactivate pathogens that were not destroyed earlier in the treatment process. Disinfection is the additional step used to decrease the number of microorganisms. While the traditional and most common disinfection method is chlorination, ultraviolet (UV) and ozone are alternate methods.

Representative POTWs of the Puget Sound Basin

Under the NPDES permit program, Ecology has permitted approximately 106 POTWs to discharge treated wastewater in the Puget Sound Basin. Ecology had discharge flow information available in its NPDES permit management database (Ecology, 2010b) for the years 2007 through 2009 for all 106 POTWs except for the ten relatively smaller facilities operated by the U.S. Navy, U.S. Army, or Tribes. Appendix A identifies the total population of 96 candidate POTWs that the project team considered for this study. Of these 96 POTWs, 83 had flow data for all 36 months, seven had flow data for at least 24 months but less than 36, five had flow data for at least 12 months but less than 24, and one had flow data for less than 12 months. The data were sufficient for determining average flows, and were comparable to the flows used for the prior Phase 2 loading estimation by EnviroVision, et al. (2008). The total discharge volume to the Puget Sound Basin employed for the Phase 2 estimation was 130,061 mgy, while the total volume employed in this study was 124,142 mgy.

Although the project team hoped to select a sufficient number of POTWs to represent the entire range of operating variables in Puget Sound Basin, due to the limited budget the number of POTWs that we could sample was limited to ten. Although all the variations of size, age, type of treatment process, and type of source cannot be adequately compared through evaluation of only ten facilities, by providing some representation of each we expected to cover a relatively wide range of conditions. Access to the facilities and their current operating status (e.g., no plant upgrades ongoing or planned between the two sampling events) also contributed to the final selection. Table 1 identifies the POTWs that we selected as the subjects of this study.

The project team selected POTWs to represent a flow-weighted cross-section of the 96 candidate POTWs. The percentages of the total flows to Puget Sound from the selected POTWs were roughly comparable to those of all 96 POTWs. These percentages were for small POTWs (<1 mgd) 0.5% for the ten selected POTWs versus 3.8% for all 96 Puget Sound POTWs, for medium POTWs (1 to 10 mgd) 6.0% versus 23.2%, and for large POTWs (>10 mgd) 93.5% versus 73.0%, respectively. Since the five largest sampled POTWs discharged about 46% of the total treated effluent discharged by the POTWs in the Puget Sound Basin, the project team determined that this distribution of facilities adequately represented the actual flows to the Sound. Table 2 shows the similarity between the distributions of the total flows among all 96 small, medium, and large POTWs and the distributions among the ten POTWs sampled in this project.

Nine of the ten selected POTWs used an activated sludge secondary treatment process. The remaining facility (Everett STP (Outfall 100)) was a trickling filter/solids contact system. Since at least 66 percent of the POTWs in the Puget Sound Basin used activated sludge for secondary treatment, weighting the selection toward this treatment process was appropriate.

Four POTWs in the Puget Sound Basin employed treatment processes to address pollutants beyond those specified in the secondary effluent standards. We sampled one of these, the Sumner STP, for this study. Since only four Ecology-permitted POTWs that discharged to surface waters in the Puget Sound Basin employed a membrane bioreactor (MBR) (Carnation WWTP, Duvall STP, Port Orchard WWTP, and Seashore Villa STP), and their discharges have been relatively small, with a combined total flow of 2.34 mgd, we sampled none of the MBR-equipped facilities for this study.

For disinfection, seven of the selected facilities used chlorine, and the remaining operations used UV. This distribution adequately represented the types of disinfection employed in the Puget Sound Basin because most of the older facilities there still use chlorine, while newer facilities often rely on UV.

In terms of source activities in the POTW service areas, five of the selected POTWs received a significant amount of industrial influent, two received minor amounts, and three treated practically only sanitary waste from their primarily residential service areas. The selected POTWs were distributed among seven of the 14 study areas in the Puget Sound Basin to ensure representative geographic coverage (Figure 1).

2.1.3 Seasonal and Temporal Sampling

The project team sampled each POTW twice. To maximize the potential seasonal variation in loading rates, we scheduled collection of those two samples to represent significantly different weather conditions: winter (wet season) and summer (dry season), in February and July 2009, respectively. As mentioned previously, we analyzed PCBs only once for six selected POTWs, in February 2009.

The limited budget prevented the project team from tracking the variation in loading rates that may occur during the course of a given day because doing so would have required analyses of many more samples. However, we did account for potential variations during a typical weekday by analyzing 24-hour composited samples collected Mondays through Fridays.

2.2 Field Methods

This section summarizes how the project team collected representative samples of treated wastewater from the ten POTWs. Additional details may be found in the Quality Assurance Project Plan (QAPP) (E & E and Herrera, 2009).

The project team conducted a site visit to each facility to assess site access, select the most appropriate locations for collecting samples, and evaluate equipment installation needs. The following bullet items describe the general sampling site location at each POTW.

- Bellingham STP – Automated and grab samples were collected from the outfall flume downstream of the chlorination and dechlorination facility.

- Bremerton STP – Automated and grab samples were collected from contact tanks downstream of the chlorination and dechlorination facility, just upstream of the outfall.

- Burlington WWTP – Automated and grab samples were collected from the inlet to the outfall pipe downstream of the UV radiation treatment.

- City of Tacoma (Central No. 1) – Automated and grab samples were collected from the contact tank near the outfall.

- Everett STP (Outfall 100) – The automated sample was collected by way of an access stand pipe located downstream of the first chlorination facility. This represented the permit compliance point for the Everett POTW for all parameters except residual chlorine and fecal coliform. This location was upstream of the comingling with the Marysville STP effluent and upstream of a pump station where additional chlorination may occur.

The grab sample was collected from a sampling spigot located downstream of this pump station at the compliance point for residual chlorine and fecal coliform. Grab samples could not be collected from the same location as the automated samples due to physical constraints.

- Gig Harbor STP – Automated and grab samples were collected from a mixed effluent contact tank downstream of the chlorination and dechlorination facility. The grab samples were collected slightly downstream of the automated sampler location.
- King County West Point – Automated and grab samples were collected from the effluent wet well downstream of the chlorination and dechlorination facility.
- Pierce County Chambers Creek STP – Automated and grab samples were collected from the contact tank mixing area downstream of the chlorination and dechlorination facility, just upstream of the outfall.
- Shelton STP – Automated and grab samples were collected from contact tanks downstream of the chlorination and dechlorination facility.
- Sumner STP – Automated and grab samples were collected near the outfall.

The project team collected all 20 treated wastewater samples as specified in the QAPP (E & E and Herrera, 2009). The 24-hour composite samples represented the treated effluent discharged during one full weekday. Tables 3 and 4 provide the specific sampling schedules for each of the ten POTWs, winter and summer, respectively. We used automated samplers to collect time-weighted composite samples for all analytes except PFCs and metals. Since parts of the automated sampling equipment were composed of Teflon and glass, we collected the aliquots for PFCs and metals analyses as discrete grab samples in appropriate containers. We collected these grab samples at two times to represent both the high and low daily flow at each POTW. We sampled all ten POTWs within a narrow time frame so that the samples represented similar weather conditions.

The project team cleaned the sample bottles (including the 9-liter [L] glass jar, the 1-L polypropylene bottle, and the 500-milliliter [ml] Teflon bottle for metals) as described in the QAPP (E & E and Herrera, 2009). Sample bottles and tubing were kept tightly sealed, and the ends of the tubing were covered with aluminum foil and placed into a pre-marked sealable plastic bag until installation at the facility.

The project team programmed the automated, refrigerated sampling devices (ISCO Avalanche®) to collect a 175-ml aliquot every 30 minutes, for a total of 48 sample aliquots collected from each POTW over the 24-hour sampling period. On the scheduled sampling day, we installed each sampling device at the site and verified the program. We then operated the sampling device manually, collecting and discharging effluent, to rinse the intake hosing and verify that the device collected 175 ml of effluent. To verify that the program had started and the automatic sampling device was working correctly, before moving to the next POTW, we waited while the ISCO-Avalanche collected at least two sample aliquots.

Upon completion of the automated collection of the 24-hour composite sample, project personnel checked the equipment to verify that no sampling errors had occurred. We capped the sample jar, removed it from the sampling device, and placed it on ice. At this time, we manually operated the sampling device to collect an aliquot of effluent to verify that 175 ml of effluent was still being collected.

The project team transported bottles for the grab portions of each sample in single resealable plastic bags. We collected grab samples from all the POTWs using the modified one-person clean hands/dirty hands procedure. In most cases it was necessary to use an extension pole and attach the sample bottle with zip ties to reach the effluent stream. We then rinsed the extension pole with deionized water before using it at the next POTW.

Once project personnel had collected both the grab and composite aliquots, we immediately capped, labeled, and put them on ice in a cooler. We then transported the samples to the Ecology Field Operations Center in Lacey and refrigerated them until delivering them the following morning to MEL for analysis.

Winter sampling occurred during the week of February 9, 2009. However, the project team resampled two of the POTWs (Tacoma Central and Chambers Creek) the following week due to the partial failure of two of the automated samplers and damage to the field duplicate sample. Thus the grab samples for these two POTWs were not collected on the same day as the composites. We successfully collected the entire set of 48 aliquots at nine of the ten facilities. However, the Burlington POTW shut down in the final hour of the sampling effort and resulted in collection of only 47 aliquots from this facility.

Summer sampling occurred during the week of July 13, 2009. All 48 aliquot were collected at all ten POTWs, and there were no irregularities associated with this event.

The project team obtained daily flow rate information from the operators of each of the POTWs for the days when samples were collected. We also reviewed the flow data that the POTWs had submitted to Ecology via their discharge monitoring reports for the 3 years from January 2007 through December 2009.

2.3 Laboratory Methods

The Ecology MEL analyzed the wastewater samples for all of the targeted toxic chemicals except PBDEs, PFCs, and PCBs. Pacific Rim analyzed its portion of the samples for PBDEs and PCBs. Axys analyzed its portion of the samples for PFCs. The analytical methods identified in the following subsection are described in detail in U.S. EPA 1999a, 2004, and 2007.

2.3.1 Analytical Methods

PAHs were analyzed using U.S. EPA SW-846 Method 8270 SIM. Method 8270 SIM is a modification of Method 8270. Selected ion monitoring (SIM) enhances sensitivity by setting the mass spectrometer (MS) to detect specific ions rather than a range of ions. Sensitivity is generally increased by a factor of 10 over standard MS measurements. The primary disadvantage of SIM is a loss of qualitative information (unable to compare spectra).

BNAs and herbicides were analyzed using U.S. EPA SW-846 Method 8270. BNA extractable compounds included the phthalates chemical class. Samples were analyzed by gas chromatography/mass spectrometry (GC/MS) following extraction and, if necessary, appropriate sample cleanup and derivatization procedures. Sample extracts were injected into a gas chromatograph (GC) equipped with a capillary column that utilized a temperature program to separate analytes that were then detected with an MS. Analytes were identified by comparing electron impact spectra to the spectra of known standards. Analytes were quantified by comparing the response of a major ion relative to an internal standard using a calibration curve developed for each analyte.

Pesticides were analyzed using U.S. EPA SW-846 Method 8081. Samples were analyzed by gas chromatography/electron capture detector (GC/ECD) following extraction and, if necessary, appropriate sample cleanup procedures. Sample extracts were injected into a GC equipped with a capillary column, which utilized a temperature program to separate analytes that were then detected with an electron capture detector (ECD). Analytes were identified by comparing the retention time of target compounds with retention times of known standards on two dissimilar columns. Analytes were quantified by comparing the sample peak response using a calibration curve developed for each target compound.

