To account for the combined effect of capillary imbibition, well operation, and buoyancy in upward fluid migration, Birdsell et al. (2015a) conducted a numerical analysis over five phases of