PBDEs were analyzed using U.S. EPA method GC/HRMS 1614. Samples were analyzed using gas chromatography/high-resolution mass spectrometry (GC/HRMS) following extraction and, if necessary, appropriate sample cleanup procedures. Sample extracts were injected into a GC equipped with a capillary column, which utilized a temperature program to separate analytes that were then detected with an HRMS. Individual compounds (i.e., congeners) were identified by comparing the retention time and ion-abundance ratio of target compounds and associated labeled analog compounds with retention times and ion-abundance ratios of known standards. Congeners were quantified using the isotopic dilution quantitation technique, comparing the area of the quantification ion to that of the 13C-labeled standard and correcting for response factors.

PFCs were analyzed using Axys Method MLA-060 (Axys Analytical Services, Ltd., 2008). Samples were analyzed by liquid chromatography-tandem mass spectrometry (LC/MS/MS) following solid-phase extraction and selective elution procedures. Sample extracts were analyzed on a high-performance liquid chromatograph coupled to a triple quadrupole mass spectrometer. Target compounds were quantified using the internal standard method, comparing the area of the quantification ion to that of the 13C-labeled standard and correcting for response factors.

PCBs were analyzed using U.S. EPA method GC/HRMS 1668A. Samples were analyzed using gas chromatography/high-resolution mass spectrometry (GC/HRMS) following extraction and, if necessary, appropriate sample cleanup procedures. Sample extracts were injected into a GC equipped with a capillary column, which utilized a temperature program to separate analytes that were then detected with an HRMS. Individual compounds (i.e., congeners) were identified by comparing the retention time and ion-abundance ratio of target compounds and associated labeled analog compounds with retention times and ion-abundance ratios of known standards. Congeners were quantified using the isotopic dilution quantitation technique, comparing the area of the quantification ion to that of the 13C-labeled standard and correcting for response factors.

Metals were analyzed using U.S. EPA Method 200.8. Samples were analyzed by inductively coupled plasma-mass spectrometry (ICP-MS) following acid extraction. Sample extracts injected into the ICP-MS were quantified by comparing instrument response to a calibration curve developed for each analyte. Results were reported for total (unfiltered) copper, lead, and zinc.

2.3.2 Data Review and Validation

The project team conducted data review and validation in general accordance with the detailed quality control (QC) procedures documented in the MEL Quality Assurance Manual (Manchester Environmental Laboratory, 2007) and Lab Users Manual (Manchester Environmental Laboratory, 2008), and in each subcontracted laboratory's quality assurance (QA) manual. One QC target for this project was for each laboratory to extract and analyze all the samples collected during each event in a single batch. By doing this, a single set of QC parameters would be applicable to all samples collected during each sampling event.

2.4 Data Analysis

2.4.1 Quality Assurance Review

The project team validated analytical data to verify they met project data quality objectives and to identify any limitations of the data, following the process outlined in Ecology QA1 review guidelines (PTI Environmental Services, 1989). Validation consisted of comparing calibration, accuracy, and precision results to the QC criteria listed in the method, the laboratory standard operating procedure, and the QAPP. If no QA guidelines existed for specific analytes, then the project team used applicable U.S. EPA national and regional data review guidelines (U.S. EPA, 1999b).

Since the Ecology MEL employs standardized analyte lists that partially overlap, they analyzed the following six chemicals with more than one method.

- 2,3,4,6-Tetrachlorophenol
- 2,4,5-Trichlorophenol
- 2,4,6-Trichlorophenol
- Dacthal
- Hexachlorobenzene
- Pentachlorophenol

For example, the laboratory used U.S. EPA Method SW-846 8270 (for semivolatile [BNA extractable] organic compounds by GC/MS) and 8270 (chlorinated herbicides by solid-phase extraction and GC/MS) to quantify the amount of pentachlorophenol in the samples. Thus, the laboratory reported more than one result for these six chemicals (i.e., two results for each sample). For each chemical, the project team selected only one of the results for use in estimating loadings – the one obtained with the more sensitive method which provided the smaller reporting limit.

The generally accepted practice is that concentrations between the method detection limit (MDL) and the reporting limit are reported as detected but not quantified, due to the potential for misuse of low-level data with relatively high quantitative uncertainty. However, for this investigation concentrations of all analytes reported between the MDL and reporting limit have been quantified and annotated with a "J" qualifier (estimated concentration), indicating a higher level of uncertainty in the quantitative value. Statistical evaluations of data whose uncertainties are "high" can lead to erroneous conclusions, especially if the sample populations are limited in size or are highly censored (high percentages of non-detect data – results where analytes are not present at detectable concentrations).

For this study, only wastewater sample results quantified at concentrations at least three times greater than the corresponding results in the method blank and in the field blank samples were considered "detected." Wastewater sample results that were not at least three times greater than the corresponding results in the method blank were qualified with a "U" to indicate "not detected." Wastewater sample results that were not at least three times greater than the corresponding results in the field or rinseate blank samples were qualified with a "UFB" to indicate "not detected due to contamination of the field or rinseate blank" for the purposes of this project only. The qualifier "U" subsequently replaced "UFB" in the data uploaded to the Ecology Environmental Information Management (EIM) system database.

2.4.2 Estimated Discharge from POTWs

The project team reviewed the wastewater discharge rates reported for January 2007 through December 2009 by the 96 POTWs listed in Appendix A (raw data in Ecology, 2010b), and determined the average annual discharge rate for each POTW. For estimating chemical loadings, we employed the average flows self-reported by the POTWs via their discharge monitoring reports.

2.4.3 Estimated Loadings of Toxic Chemicals from Each of the Ten POTWs

Using the toxic chemical concentration data obtained through this study, the project team developed annual loading rates for each of the ten sampled POTWs. We calculated annual loading rates by multiplying the average annual discharge rate from each facility by the average concentration for each toxic chemical. The average concentration depended on the number of detect and non-detect values from the two sampling events. We used the following procedures to compute annual loading rates for each POTW:

- If a chemical were detected during both sampling events, an average concentration was computed using the two detect values. We then used this average in the subsequent loading calculation.

- If a chemical were analyzed during only one sampling event and were detected, we used the reported concentration in the subsequent loading calculation.

- If a chemical were analyzed during both sampling events and were detected during only one of them, we computed an average concentration using the detect value and one-half the reporting limit for the non-detect value. We then used this average in the subsequent loading calculation.

- If a chemical were analyzed during both sampling events and were not detected during either of them, we did not generate a loading estimate.

2.4.4 Estimated Total Loadings to Puget Sound

The project team computed annual loading rates of each toxic chemical or chemical class for each of the 14 study areas in Puget Sound by multiplying the average annual volume of treated wastewater discharged from all the POTWs located in each study area by a representative concentration for each toxic chemical or chemical class. The average annual discharge volume for each study area was the sum of the discharge volumes from the POTWs located within the area. Table 6 identifies the average annual total discharge of wastewater from POTWs for each study area and compares the values used in this Phase 3 study with those that were used and that should have been used in the Phase 2 study (EnviroVision, et al., 2008). The discharge volumes were quite similar after correction for the mis-location of several POTWs in the Phase 2 study.

In determining some of the representative concentrations, the project team employed Regression on Order Statistics (ROS) to account for non-detect results, as described in the calculation steps provided later in this section. ROS is a commonly used procedure for estimating summary statistics from data sets that contain below-detection-limit (censored) observations (Helsel, 2005). The procedure first computes the Weibull-type plotting positions of the combined uncensored and censored observations. A linear regression model is then generated from the plotting positions of the uncensored observations and their normal quantiles. This linear regression model is the basis for estimating the concentration of the censored observations as a function of their normal quantiles. Finally, the observed uncensored values are combined with the modeled censored values to estimate summary statistics for the entire population. In this application, the project team used ROS to estimate summary statistics (i.e., 5th, 25th, 50th, 75th, and 95th percentiles) for individual and classes of toxic chemicals.

The project team compared the summary statistics derived from the treatment of non-detect results using the ROS method with those derived from three simpler substitution methods. They employed substitutions of non-detect data with zero, half the reporting limit, and the full reporting limit.

Individual Chemicals

To obtain representative concentrations for each toxic chemical, the project team pooled the data from samples collected at all ten POTWs during both the winter and summer sampling events. After pooling the data, we used different procedures to obtain a representative concentration for each chemical. The selected procedure for each chemical depended on the total number of results and the number of detect and non-detect values. We used the following steps to calculate representative concentrations if ten or more results were available for a given chemical:

1. Compute the detection frequency for each chemical by dividing the number of detect values by the total number of valid values, after excluding from both counts any rejected results. The number of valid values varied for each chemical because some values were rejected for quality assurance reasons, and some chemicals were analyzed a different number of times. Appendix D summarizes these detection frequencies.

2. Screen the frequencies from Step 1 to identify only those chemicals that had a detection frequency of 50 percent or greater. Given that the maximum number of results possible for any chemical was 20, this 50 percent detection frequency was the minimum likely to provide meaningful loading rate estimates.

3. Calculate the 5th, 25th, 50th, 75th, and 95th percentiles from the subset of chemicals identified in Step 2 using ROS, a statistical method for calculating summary statistics on censored datasets. Appendix E summarizes these percentiles.

4. Use the 25th, 50th, and 75th percentiles from Step 3 as the representative concentrations in the loading calculations to provide a measure of the central tendency and overall variability of the loading rates.

If fewer than ten results were available for a given chemical, the project team used the following steps to compute representative concentrations:

1. Compute the detection frequency for each chemical by dividing the number of detect values by the total number of valid values, after excluding from both counts any rejected results. The number of valid values varied for each chemical because some values were rejected for quality assurance reasons, and some chemicals were analyzed a different number of times. Appendix D summarizes these detection frequencies.

2. Screen the frequencies from Step 1 to identify only those chemicals that had a detection frequency of 65 percent or greater. For chemicals with fewer than ten results, this 65 percent detection frequency was the minimum likely to provide meaningful loading rate estimates.

3. Calculate the 5th, 25th, 50th, 75th, and 95th percentiles for each of the chemicals identified in Step 2, substituting one-half the reporting limit for all non-detect values in the data. Appendix E summarizes these percentiles.

4. Use the 25th, 50th, and 75th percentiles from Step 3 as the representative concentrations in the loading calculations to provide a measure of the central tendency and overall variability of the loading rates.

Further statistical and loading calculations employed only those chemicals selected by one of the two options described above.

Classes of Toxic Chemicals

Chemical classifications reflect the general internal structure of a group of chemicals or the reactive groups attached to that general structure. Aggregating chemicals into groups or classes with similar structures or reactive groups is sometimes useful because chemical classifications often indicate that the chemicals within such a group might share a single source, behave or affect environmental receptors in a similar manner, or all be amenable to particular treatments or other control actions that remove them from the waste stream.

The specific analytical method by which a chemical may be measured need not correspond with how that chemical may be "classified." For this study, the project team grouped the toxic chemicals of concern into classifications that did not necessarily reflect the analytical method that the laboratories used. Thus, for example, although pentachlorophenol is one of the BNA extractable analytes and is also detectable using the chlorinated herbicides method, we reported it, only once, as a member of the class of other BNA extractables and used the herbicide result because it was derived from the more sensitive analytical method.

The project team grouped the toxic chemicals into the 11 different classes listed below. Where we had sufficient data, we calculated the summary statistics and loading rates for individual chemicals. Where we had sufficient data, we also calculated the summary statistics and loading rates for certain chemical classes, comprised of specific individual compounds, as shown below. A "congener" is an example of a specific compound. For this project, a "homolog" is the group of compounds that contains a specific number of chlorine or bromine atoms. For example, the dibrominated diphenyl ether homolog group consists of the three individual congeners BDE-007, BDE-010, and BDE-015. Carcinogenic PAHs (cPAHs) constituted a subset of the heavy PAHs (HPAHs). A complete list of the chemicals and classes is provided in Appendix C.

Chemical Class	Number of Chemicals	Loading for Chemicals	Loading for Class
PAHs (light, heavy, and carcinogenic)	16 (6, 10, 7)	Yes	Yes
Phthalates	6	Yes	Yes
Other Base/Neutral/Acid Extractables	55	Yes	No
Pesticides	34	Yes	No
Herbicides	18	Yes	No
PBDEs (congeners)	38	Yes	Yes
PBDEs (homologs)	9	Yes	No
PFCs	13	Yes	Yes
PCBs (congeners)	209	Yes	Yes
PCBs (homologs)	10	Yes	No
Metals (copper, lead, and zinc)	3	Yes	No

To determine a representative concentration for each toxic chemical class, the project team pooled the data from all the samples collected from all ten POTWs during both the winter and summer sampling events. We summed the reported concentrations of each chemical within each class of chemicals for each sampling event at each POTW. We used the following steps to derive representative concentrations for each class of toxic chemicals:

1. For these summations, substitute zero for all non-detect values of individual chemicals unless all the reported values of the individual chemicals of a given chemical class/event/POTW combination were non-detects. In that case, use the highest reporting limit of all the individual chemicals within that chemical class/event/POTW combination to represent the non-detect concentration for that chemical class/event/POTW combination.

2. If none of the summed concentrations for a chemical class were non-detect, calculate the 5th, 25th, 50th, 75th, and 95th percentiles from those summed concentrations. If any of the

summed concentrations were non-detect, calculate the 5th, 25th, 50th, 75th, and 95th percentiles using ROS. Appendix E summarizes these percentiles.

3. Use the 25th, 50th, and 75th percentiles from Step 2 as the representative concentrations in the loading calculations to provide a measure of the central tendency and overall variability of the loading rates.

3. Results

3.1 Field Work

Table 5 shows the average daily flows for 2007 through 2009 compared with the average of measured discharge flow rates that each POTW operator provided for the two sampling events, and presents the annual flows that we used in calculating toxic chemical loadings. The flow values that the project team selected for loading calculations were based on the more representative monthly monitoring results reported by the POTWs to Ecology to comply with their NPDES permits.

3.2 Laboratory Work

3.2.1 Review of Data Quality

Appendix B contains copies of the Data Usability Summary Reports that document the results of the Level 1 data quality review. Brief descriptions of the data quality are provided below for each analytical method.

Polycyclic Aromatic Hydrocarbons

The Ecology MEL analyzed samples from February and July for PAHs using U.S. EPA Method SW-846 Method 8270D SIM (Polycyclic Aromatic Hydrocarbons by GC/MS) in accordance with the QAPP. The 320 PAH results generally met the project data quality objectives for reporting and QC limits. The project team qualified 35 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. Of the results that indicated a detectable amount of pollutant ("detect results"), 52 percent were qualified with a "J."

Base/Neutral/Acid Extractable Compounds

The Ecology MEL analyzed samples from February and July for BNAs using U.S. EPA Method SW-846 Method 8270 (Semivolatile Organic Compounds by GC/MS) in accordance with the QAPP. BNA extractable compounds included the phthalates chemical class. The 1,160 BNA results generally met the project data quality objectives for reporting and QC limits. The project team qualified 30 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. Of the detect results, 60 percent were qualified with a "J." Four of the detect results were also qualified as tentatively identified when qualitative QC criteria were not met. We rejected 70 results for failing to meet QC criteria (6.0 percent of the total possible BNA results). The following ten compounds had rejected results:

- 2,4-Dimethylphenol........... 2 Rejects
- 2-Nitroaniline .... 5 Rejects
- 3,3'-Dichlorobenzidine......11 Rejects
- 3-Nitroaniline .... 5 Rejects
- 4-Chloroaniline..................20 Rejects
- 4-Nitroaniline ....10 Rejects
- 4-Nonylphenol.......................... 4 Rejects
- bis(2-Chloroethoxy) methane... 5 Rejects
- Bisphenol A.............................. 5 Rejects
- Caffeine .... 3 Rejects

The Ecology MEL analyzed all of the required BNAs with the exception of benzidine (in both events) and N-nitrosodimethylamine (in July). In both February and July, the laboratory also provided data for the following five chemicals, not specified in the QAPP.

- 2-Methylphenol
- 4-Methylphenol
- Caffeine
- Triclosan
- Triethyl citrate

In July only, the laboratory provided data for the following five chemicals, also not specified in the QAPP.

- 3B-Coprostanol
- Benzoic acid
- Benzyl alcohol
- Cholesterol
- 2-Chloroethanol phosphate (3:1)

The BNA data met the project data quality objectives, although the reporting limits for several of the analytes were slightly greater than the values identified in the QAPP.

Pesticides

The Ecology MEL analyzed samples from February and July for pesticides using U.S. EPA Method SW-846 Method 8081 (Chlorinated Pesticide Compounds by GC/ECD) in accordance with the QAPP. The 650 pesticide results generally met the project data quality objectives for reporting and QC limits. The project team qualified 43 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. Of the detect results, 62 percent were qualified with a "J."

In July only, the Ecology MEL provided data for the following seven chemicals that were not specified in the QAPP.

- 2,4'-DDD
- 2,4'-DDE
- 2,4'-DDT
- Chlordane, technical
- DDMU
- Mirex
- Pentachloroanisole

Herbicides

The Ecology MEL analyzed samples from February and July for herbicides using U.S. EPA Method SW-846 Method 535/8270 (Chlorinated Herbicides by Solid-Phase Extraction and GC/MS) in accordance with the QAPP. The 360 herbicide results generally met the project data quality objectives for reporting and QC limits. The project team qualified 12 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. Of the detect results, 79 percent were qualified with a "J." Eleven of the detect results were also qualified as tentatively identified when qualitative QC criteria were not met. We rejected five results for failing to meet QC criteria (1.4 percent of the total possible herbicide results). The following four compounds had rejected results:

- 2,4-DB..................1 Reject
- Acifluorfen...........1 Reject
- Dinoseb ....1 Reject
- Picloram .... 2 Rejects

Polybrominated Diphenyl Ethers
Pacific Rim analyzed samples from February and July for PBDE congeners using U.S. EPA SW-846 Method 1614 (Brominated Diphenyl Ethers in Water, Soil, Sediment, and Tissue by HRGC/HRMS) rather than U.S. EPA Method 1668 as specified in the QAPP. This variation was acceptable because it provided equivalent or better data than required to meet project data quality objectives.

The 710 PBDE results generally met the project data quality objectives for reporting and QC limits. The project team qualified 37 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. Of the detect results, 23 percent were qualified with a "J." Ten of the detect results were also qualified as tentatively identified when qualitative QC criteria were not met.

Pacific Rim analyzed all the required congeners, except that in both February and July the results for BDE-197 and BDE-204 were reported as a total value rather than separately, and in February the results for BDE-049 and BDE-071 were reported as a total value rather than separately. The inability of the laboratory to separate these very similar congeners did not negatively impact the data usability. In addition, Pacific Rim provided data for the following three congeners that were not specified in the QAPP.

- BDE-007
- BDE-010
- BDE-015

Perfluorinated Organic Compounds
Axys analyzed samples from February and July for PFCs using Method MLA-060 (Analytical Procedure for Perfluorinated Organic Compounds in Aqueous Samples by LC-MS/MS) in accordance with the QAPP. In addition, the laboratory provided data for perfluorooctane sulfonamide (PFOSA).

Although the 260 PFC results complied with all other project data quality objectives, Axys employed reporting limits that were approximately an order of magnitude greater than the reporting limits identified in the QAPP. While this made no difference for detected congeners, and the quality of the non-detect results was acceptable, a possibility exists that the actual total concentrations of PFCs, and thus their loadings to Puget Sound, was greater than the estimate provided by this study.

Polychlorinated Biphenyls
Pacific Rim analyzed samples from February for PCB congeners using U.S. EPA Method 1668 (Chlorinated Biphenyl Congeners by HRGC/HRMS) in accordance with the QAPP. The 1,134 PCB results generally met the project data quality objectives for reporting and QC limits. The project team qualified less than 0.1 percent of the results with a "J" qualifier to indicate uncertainty in the quantitative measurements. None of the detect results were qualified with a "J." Seventeen of the detect results were also qualified as tentatively identified when qualitative QC criteria were not met.

Metals
The Ecology MEL analyzed samples for total metals (copper, lead, and zinc) using U.S. EPA Method 200.8 (Inductively Coupled Plasma – Mass Spectrometry) in accordance with the QAPP. The 60 metals results met the project data quality objectives for reporting and QC limits, and none of them were qualified.

3.2.2 Summary of Analytical Results

Excluding duplicate and field blank/rinseate samples, this project generated a total of 4,579 valid analytical results that characterized 20 samples of treated wastewater from ten subject POTWs (two samples from each POTW). Through data review and validation, the project team qualified 95 results as non-detects (with the "UFB" qualifier) due to potential contamination during handling based on the results of field/rinseate samples. A detectable amount of target analyte was present from every class of toxic chemicals that the project team assessed in one or more of the treated wastewater discharges. We detected a total of 230 chemicals, not counting PBDE and PCB homologs (212 chemicals if PCB co-elutants are considered individual analytes). Except for the PFC class, the range (i.e., variability) of the total concentrations of each chemical class among the POTWs was greater in summer than in winter. Appendix C summarizes all of the results from the chemical analyses. Appendix D summarizes for each analyzed chemical the number of valid results and the percentage of those results that indicated the detectable presence of that chemical. Table 7 shows the number of chemicals detected within each of the chemical classes. Note that all data provided in the text, tables, and appendices are precise to only two significant figures.

Polycyclic Aromatic Hydrocarbons
The project team analyzed for 16 PAHs, consisting of six low molecular weight compounds (LPAHs) and ten high molecular weight compounds (HPAHs). The greatest number of PAHs detected in any of the 20 samples was eight, and the largest single PAH concentration was 0.37 micrograms per liter (μg/L) of naphthalene. The most frequently detected PAHs were fluorene, fluoranthene, phenanthrene, and pyrene.

Each one of the six LPAHs was detected in effluent samples from at least one POTW. LPAHs were detected in all but four samples and in all but one POTW, and the largest concentration of total LPAHs in any sample was 0.79 μg/L. For the ten samples collected in February, the number of detected LPAHs ranged from zero to five, and the largest sum of the LPAHs was 0.14 μg/L. For the ten samples collected in July, the number of detected LPAHs ranged from zero to six, and the largest sum of the LPAHs was 0.79 μg/L.

Seven of the ten HPAHs were detected in effluent samples from at least one POTW. HPAHs were detected in all but two samples, those from a single POTW. The number of detected HPAHs ranged from zero to five, and the largest sum of the HPAHs was 0.076 μg/L. For the ten samples collected in February, the number of detected HPAHs ranged from zero to four, and the largest sum of the HPAHs ranged was 0.047 μg/L. For the ten samples collected in July, the number of detected HPAHs ranged from zero to five, and the largest sum of the HPAHs was 0.076 μg/L.

The effluent samples from only two POTWs contained detectable carcinogenic PAHs (cPAHs).

Phthalates

The project team analyzed for six phthalates. For the ten samples collected in February, the number of detected phthalates ranged from one to three, and the sum of phthalates ranged from 0.31 to 3.4 µg/L. For the ten samples collected in July, only bis(2-ethylhexyl) phthalate phthalate was detected, at concentrations ranging from 0.19 to 5.3 µg/L.

Other Base/Neutral/Acid Extractables

The project team analyzed 55 semi-volatile compounds (BNA extractables) that were not grouped within another chemical class. Thirty of these compounds were detected in the wastewater samples, and each of the 20 samples contained detectable concentrations of from four to 15 of them. The three chemicals that typically showed the greatest concentrations were 3B-coprostanol, caffeine, and cholesterol. When these three compounds were excluded (due to absent analyses or rejected results for the February samples), the results for the remaining 27 compounds did not indicate the existence of a seasonal pattern.

Pesticides

The project team analyzed 20 samples for 34 pesticides and detected six. Endosulfan I and alpha-BHC were detected only in winter, at three and two POTWs, respectively. Chlorpyriphos, pentachloroanisole, and toxaphene were detected only in summer, at one, three, and two POTWs, respectively. Hexachlorobenzene was detected in the wastewater from one POTW in the summer, and from another POTW in the winter.

Herbicides

The project team analyzed 20 samples for 18 herbicides and detected only five, generally more frequently in the summer than in the winter. Detectable concentrations of MCPP and triclopyr were present in only five of the wastewater samples. Detectable concentrations of 2,4-D; Dicamba I; and MCPA were present in three samples.

Polybrominated Diphenyl Ethers

Congeners

The project team analyzed for 38 PBDE congeners, with six of them co-eluting with another congener, producing three combinations. Considering the co-eluting congener combinations to be individual analytes, for the ten samples collected in February, the number of detected PBDEs ranged from 11 to 25, and the sum of PBDEs ranged from 9,100 to 125,000 picograms per liter (pg/L). For the ten samples collected in July, the number of detected PBDEs ranged from 11 to 31, and the sum of PBDEs ranged from 8,600 to 135,000 pg/L.

Homologs

The project team calculated concentrations for the nine PBDE homologs based upon the congener data. PBDEs from each homolog group were detected, and four of the homolog groups were detected in every sample (the hexa-, penta-, tetra-, and tri-BDEs).

Perfluorinated Compounds

The project team analyzed for 13 PFCs and detected from six to ten of these toxic chemicals in each of the wastewater samples. The four compounds that were typically present in the greatest concentrations were perfluorohexanoate (maximum of 52 nanograms per liter (ng/L)), perfluorononanoate (maximum of 134 ng/L), perfluorooctane sulfonate (maximum of 55 ng/L), and perfluorooctanoate (maximum of 70 ng/L). All 20 samples contained detectable concentrations of these four chemicals.

Polychlorinated Biphenyls

Congeners

The project team analyzed the six wastewater samples collected in February for 209 PCB congeners, with 37 of them co-eluting in one or another of 17 combinations. Considering the 17 co-eluting congener combinations to be individual analytes, the number of detected PCB congeners ranged from five to 105, and the sum of PCB congeners ranged from 69 to 15,400 pg/L. Every effluent sample contained PCBs.

Homologs

The MEL calculated concentrations for the ten PCB homologs based upon the congener data. PCBs in each homolog group were detected, and eight of the homologs were detected in at least half of the samples.

Metals

The project team detected copper, lead, and zinc in all 20 samples of wastewater. The smallest reported concentrations were 2.6 µg/L for copper, 0.15 µg/L for lead, and 13 µg/L for zinc. The two greatest concentrations of copper were in the wastewaters from the King County West Point and Sumner POTWs (14 and 17 µg/L, respectively). The two greatest concentrations of lead were in the wastewaters from the Everett STP and City of Tacoma (Central No. 1) POTWs (1.2 and 0.72 µg/L, respectively). The two greatest concentrations of zinc were in the wastewaters from the Gig Harbor STP (95 and 76 µg/L, for summer and winter, respectively).

Summary Statistics

Using the calculation methods described in Section 2.4.4, the project team quantified the variability of the results of each chemical and class of chemicals for which Puget Sound-wide loadings were later calculated. Appendix E summarizes these summary statistics, listing the expected concentration of each chemical and class of chemicals at the 5th, 25th, 50th, 75th, and 95th percentiles.

When comparing the methods for handling non-detect data, the project team found that the median concentrations obtained by substituting half the reporting limit were the most similar to those derived by the ROS method. Of the 63 chemicals and chemical classes where ROS was used, the corresponding median concentrations for 60 of them were the same or within a 10% relative difference, and for two others were within a 15% relative difference. Substituting half the reporting limit gave median values slightly larger than the ROS method for 4-methylphenol (58% relative difference). These results were consistent with those of Antweiler and Taylor, 2008. Appendix F contains additional details of this comparison.

3.3 Estimated Loadings of Toxic Chemicals from Each of the POTWs

The project team multiplied the average flows of wastewater discharge shown in Table 5 by the chemical concentrations selected as described in Section 2.4.3 to estimate rough annual loading rates from each of the ten subject POTWs. Appendix G summarizes the annual loadings from each POTW to the Puget Sound Basin.

Polycyclic Aromatic Hydrocarbons
Of the 16 PAHs analyzed among the ten POTWs, the number of PAHs detected in the discharge from any given POTW ranged from two to eight. Only five chemicals (fluoranthene, fluorene, naphthalene, phenanthrene, and pyrene) comprised almost all of the total PAH loadings (61 to 100 percent) from nine of the POTWs. The effluent from one of the POTWs (Everett (outfall 100)) contained five PAHs not usually found in the other discharges, among which were four cPAHs.

Phthalates
Of the six phthalates analyzed among the ten POTWs, the number of phthalates detected at any given POTW ranged from one to three. All ten POTWs discharged bis(2-ethylhexyl) phthalate, which constituted 52 to 100 percent of their total loadings of phthalates via treated effluent.

Other Base/Neutral/Acid Extractables
Of the 55 miscellaneous BNA extractable chemicals discharged by the ten subject POTWs, the project team detected seven of them in all 20 samples of wastewater. These were 1,4-dichlorobenzene; 2,4,6-trichlorophenol; 2-chloroethanol phosphate; cholesterol; dibenzofuran; triclosan; and triethyl citrate. The three chemicals discharged in the greatest amounts were 3B-coprostanol (ranging from not detectable to 1,100 kilograms per year (kg/year)), caffeine (ranging from not detectable to 54 kg/year), and cholesterol (ranging from 14 to 1,500 kg/year).

Pesticides
Of the ten POTWs, the treated wastewater discharges of three of them contained no detectable amount of the 34 analyzed pesticides. Only five chemicals (chlorpyriphos, endosulfan I, hexachlorobenzene, pentachloroanisole, and toxaphene) comprised 96 to 100 percent of the total pesticide loadings from each of the other seven POTWs.

Herbicides
Of the ten POTWs, the treated wastewater discharges of three of them contained no detectable amount of the 18 analyzed herbicides. Only four chemicals (2,4-D; MCPA; MCPP; and triclopyr) comprised 84 to 100 percent of the total herbicide loadings from each of the other seven POTWs.

Polybrominated Diphenyl Ethers
Congeners
Of the 38 PBDEs analyzed among the ten POTWs, the number of PBDEs detected at any given POTW ranged from 18 to 32 (when considering the three co-eluting congener combinations as

individual analytes). Only three congeners (BDE-047, BDE-099, and BDE-209) comprised 69 to 82 percent of the total PBDE loadings from each of the ten POTWs.

Homologs

The two homologs that constituted the greatest portion of the PBDE loadings (from 45 to 81 percent) were the penta- and tetra-bromodiphenyl ethers. Decabromodiphenyl ether represented 43 percent of the total loading discharged by the Gig Harbor STP. The Everett STP (Outfall 100), King County West Point, and City of Tacoma (Central No. 1) facilities discharged the largest amounts of PBDEs annually, from 2.6 to 64 times as much as any of the other POTWs.

Perfluorinated Compounds

Of the 13 PFCs analyzed among the ten POTWs, the number detected at any given POTW ranged from eight to ten. Five of these compounds were detected in every one of the 20 sample analyzed. Only four chemicals (perfluorohexanoate, perfluorononanoate, perfluorooctane sulfonate, and perfluorooctanoate) comprised 56 to 87 percent of the total PFCs discharged from each of the POTWs.

Polychlorinated Biphenyls

Congeners

Of the 209 PCB congeners analyzed among the six sampled POTWs, the number detected at any given POTW ranged from five to 105 (when considering the 17 co-eluting congener combinations as individual analytes). The variety of congeners detected at a given POTW generally corresponded with their total loadings. The five congeners that the six POTWs discharged in the greatest amounts were PCBs-004, 052/064, 118, and 138. The total loading of these five congeners constituted about 19 percent of the total loading of PCB congeners.

Homologs

Of the ten homolog groups, the number detected at the six sampled POTWs ranged from one to nine. For three of the POTWs, the tetra-, penta-, and hexa-chlorobiphenyl homologs constituted 63 to 70 percent of their discharges. For the Shelton STP, the tri-, tetra-, and hepta-chlorobiphenyl homologs constituted 94 percent of its discharge. For the Pierce County Chambers Creek STP, the di-, tri, and tetra-chlorobiphenyl homologs constituted 93 percent of its discharge.

Metals

The ranges of the loadings of the three analyzed metals from the ten sampled POTWs varied considerably. The median annual loading of copper was 59 kg/year, within an 180-fold high-to-low range. The median annual loading of lead was 4.3 kg/year, within a 90-fold high-to-low range. The median annual loading of zinc was 240 kg/year, within a 48-fold high-to-low range.

3.4 Estimated Total Loadings to Puget Sound

Based on the total number of valid analyses and the frequencies of detection, the project team identified 68 individual chemicals, discounting PBDE and PCB homologs, for which we could reliably estimate total loadings to Puget Sound (using the method described in Section 2.4.4).

The data also allowed calculation of estimates for the total loadings of 13 PBDE and PCB homologs and seven chemical classes. Appendix E identifies the summary statistics (the 5th, 25th, 50th, 75th, and 95th percentiles) for these individual chemicals and chemical classes. Appendix H summarizes the estimated loadings of these chemicals and chemical classes in the 14 study areas of Puget Sound (25th, 50th, and 75th percentiles only).

Since the available data required the grouping of chemical results from all ten of the subject POTWs, the areal distribution of loadings to the Puget Sound Basin directly corresponded to the total discharge rates from the POTWs within each study area. Since no POTWs were located within the Elliott Bay study area, the loadings from that study area were zero. The following bullets identify the estimated ranges of total loadings for toxic chemical classes and the three metals to the Puget Sound Basin from all the POTWs in the 14 study areas, shown as from the 25th to the 75th percentiles. Appendix H presents additional details along with the loading estimates for the other chemicals.

- Total PAHs: 7.6 to 46 kg/year.
  LPAHs comprised from 43 to 76 percent of the total PAHs annually discharged to Puget Sound. The amount of LPAHs ranged from 3.3 to 35 kg/year.

- Total phthalates: 220 to 910 kg/year.
  Bis(2-ethylhexyl) phthalate comprised 80 to 100 percent of the total phthalates annually discharged to Puget Sound. The amount of bis(2-ethylhexyl) phthalate ranged from 220 to 900 kg/year.

- Total PBDEs: 7.0 to 21 kg/year.
  From 71 to 79 percent of the PBDE congeners annually discharged to Puget Sound were BDE-047, BDE-099, and BDE-209, constituents within the tetra-, penta-, and deca-bromodiphenyl ether homolog groups, respectively.

- Total PFCs: 31 to 59 kg/year.
  From 39 to 49 percent of the PFCs annually discharged to Puget Sound consisted of perfluorohexanoate and perfluorooctanoate.

- Total PCBs: 0.13 to 1.8 kg/year.
  Approximately 55 percent of the PCB congeners annually discharged to Puget Sound were distributed among the tri-, tetra-, and penta-chlorobiphenyl homolog groups.

- Copper: 2,500 to 5,500 kg/year.

- Lead: 140 to 250 kg/year.

- Zinc: 16,000 to 24,000 kg/year.

4. Discussion

4.1 Comparison with Results from Phase 2

Most of the difference in estimated loadings between the Phase 2 study in 2008 and this Phase 3 study appeared to be due to variations in the concentrations rather than total discharge volume of treated wastewater. Table 6 shows the similarity between the Phase 2 and Phase 3 studies of the average total flows from POTWs to the 14 Puget Sound study areas.

Based on the limited suite of NPDES self-monitoring analytes and the use of standard analytical reporting limits (i.e., larger than those used for this study), the Phase 2 study provided estimates of total loadings for seven chemicals: copper, lead, mercury, zinc, chloroform, bis(2-ethylhexyl) phthalate, and phenolics. The total estimated loadings of copper and zinc to Puget Sound from this study were about 70 and 97 percent, respectively, of the Phase 2 study estimates. The estimated loadings of lead and bis(2-ethylhexyl)phthalate from this study were 18 and 17 percent, respectively, of the Phase 2 study estimates. For each of the 14 Puget Sound study areas, Table 8 compares the loading rate estimates of the four chemicals that we assessed in Phase 2 with the results from this study.

In general, the current study has improved and extended the results from Phase 2, and has clearly demonstrated that POTWs discharge toxic chemicals in their treated wastewater effluents.

4.2 Comparison with Results from Other Studies

The project team evaluated whether the results from this study for these particular ten POTWs were similar to or differed from the discharges of treated effluents from other POTWs in Washington State. We focused primarily on PCBs, which are legacy pollutants, and PFCs, which are pollutants of emerging concern.

Polychlorinated Biphenyls
PCBs are the class of toxic organic chemicals for which Ecology had the greatest amount of historical data. The following studies addressed historical discharges of PCBs from POTWs:

• Albion, Colfax, Pullman	Lubliner, 2009.
• College Place, Walla Walla	Lubliner, 2007.
• Liberty Lake, Spokane	Golding, 2002.
• Okanogan, Omak, Oroville	Serdar, 2003.
• 18 POTWs in the Yakima River watershed	Johnson, et al., 2009.

For all of these studies, the analytical laboratories employed methods that reduced the final detection limits to values lower than normal, similar to this study. Figure 2 illustrates the total concentrations of PCBs discharged from these facilities and shows that the results found in this study were similar to results from elsewhere. This study found that the concentrations of total PCBs from the Everett STP (Outfall 100) and City of Tacoma (Central No. 1) facilities were greater than the other POTWs shown in Figure 2. However, these results were based upon only a single composite sample from each facility. Further analyses are required to support any conclusions.

Ten of the PCB congeners (and their three co-elutants) detected most frequently and at the greatest concentrations in this study were the same PCB congeners that Ross, et al. (2000) found at the greatest concentrations in blubber tissue samples from the northern and southern resident populations of Orca whales. These ten congeners were PCBs-052, 099, 101, 105, 118, 138, 149, 153, 180, and 187. They and their co-elutants were among the top 12 percent of all PCB congeners ranked according to the greatest average concentration discharged from the six POTWs and among the top 25 percent frequency of detection, and contributed 31 percent of the total average concentration of all the PCB congeners. Four of the 21 congeners for which Ecology estimated loadings were among the ten that Ross, et al. identified as the greatest in the Orca whales. These congeners and their two co-elutants comprised from 9.7 to 23 percent of the total loading of PCBs from POTWs to Puget Sound.

Since the manufacture of PCBs ceased several decades ago, the frequent detection of PCBs in POTW wastewaters indicated that legacy contamination remains a significant source of PCBs. The presence of PCBs in a variety of building materials (e.g., caulking, paint, insulation, roofing, siding, and asphalt) is an ongoing source that slowly and continually releases small amounts of PCBs into the environment and the regional wastewater infrastructure. The U.S. EPA (1997) summarized data that indicated that 32 to 65 metric tons of PCBs had been incorporated into caulking materials alone in the Puget Sound region (Ecology, 2011 in preparation). Since PCBs degrade very slowly and adhere to organic matter, the majority of residual PCBs appear to have bound to particles, and some have become trapped in wastewater systems (i.e., in the sediments in the piping). Therefore, uncontrolled construction or cleaning activities may mobilize these residuals and release additional pulses of PCBs into the environment for many more years.

Perfluorinated Compounds

Ecology has only recently begun to acquire monitoring data concerning PFCs in wastewater discharges. A recent study (Furl and Meredith, 2010) assessed the PFCs discharged in 2008 from four Washington state POTWs. Figure 3 illustrates the concentrations of total PFCs discharged from those four facilities and compares them with the results from the ten POTWs sampled in this study. The results from the two studies were similar. Almost all the total PFC concentrations in the treated wastewaters were between 50 and 200 ng/L.

Phthalates

Information about discharges of phthalates from POTWs in Washington state is limited. One study estimated the loading of bis(2-ethylhexyl) phthalate to POTWs in the Puget Sound region (Washington Toxics Coalitions and People for Puget Sound, 2009). Based upon analyses of residential dust and laundry wastewaters, the authors determined that approximately 959 kg of bis(2-ethylhexyl) phthalate flows annually from residences to POTWs in the Puget Sound region. This loading is consistent with our estimate in this study that POTWs discharge from 220 to 900 kg of bis(2-ethylhexyl) phthalate. The smaller amount discharged from POTWs than discharged to POTWs likely indicates that POTWs successfully treat or remove some of the phthalates in their wastewaters.

4.3 Seasonal Comparisons

The original intent for collecting treated effluent samples in February and July was to characterize possible differences in the concentrations and loadings of toxic chemicals during the wet and dry seasons. The project team suspected that a greater amount of precipitation and a higher groundwater table in the winter might increase the flow to POTWs and possibly affect the contaminant loads entering the POTWs and the degree of treatment they experienced prior to discharge. Also seasonal differences in the activities of wastewater producers may have caused the loadings of certain toxic chemicals to vary from one part of the year to another.

Unfortunately, the weather did not cooperate, and January to early February 2009 was an unusually dry period. Although some precipitation did occur in mid-February when samples were collected, the flow volumes from several of the POTWs were less in February than in July (Table 5).

Given that the measured effluent concentrations and flows varied substantially among the POTWs and that one day of sampling could not represent an entire season, this study could not distinguish a seasonal pattern. However, the winter samples from the three largest facilities (based on flow) contained from two to seven times as many detected PAHs and total concentrations from four to 19 times as great as the other POTWs. Whether this variation was due to a seasonal difference is not clear. Additional study may be warranted in the future.

4.4 Limitations

1. Based on 4,579 valid concentration results for toxic chemicals in 20 samples of wastewater, the results represented only a small portion of the total amount of wastewater treated and discharged by the POTWs in the Puget Sound Basin. Some comparisons are:

    - The Puget Sound Basin contained 106 permitted POTWs, and flow information was available for 96 of them.
      However, the project team collected samples from only ten POTWs and based loading estimates for the entire Sound on only 20 samples (six samples for PCBs).

    - The total flow from the 96 Puget Sound POTWs was approximately 124,140 mgy.
      However, the project team collected samples from POTWs whose discharges totaled 59,900 mgy (Table 5) – only 48 percent of the total POTW discharge to the Sound.

    - The rates of toxic chemical loadings from POTW discharges vary day-to-day throughout the year.
      However, the project team collected samples that represented only two days of the year (one day for PCBs).

2. Almost 73 percent of the analytical results were "non-detects." As a consequence, the project team did not estimate loadings from all 96 Puget Sound POTWs for 303 of the total 371 individual chemicals that we analyzed, not counting the PBDE and PCB homologs and

PCB co-elutants. However, a non-detect result did not mean that the amount of a particular chemical in a given wastewater sample was zero. Thus, this study could not support conclusions about whether any of these 303 chemicals were or were not threats to the health of the Puget Sound ecosystem.

3. The project team used the ROS method to “fill in” values for 48 individual chemicals, eight homolog groups, and seven chemical classes for which only some of the results were non-detect (less than 35 percent for individual chemicals with fewer than ten results, and less than 50 percent for the other individual chemicals). Therefore, the concentration summary statistics in Appendix E and the loading estimates in Appendix H were accurate only to the extent that the assumptions behind the ROS method were true for these data.

5. Conclusions

The goals of this project were (1) to screen treated wastewater discharges for toxic chemicals that POTW operators do not routinely monitor, and (2) to improve the loading estimates for certain toxic chemicals by employing more sensitive analytical methods.

This study developed improved estimates for the loadings of toxic chemicals discharged from permitted POTWs into the surface waters of the Puget Sound Basin. These new loading estimates are improved and more accurate than the Phase 2 estimates because the project team:

(a) Sampled from facilities that employed a wide variety of treatment techniques.
(b) Applied uniform and approved methods for sampling and analyses.
(c) Used more recent data than in prior studies.
(d) Covered a much broader list of chemicals than normally monitored.
(e) Employed more sensitive analytical methods than normally used.

POTWs are a significant secondary source of toxic chemicals. The results from this study will support development and prioritization of future control actions to improve and protect the Puget Sound ecosystem.

Tables

Table 1. Characteristics of the Ten Subject POTWs

POTW Name	Permit Number	Study Area	Treatment Process	Industrial Influent	Max Month Avg Design Flow (MGD)	Representative Flow (MGD)
Bellingham STP	WA0023744	Strait of Georgia	Secondary oxygen-activated sludge with chlorine.	Yes	37	12.3
Bremerton STP	WA0029289	Sinclair-Dyes Inlet	Secondary activated sludge with chlorine.	Yes	10.1	4.30
Burlington WWTP	WA0020150	Whidbey Basin	Secondary activated sludge with UV disinfection.	Negligible	3.79	1.64
City of Tacoma (Central No.1)	WA0037087	Commencement Bay	Secondary activated sludge with chlorine.	Yes	60	19.9
Everett STP (Outfall 100)	WA0024490	Port Gardner	Trickling filter and solids contact with chlorine.	Yes	21.0	10.6
Gig Harbor STP	WA0023957	South Sound East	Secondary activated sludge with chlorine.	Negligible	1.6	0.809
King County West Point	WA0029181	Main Basin	Secondary activated sludge with chlorine.	Yes	215	92.5
Pierce County Chambers Creek STP	WA0039624	South Sound East	Secondary activated sludge (aerobic and anoxic) with UV.	Minimal	28.7	17.9
Shelton STP	WA0023345	South Sound East	Secondary activated sludge in oxidation ditch with chlorine.	Negligible	4.02	1.99
Sumner STP	WA0023353	Commencement Bay	Activated sludge with UV disinfection and anaerobic sludge digestion.	Minimal	4.59	2.01

Key:

MGD = Million gallons per day.
POTW = Publicly Owned Treatment Works.
STP = Sewage Treatment Plant.
UV = Ultraviolet.
WWTP = Wastewater Treatment Plant.

Table 2. Comparison of Sampled POTWs with All POTWs in the Puget Sound Basin

Size of the Average Flow	POTWs in the Puget Sound Basin (a)			POTWs Sampled in This Project		
	Number	Total Flow from POTWs Considered (MGY)	Percentage of Total Flow	Number	Total Flow from POTWs Sampled (MGY)	Percentage of Total Flow
Small (<1 MGD)	60	4,710	3.8%	1	295	0.5%
Medium (1 to 10 MGD)	29	28,770	23.2%	4	3,630	6.0%
Large (>10 MGD)	7	90,660	73.0%	5	56,900 (b)	93.5%
Total =	96	124,140	100.0%	10	60,800 (c)	100.0%

Key:

The precision of the data in this table is only two significant figures.

The flows may not add up due to rounding.

The flows are based upon the average monthly flows self-reported by each POTW from January 2007 through December 2009 (Ecology, 2010b).

MGD = Million gallons per day.
MGY = Million gallons per year.
POTW = Publicly Owned Treatment Works.
(a) = Excluding the ten small facilities operated by the U.S. Army and Navy and the Tribes.
(b) = Includes only the sampled Outfall 100 at the Everett STP.
(c) = This value differs from the corresponding total in Table 5 due to rounding.

Table 3. Summary of Winter Samples

POTW Name	Composite Samples					Grab Samples	
	Volume Submitted to Laboratory (Liter)	Number of Aliquots	Start (date/time)	End (date/time)	Collected (date/time)	Grab 1 (date/time)	Grab 2 (date/time)

Table 5. Average Flow Volumes for the Ten POTWs

	Phase 2 (a) (MGD / MGY)	Self-Reported via DMRs (b) (MGD)	Phase 3 (this study)			
			February Event (MGD)	July Event (MGD)	Average (MGD / MGY)	Value Used for Loading Estimates (MGD / MGY)
Bellingham STP	12.1 / 4,430	12.3 (c)	10.94	9.98 (d)	10.5 / 3,820	12.3 / 4,490
Bremerton STP	5.04 / 1,840	4.30 (e)	3.71	4.91	4.31 / 1,570	4.30 / 1,570
Burlington WWTP	1.56 / 569	1.64 (e)	no data	no data	no data	1.64 / 599
City of Tacoma (Central No. 1)	19.7 / 7,190	19.9 (e)	17.28	16.25	16.8 / 6,120	19.9 / 7,260
Everett STP (Outfall 100)	12.6 / 4,620	10.6 (e)	11.98	14.58	13.3 / 4,470 (f)	10.6 / 3,870
Gig Harbor STP	0.800 / 292	0.809 (e)	0.7133	0.6725	0.693 / 253	0.809 / 295
King County West Point	102 / 37,400	92.5 (g)	110.9	66.24	88.6 / 32,300	92.5 / 33,800
Pierce County Chambers Creek STP	17.8 / 6,480	17.9 (e)	8.52	15.72	12.1 / 4,420	17.9 / 6,530
Shelton STP	2.13 / 776	1.99 (e)	2.13	no data	2.13 / 777 (h)	1.99 / 726
Sumner STP	1.89 / 690	2.01 (e)	1.95	1.96	1.96 / 714	2.01 / 734

Key:

DMR = Discharge Monitoring Report required by NPDES permit.

MGD = Million gallons per day.

MGY = Million gallons per year.

POTW = Publicly Owned Treatment Works.
STP = Sewage Treatment Plant.
WWTP = Wastewater Treatment Plant.
(a) = From EnviroVision, et al., 2008.
(b) = From Ecology PARIS database of permittee-reported monitoring results (Ecology, 2010b).
(c) = December 2007 through December 2009.
(d) = Average of daily flows for July 15 and 16, 2009 (Wendling, 2010).
(e) = January 2007 through December 2009.
(f) = Annual flow was adjusted to account for an average of 29 days per year out of service.
(g) = July 2009 through December 2009.
(h) = Only one data point.

Table 6. Average Total POTW Flow Volumes for the 14 Puget Sound Study Areas

Study Area	Average Total POTW Flows (MGY)			Comparison Phase 3 versus Phase 2 (corrected) (percent)
	Phase 2	Phase 2 (corrected)	Phase 3 (this study)	
Admiralty Inlet	338	338	332	- 1.8
Commencement Bay	12,126	12,162	12,169	+ 0.058
Elliott Bay	0	0	0	0
Hood Canal (North)	4	270	73.4	- 73.
Hood Canal (South)	0	5.9	5.9	0
Main Basin	77,329	77,161	72,543	- 6.0
Port Gardner	12,634	12,935	11,736	- 9.3
San Juan Islands	1,529	858	828	- 3.5
Sinclair-Dyes Inlet	3,798	3,796	3,624	- 4.5
South Sound (East)	7,832	7,062	7,097	- 0.50
South Sound (West)	4,243	4,904	4,731	- 3.5
Strait of Georgia	5,943	5,943	6,068	- 2.1
Strait of Juan de Fuca	1,160	1,160	1,110	- 4.3
Whidbey Basin	3,126	3,701	3,825	- 3.4
Total =	**130,061**	**130,296**	**124,142**	**- 4.7**

Key:

The precision of the data in this table is only two significant figures.
Values may not appear to sum correctly due to rounding.

MGY = Million gallons per year.

POTW = Publicly Owned Treatment Works.

The POTWs reassigned to their correct Study Areas were:

Alderbrook Resort and Spa
Carnation WWTP
Granite Falls STP STP
Messenger House Care Center
North Bend STP
Oak Harbor STP

Olympic Water and Sewer, Inc.
Penn Cove WWTP
Pope Resources
Rainier State School
Shelton STP
Taylor Bay STP

Table 7. Number of Chemicals Detected within Each Chemical Class

Chemical Class	Number of Chemicals			
	Analyzed	Detected (a)	Detected >= 50% (b)	Detected >= 65% (b)
Polycyclic Aromatic Hydrocarbons (PAHs)	16	13	4	nc
Phthalates	6	4	1	nc
Other Base/Neutral/Acid Extractables	55	30	(c)	nc
Pesticides	34	6	0	nc
Herbicides	18	5	0	nc
Polybrominated Diphenyl Ethers (PBDE Congeners)	38	33	18	nc
Polybrominated Diphenyl Ethers (PBDE Homologs)	9	9	8	nc
Perfluorinated Compound (PFCs)	13	12	9	nc
Polychlorinated Biphenyls (Congeners) (PCB Congeners)	209	124	nc	21
Polychlorinated Biphenyls (Homologs) (PCB Homologs)	10	10	nc	5
Metals (Copper, Lead, and Zinc)	3	3	nc	nc

Key:

nc = Not calculated.
(a) = Derived from data in Appendix C; used for determining loadings by chemical class.
(b) = Derived from Percent Detection column in Appendix D; used for determining loadings for individual chemicals.
(c) = Total loading rates were not determined for these groups of chemicals.

Table 8. Comparison of Estimated Loadings from Phase 1 and Phase 2

Study Area	Copper				Lead				Zinc				bis(2-Ethylhexyl) Phthalate			
	Phase 2 (a) Best Estimate (kg/year)	Phase 3 (this study)			Phase 2 (a) Best Estimate (kg/year)	Phase 3 (this study)			Phase 2 (a) Best Estimate (kg/year)	Phase 3 (this study)			Phase 2 (a) Best Estimate (kg/year)	Phase 3 (this study)		
		25th Percentile (kg/year)	50th Percentile (kg/year)	75th Percentile (kg/year)		25th Percentile (kg/year)	50th Percentile (kg/year)	75th Percentile (kg/year)		25th Percentile (kg/year)	50th Percentile (kg/year)	75th Percentile (kg/year)		25th Percentile (kg/year)	50th Percentile (kg/year)	75th Percentile (kg/year)

Key:

The precision of the data in this table is only two significant figures.

The loadings from POTWs to the Elliott Bay Study Area was zero because this area of Puget Sound had no POTWs discharging to it.

kg/year = Kilograms per year.

(a) = From EnviroVision, et al., 2008; and Maroncelli, James, 2009.
The estimated loadings were based on: (1) Replacement of non-detect results with one-half the method detection limit or method reporting limit;
and (2) Extrapolations for those POTWs without analytical results by using the median concentration of all POTWs.

Puget Sound Total =		**MGY =**	**124,143**

Key:

The precision of the data in this table is only two significant figures.

MGD = Million gallons per day.

MGY = Million gallons per year.

POTW = Publicly Owned Treatment Works.

(a) = Although the Pope Resources facility treats Port Gardner's sanitary wastewater, it is privately owned.

Appendix B.

Data Usability Summary Reports

Quality Assurance Review Level 1 Report	**Project: Ecology – POTW Pollution Scans**
Date Completed: March 31, 2008	**Completed by: David Ikeda**

The analytical data provided by the laboratory were reviewed for precision, accuracy, and completeness per Washington Department of Ecology (Ecology) Quality Assurance Review Guidance for the quality assurance level 1 review (QA1) (PTI, 1989). Specific criteria for QC limits were obtained from the project QAPP. Compliance with the project QA program is indicated on the in the checklist and tables. Any major or minor concern affecting data usability is summarized below. The checklist and tables also indicate whether data qualification is required and/or the type of qualifier assigned.

Table 2 Work Orders, Tests and Number of Samples included in this DUSR

Work Orders	Matrix	Test Method	Method Name	Number of Samples
0902008	Water	SW846 8270 SIM	Polycyclic Aromatic Hydrocarbons by Gas Chromatography/Mass Spectrometry-SIM	11

General Sample Information	
Do Samples and Analyses on COC check against Lab Sample Tracking Form?	Yes
Did coolers arrive at lab between 0 °C and 6°C and in good condition as indicated on COC and Cooler Receipt Form?	Yes
Frequency of Field QC Samples Correct? Field Duplicate – Not required. Field Blank – 1/20 samples. MS/MSD samples – 1/20 samples.	Yes
Case narrative present and complete?	Yes
Any holding time violations?	No - All samples were prepared and analyzed within holding times.

The following tables are presented at the end of this QA1 Review Memorandum and provided summaries of results outside QC criteria.

- Method Blanks Results (Table 3);

- Surrogates Outside Limits (Table 4);
- MS/MSD Outside Limits (Table 5);
- LCS Outside Limits (Table 6); and
- Re-analysis Results (Table 7).

The PAH data was originally reviewed Dickey Huntamer, Manchester Environmental Laboratory (MEL) on March 10, 2009. The laboratory provided analytical summaries for samples, including QC samples. No raw data was provided by the laboratory.

Polycyclic Aromatic Hydrocarbons (PAHs) by GC/MS SIM

Description	Notes and Qualifiers
Any compounds present in method and field blanks?	Yes, refer to Table 3.
For samples, if associated results are <5 times the method blank or <3 times the field blank then "U" flag data.	Samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U.
Laboratory QC frequency of one blank and LCS with each batch and one set of MS/MSD per 20 samples?	Yes.
Surrogate standard recovery values for samples, MS/MSD, method blanks, and LCS/LCSD samples within laboratory QC limits?	No, please refer to Table 4. No action was taken for one surrogate outlier.
Internal standard recovery values for samples, MS/MSD, method blanks, and LCS/LCSD samples within laboratory QC limits?	Yes.
MS/MSD percent recovery values within laboratory QC criteria?	Yes.
MS/MSD relative percent difference values within QC criteria (see Table 4) of <35%?	Yes.
LCS percent recovery values within laboratory QC criteria (see Table 5)? If the value is high with no positive values in the associated data; then no data qualification is required.	Yes.
Is initial calibration for target compounds <20 % RSD or curve fit?	Yes
Is initial calibration verification standard for target compounds <30 %?	Yes.
Is continuing calibration for target compounds < 20%?	Yes
Were any samples re-analyzed or diluted (see Table 6)? For any sample re-analysis and dilutions is only one reportable result by flagged?	No

Summary of Potential Impacts on Data Usability

Major Concerns

None

Minor Concerns

Samples results below the PQL are reported at the PQL and flagged not detected (U) due to method blank contamination. Matrix spike (B09B138-MS1, parent sample Tacoma) percent recovery values were outside QC limits, the sample results were qualified (refer to Table 4). Laboratory control sample percent recovery values were outside QC limits, associated samples were qualified (refer to Table 5).

Key:
A = Analyte
NC = Not Calculated
ND = Not Detected
PQL = Practical Quantitation Limit
RPD = Relative Percent Difference

Data Validation Qualifiers:

Code	Description
B	Analyte detected in sample and method blank. Reported result is sample concentration without blank correction or associated quantitation limit.
JG	Analyte was positively identified. Value may be greater than the reported estimate.
JK	Analyte was positively identified. Reported result is an estimate with unknown bias.
JL	Analyte was positively identified. Value may be less than the reported estimate.
JT	Analyte was positively identified. Reported result is an estimate below the associated quantitation limit but above the MDL.
JTG	Analyte was positively identified. Value may be greater than the reported result, which is an estimate below the associated quantitation limit but above the MDL.
JTK	Analyte was positively identified. Reported result is an estimate with unknown bias, below the associated quantitation limit but above the MDL.
JTL	Analyte was positively identified. Value may be less than the reported result which is an estimate below associated quantitation limit but above MDL.
NJ	There is evidence that the analyte is present in the sample. Reported result for the tentatively identified analyte is an estimate.
NJT	There is evidence the analyte is present in the sample. Reported result for the tentatively identified analyte is an estimate below the associated quantitation limit but above the MDL.
NU	There is evidence the analyte is present in the sample. Tentatively identified analyte was not detected at or above the reported result.
NUJ	There is evidence the analyte is present in the sample. Tentatively identified analyte was not detected at or above the reported estimate.
REJ	Data are unusable for all purposes. Sample results rejected due to serious deficiencies in the ability to analyze the sample and meet quality control criteria. The presence or absence of the analyte cannot be verified.
U	Analyte was not detected at or above the reported result.
UJ	Analyte was not detected at or above the reported estimate
UJG	Analyte was not detected at or above the reported estimate with likely low bias.
UJK	Analyte was not detected at or above the reported estimate with unknown bias.
UJL	Analyte was not detected at or above the reported estimate with likely high bias.

Quality Assurance Review Level 1 Report	**Project: Ecology – POTW Pollution Scans**
Date Completed: October 14, 2009	**Completed by: Mark Woodke**

The analytical data provided by the laboratory were reviewed for precision, accuracy, and completeness per Washington Department of Ecology (Ecology) Quality Assurance Review Guidance for the quality assurance review level 1 review (QA1, PTI, 1989). Specific criteria for QC limits were obtained from the project QAPP. Compliance with the project QA program is indicated on the in the checklist and tables. Any major or minor concern affecting data usability is summarized below. The checklist and tables also indicate whether data qualification is required and/or the type of qualifier assigned.

Reference:

Table 1 Sample Summary Tables from Electronic Data Deliverable

Work Order	Sample ID	Lab ID	Sample Date	Lab QC	ID Corrections
0907021	Gig Harbor	0907021-01	07/14/2009	Batch	
0907021	Bremerton	0907021-02	07/14/2009		
0907021	West Point	0907021-04	07/14/2009		
0907021	Burlington	0907021-05	07/14/2009		
0907021	Tacoma	0907021-06	07/16/2009		
0907021	Chambers Creek	0907021-07	07/16/2009

0907021	Shelton	0907021-13	07/15/2009		
0907021	Rinsate	0907021-12	07/10/2009		

Table 2 Work Orders, Tests and Number of Samples included in this DUSR

Work Order	Matrix	Test Method	Method Name	Number of Samples
0907021	Water	EPA 8270D SIM	Polycyclic Aromatic Hydrocarbons by GC/MS	11

General Sample Information	
Do Samples and Analyses on COC check against Lab Sample Tracking Form?	Yes.
Did coolers arrive at lab less than 6°C and in good condition as indicated on COC and Cooler Receipt Form?	Assumed based on the data review memoranda by Dickey Huntamer.
Frequency of Field QC Samples Correct? Field Duplicate – Not required.	Yes
Case narrative present and complete?	Yes.
Any holding time violations?	Yes according to the data review memorandum by Dickey Huntamer. Sample extracts for Gig Harbor and Burlington were re-analyzed after the extraction holding time. Associated sample results were qualified estimated biased low (JG or UJG).

The following tables are presented at the end of this QA1 Review Memorandum and provided summaries of results outside QC criteria.

- Method Blanks Results (Table 3);
- Surrogates Outside Limits (Table 4);
- MS/MSD Outside Limits (Table 5);
- LCS Outside Limits (Table 6); and
- Re-analysis Results (Table 7)

The semivolatile organic analyses (BNAs) data was originally reviewed by Dickey Huntamer, Manchester Environmental Laboratory (MEL) on October 22, 2009. The laboratory provided analytical summaries for samples, including QC samples. No raw data was provided with the deliverable.

Polycyclic Aromatic Hydrocarbons by GC/MS-SIM	
Description	**Notes and Qualifiers**
Any compounds present in method, trip, and field blanks (see Table 3)?	Yes.
For samples, if results are <5 times the blank or < 10 times blank for common laboratory contaminants then "U" flag data. Qualification also applies to TICs.	Samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U.
Laboratory QC frequency of one method blank and LCS with each batch and one set of MS/MSD per 20 samples?	Yes
Surrogate recovery values for method blanks and LCS/LCSD samples within laboratory QC limits?	No
Surrogate recovery values for samples and MS/MSD within laboratory QC limits? All samples should be re-analyzed for VOCs? Samples should be re-analyzed if >1 BN and/or AP for SVOCs is out.	No
MS/MSD percent recovery values within laboratory QC criteria (see Table 5)?	No – Several compounds were outside QC limits. The analytes were qualified in the parent sample “JG” and “UJG” for low MS/MSD recovery. If both MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
MS/MSD relative percent difference values within QC criteria (see Table 5) of <35%?	No – Several compounds were outside QC limits. The analytes were qualified in the parent sample “JK” and “UJK” for relative percent difference outliers.
LCS percent recovery values within Laboratory QC criteria (see Table 6)?	No – Several compounds were outside QC limits. All analytes were qualified in associated samples “JG” and “UJG” for low LCS/LCSD recovery. If LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
Do internal standards areas and retention time meet criteria? If not was sample re-analyzed to establish matrix?	No, several IS were outside QC limits in all samples except Burlington; associated sample results were flagged as estimated by Dickey Huntamer.
Is initial calibration for target compounds <20 % RSD or curve fit?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.
Is continuing calibration for target compounds < 20%?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.

Polycyclic Aromatic Hydrocarbons by GC/MS-SIM	
Description	**Notes and Qualifiers**
Were any samples re-analyzed or diluted (see Table 7)? For any sample re-analysis and dilutions is only one reportable result by flagged?	Yes.

Summary of Potential Impacts on Data Usability
Major Concerns
None
Minor Concerns
Analytes were detected in the method and field blanks. The associated sample results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U. Several MS/MSD compound percent recovery values were outside QC limits. The analytes were qualified in the parent sample "JG" and "UJG" for low MS/MSD recovery. If both MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several LCS/LCSD compound percent recovery values were outside QC limits. All analytes were qualified in associated samples "JG" and "UJG" for low LCS/LCSD recovery. If both LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several compounds were above the initial and continuing calibrations QC limit, all associated samples results were qualified estimated quantities (UJK, JH, JTK, or JK). Sample results greater than MDL and less than PQL are flagged estimated (JT). Sample results associated with internal standard outliers were qualified as estimated quantities with an unknown bias (JK or UJK). Sample results associated with holding time exceedances were qualified as estimated quantities with a low bias (JG or UJG).

Table 7 –Samples that were Reanalyzed

Sample ID	Reason for Reanalysis
Gig Harbor	Sample was reanalyzed due to initial poor analysis.

Data Validation Qualifiers:

Code	Description
G	Value is likely greater than the reported result. Reported result may be biased low.
J	The analyte was positively identified; the associated numerical value is the approximate concentration of the analyte in the sample.
K	Bias could not be determined.
REJ	Data are unusable for all purposes. Sample results rejected due to serious deficiencies in the ability to analyze the sample and meet quality control criteria. The presence or absence of the analyte cannot be verified.
T	The associated positive result is less than the quantitation limit.
U	Analyte was not detected at or above the reported result.
UJ	The analyte was not detected above the reported sample quantitation limit. However, the reported quantitation limit is approximate and may or may not represent the actual limit of quantitation necessary to accurately and precisely measure the analyte in the sample.

Quality Assurance Review Level 1 Report	**Project: Ecology – POTW Pollution Scans**
Date Completed: June 12, 2009	**Completed by: David Ikeda**

The analytical data provided by the laboratory were reviewed for precision, accuracy, and completeness per Washington Department of Ecology (Ecology) Quality Assurance Review Guidance for the quality assurance review level 1 review (QA1, PTI, 1989). Specific criteria for QC limits were obtained from the project QAPP. Compliance with the project QA program is indicated on the in the checklist and tables. Any major or minor concern affecting data usability is summarized below. The checklist and tables also indicate whether data qualification is required and/or the type of qualifier assigned.

Table 2 Work Orders, Tests and Number of Samples included in this DUSR

Work Order	Matrix	Test Method	Method Name	Number of Samples
0902008	Water	EPA 8270	Semivolatile Organic Compounds by GC/MS	11

General Sample Information	
Do Samples and Analyses on COC check against Lab Sample Tracking Form?	Yes.
Did coolers arrive at lab less than 6°C and in good condition as indicated on COC and Cooler Receipt Form?	Yes, according to the data review memoranda by Dickey Huntamer.
Frequency of Field QC Samples Correct? Field Duplicate – Not required.	Yes
Case narrative present and complete?	Yes.
Any holding time violations?	Yes, according to the data review memoranda by Dickey Huntamer. Sample extracts for Sumner, Everett, and Field blank were analyzed after the extraction holding time. Associated sample results were qualified estimated biased low (JG or UJG).

The following tables are presented at the end of this QA1 Review Memorandum and provided summaries of results outside QC criteria.

- Method Blanks Results (Table 3);
- Surrogates Outside Limits (Table 4);
- MS/MSD Outside Limits (Table 5);
- LCS Outside Limits (Table 6); and
- Re-analysis Results (Table 7)

The semivolatile organic analyses (BNAs) data was originally reviewed by Dickey Huntamer, Manchester Environmental Laboratory (MEL) on May 22, 2009. The laboratory provided analytical summaries for samples, including QC samples. No raw data was provided with the deliverable.

Semivolatile Organics (including organotins) by GCMS	
Description	**Notes and Qualifiers**
Any compounds present in method, trip, and field blanks (see Table 2)?	Yes.
For samples, if results are <5 times the blank or < 10 times blank for common laboratory contaminants then "U" flag data. Qualification also applies to TICs.	Samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U.
Laboratory QC frequency of one method blank and LCS with each batch and one set of MS/MSD per 20 samples?	Yes
Surrogate recovery values for method blanks and LCS/LCSD samples within laboratory QC limits?	Yes
Surrogate recovery values for samples and MS/MSD within laboratory QC limits? All samples should be re-analyzed for VOCs? Samples should be re-analyzed if >1 BN and/or AP for SVOCs is out.	Yes
MS/MSD percent recovery values within laboratory QC criteria (see Table 4)?	No – Several compounds were outside QC limits. The analytes were qualified in the parent sample “JG” and “UJG” for low MS/MSD recovery. If MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
MS/MSD relative percent difference values within QC criteria (see Table 4) of <35%?	No – Several compounds were outside QC limits. No action was taken.
LCS percent recovery values within Laboratory QC criteria (see Table 5)?	No – Several compounds were outside QC limits. All analytes were qualified in associated samples “JG” and “UJG” for low LCS/LCSD recovery. If LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
Do internal standards areas and retention time meet criteria? If not was sample re-analyzed to establish matrix (see Table 6)?	No, several IS were low in samples Sumner, Everett, Bellingham, and Field blank; associated sample results were flagged as estimated, biased high (UJ or J) by Dickey Huntamer.
Is initial calibration for target compounds <20 % RSD or curve fit?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.
Is continuing calibration for target compounds < 20%?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.

Semivolatile Organics (including organotins) by GCMS	
Description	**Notes and Qualifiers**
Were any samples re-analyzed or diluted (see Table 6)? For any sample re-analysis and dilutions is only one reportable result by flagged?	Yes.

Summary of Potential Impacts on Data Usability

Major Concerns

None

Minor Concerns

Analytes were detected in the method and field blanks. The associated amples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U. Several MS/MSD compound percent recovery valuess were outside QC limits. The analytes were qualified in the parent sample "JG" and "UJG" for low MS/MSD recovery. If MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several LCS/LCSD compound percent recovery values were outside QC limits. All analytes were qualified in associated samples "JG" and "UJG" for low LCS/LCSD recovery. If LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several IS recovery were low in samples Sumner, Everett, Bellingham, and Field blank; associated sample results were flagged as estimated, biased high (UJ or J) y Dickey Huntamer. Several compounds were above the initial and continuing calibrations QC limit, all associated samples results were qualified estimated, bias unknown (UJK, JTK, or JK). Sample results greater than MDL and less than PQL are flagged estimated (JT).

Table 7 –Samples that were Reanalyzed

Sample ID	Reason for Reanalysis
Sumner	Sample was reanalyzed due to IS outliers.
Everett	Sample was reanalyzed due to IS outliers.
Bellingham	Sample was reanalyzed due to QC outliers.
Field blank	Sample was reanalyzed due to QC outliers.

Data Validation Qualifiers:

Code	Description
G	Value is likely greater than the reported result. Reported result may be biased low.
J	The analyte was positively identified; the associated numerical value is the approximate concentration of the analyte in the sample.
K	Bias could not be determined.
REJ	Data are unusable for all purposes. Sample results rejected due to serious deficiencies in the ability to analyze the sample and meet quality control criteria. The presence or absence of the analyte cannot be verified.
U	Analyte was not detected at or above the reported result.
UJ	The analyte was not detected above the reported sample quantitation limit. However, the reported quantitation limit is approximate and may or may not represent the actual limit of quantitation necessary to accurately and precisely measure the analyte in the sample.

Quality Assurance Review Level 1 Report	**Project: Ecology – POTW Pollution Scans**
Date Completed: October 14, 2009	**Completed by: Mark Woodke**

The analytical data provided by the laboratory were reviewed for precision, accuracy, and completeness per Washington Department of Ecology (Ecology) Quality Assurance Review Guidance for the quality assurance review level 1 review (QA1, PTI, 1989). Specific criteria for QC limits were obtained from the project QAPP. Compliance with the project QA program is indicated on the in the checklist and tables. Any major or minor concern affecting data usability is summarized below. The checklist and tables also indicate whether data qualification is required and/or the type of qualifier assigned.

Work Order	Matrix	Test Method	Method Name	Number of Samples
0907021	Water	EPA 8270	Semivolatile Organic Compounds by GC/MS	11

General Sample Information	
Do Samples and Analyses on COC check against Lab Sample Tracking Form?	Yes.
Did coolers arrive at lab less than 6°C and in good condition as indicated on COC and Cooler Receipt Form?	Yes, assumed based on the data review memorandum by Dickey Huntamer.
Frequency of Field QC Samples Correct? Field Duplicate – Not required.	Yes
Case narrative present and complete?	Yes.
Any holding time violations?	No.

The following tables are presented at the end of this QA1 Review Memorandum and provided summaries of results outside QC criteria.

- Method Blank Results (Table 3);
- Surrogates Outside Limits (Table 4);
- MS/MSD Outside Limits (Table 5);
- LCS Outside Limits (Table 6); and
- Re-analysis Results (Table 7)

Quality Assurance Review Level 1 Report	Project: Ecology – POTW Pollution Scans
Date Completed: October 14, 2009	**Completed by: Mark Woodke**

The semivolatile organic analyses (BNAs) data was originally reviewed by Dickey Huntamer, Manchester Environmental Laboratory (MEL) on September 22, 2009. The laboratory provided analytical summaries for samples, including QC samples. No raw data was provided with the deliverable.

Semivolatile Organics (including organotins) by GCMS	
Description	**Notes and Qualifiers**
Any compounds present in method, trip, and field blanks (see Table 2)?	Yes.
For samples, if results are <5 times the blank or < 10 times blank for common laboratory contaminants then "U" flag data. Qualification also applies to TICs.	Samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U.
Laboratory QC frequency of one method blank and LCS with each batch and one set of MS/MSD per 20 samples?	Yes
Surrogate recovery values for method blanks and LCS/LCSD samples within laboratory QC limits?	No
Surrogate recovery values for samples and MS/MSD within laboratory QC limits? All samples should be re-analyzed for VOCs? Samples should be re-analyzed if >1 BN and/or AP for SVOCs is out.	No
MS/MSD percent recovery values within laboratory QC criteria (see Table 4)?	No – Several compounds were outside QC limits. The analytes were qualified in the parent sample “JG” and “UJG” for low MS/MSD recovery. If MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
MS/MSD relative percent difference values within QC criteria (see Table 4) of <35%?	Yes.
LCS percent recovery values within Laboratory QC criteria (see Table 5)?	No – Several compounds were outside QC limits. All analytes were qualified in associated samples “JG” and “UJG” for low LCS/LCSD recovery. If LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected “REJ”.
Do internal standards areas and retention time meet criteria? If not was sample re-analyzed to establish matrix (see Table 6)?	Yes.
Is initial calibration for target compounds <20 % RSD or curve fit?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.
Is continuing calibration for target compounds < 20%?	No – several compounds were above the QC limit, all associated samples results were qualified “JK or UJK”.
Were any samples re-analyzed or diluted (see Table 6)? For any sample re-analysis and dilutions is only one reportable result by flagged?	Yes.

Summary of Potential Impacts on Data Usability
Major Concerns
None
Minor Concerns

Analytes were detected in the method blanks. The associated samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged UJ. Several MS/MSD compound percent recovery values were outside QC limits. The analytes were qualified in the parent sample "JG" and "UJG" for low MS/MSD recovery. If both MS/MSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several LCS/LCSD compound percent recovery values were outside QC limits. All analytes were qualified in associated samples "JG" and "UJG" for low LCS/LCSD recovery. If both LCS/LCSD percent recovery values were below 10%, then non-detect results were flagged as rejected "REJ". Several compounds were above the initial and continuing calibrations QC limit, all associated samples results were qualified estimated, bias unknown (UJK, JTK, or JK). Sample results greater than MDL and less than PQL are flagged estimated (JT).

Table 7 –Samples that were Reanalyzed

Sample ID	Reason for Reanalysis
B09G117-BS1	Sample was reanalyzed due to overwriting file.
B09G161-BS1	Sample was reanalyzed due to overwriting file.

Data Validation Qualifiers:

Code	Description
G	Value is likely greater than the reported result. Reported result may be biased low.
J	The analyte was positively identified; the associated numerical value is the approximate concentration of the analyte in the sample.
K	Bias could not be determined.
REJ	Data are unusable for all purposes. Sample results rejected due to serious deficiencies in the ability to analyze the sample and meet quality control criteria. The presence or absence of the analyte cannot be verified.
T	The associated positive result is less than the quantitation limit.
U	Analyte was not detected at or above the reported result.
UJ	The analyte was not detected above the reported sample quantitation limit. However, the reported quantitation limit is approximate and may or may not represent the actual limit of quantitation necessary to accurately and precisely measure the analyte in the sample.

Quality Assurance Review Level 1 Report	Project: Ecology – POTW Pollution Scans
Date Completed: March 31, 2008	**Completed by: David Ikeda**

The analytical data provided by the laboratory were reviewed for precision, accuracy, and completeness per Washington Department of Ecology (Ecology) Quality Assurance Review Guidance for the quality assurance level 1 review (QA1) (PTI, 1989). Specific criteria for QC limits were obtained from the project QAPP. Compliance with the project QA program is indicated on the in the checklist and tables. Any major or minor concern affecting data usability is summarized below. The checklist and tables also indicate whether data qualification is required and/or the type of qualifier assigned.

Table 2 Work Orders, Tests and Number of Samples included in this DUSR

Work Orders	Matrix	Test Method	Method Name	Number of Samples
0902008	Water	SW846 8270	Acid Herbicides by Gas Chromatography/Mass Spectrometry	11

General Sample Information	
Do Samples and Analyses on COC check against Lab Sample Tracking Form?	Yes
Did coolers arrive at lab between 0 °C and 6°C and in good condition as indicated on COC and Cooler Receipt Form?	Yes
Frequency of Field QC Samples Correct? Field Duplicate – Not required. Field Blank – 1/20 samples. MS/MSD samples – 1/20 samples.	Yes
Case narrative present and complete?	Yes
Any holding time violations?	No - All samples were prepared and analyzed within holding times.

The following tables are presented at the end of this QA1 Review Memorandum and provided summaries of results outside QC criteria.

- Method Blanks Results (Table 3);
- Surrogates Outside Limits (Table 4);

- MS/MSD Outside Limits (Table 5);
- LCS Outside Limits (Table 6); and
- Re-analysis Results (Table 7).

The acid herbicides data was reviewed by Bob Carrell, Manchester Environmental Laboratory (MEL) on March 11, 2009. The laboratory provided the analytical summaries for samples, including QC samples. No raw data was provided by the laboratory.

Acid Herbicides by GC/MS	
Description	**Notes and Qualifiers**
Any compounds present in method and field blanks?	No.
For samples, if results are <5 times the blank then "U" flag data.	Samples results below the PQL are reported at the PQL and flagged U. Sample results greater than PQL are not changed and flagged U.
Laboratory QC frequency of one blank and LCS with each batch and one set of MS/MSD per 20 samples?	Yes.
Surrogate standard recovery values for samples, MS/MSD, method blanks, and LCS/LCSD samples within laboratory QC limits?	No, please refer to Table 4. No action was taken for LCS surrogate outliers.
Internal standard recovery values for samples, MS/MSD, method blanks, and LCS/LCSD samples within laboratory QC limits?	Yes.
MS/MSD percent recovery values within laboratory QC criteria?	No, please refer to Table 5.
MS/MSD relative percent difference values within QC criteria (see Table 4) of <40%?	No, please refer to Table 5. No action was taken, since results were qualified due to MS/MSD recovery.
LCS percent recovery values within laboratory QC criteria (see Table 5)? If the value is high with no positive values in the associated data; then no data qualification is required.	No, please refer to Table 6.
Is initial calibration for target compounds <20 % RSD or curve fit?	Yes
Is initial calibration verification standard for target compounds <30 %?	No, 4-nitrophenol and dinoseb were outside QC limits. No action was taken since the anayltes were not detected in the associated samples.
Is continuing calibration for target compounds < 20%?	Yes
Were any samples re-analyzed or diluted (see Table 6)? For any sample re-analysis and dilutions is only one reportable result by flagged?	No

Summary of Potential Impacts on Data Usability
Major Concerns
None
Minor Concerns
Matrix spike (B09B138-MS1 and –MSD, parent sample Tacoma) percent recovery values were outside QC limits, the sample results were qualified (refer to Table 4). Laboratory control sample percent recovery values were outside QC limits, associated samples were qualified (refer to Table 5).

Table 3 - List of Positive Results for Blank Samples

None

Table 3A - List of Samples Qualified for Method Blank Contamination

None

Table 4 - List of Samples with Surrogates outside Control Limits

Method	Sample ID	Analyte	Recovery	QC Limit	Sample Qualification
SW846 8270	B09B102-BS1	2,4-Dichlorophenylacetic Acid	24	40 - 130	None

Table 5 - List MS/MSD Percent Recovery Values and RPDs outside Control Limits

Method	Sample ID	Analyte	Recovery	QC Limit	Sample Qualification
SW846 8270	B09B138-MS1	2,4-DB	0	40 - 130	R
SW846 8270	B09B138-MS1	4-Nitrophenol	23	40 - 130	UJL or JL
SW846 8270	B09B138-MS1	Acifluorfen (Blazer)	0	40 - 130	R
SW846 8270	B09B138-MS1	Clopyralid	38	40 - 130	UJL or JL
SW846 8270	B09B138-MS1	Dinoseb	0	40 - 130	R
SW846 8270	B09B138-MS1	Picloram	15	40 - 130	None
SW846 8270	B09B138-MSD1	2,4-DB	0	40 - 130	R
SW846 8270	B09B138-MSD1	4-Nitrophenol	19	40 - 130	UJL or JL
SW846 8270	B09B138-MS1	Clopyralid	34	40 - 130	UJL or JL
SW846 8270	B09B138-MS1	Dinoseb	34	40 - 130	R
SW846 8270	B09B138-MS1	Picloram	0	40 - 130	R
SW846 8270	B09B138-MS1	2,4-DB	RPD = NC	40	None
SW846 8270	B09B138-MS1	Acifluorfen (Blazer)	RPD = NC	40	None
SW846 8270	B09B138-MS1	Dinoseb	RPD = NC	40	None
SW846 8270	B09B138-MS1	Picloram	RPD = NC	40	None

Table 6 - List LCS Percent Recovery Values outside Control Limits

Method	Sample ID	Analyte	Recovery	QC Limit	Sample Qualification
SW846 8270	B09B102-BS1	2,3,4,5-Tetrachlorophenol	24	40 - 130	UJL or JL
SW846 8270	B09B102-BS1	2,3,4,6-Tetrachlorophenol	39	40 - 130	UJL or JL
SW846 8270	B09B102-BS1	2,4,5-T	36	40 - 130	UJL or JL
SW846 8270	B09B102-BS1	2,4,5-Trichlorophenol	21	40 - 130	UJL or JL
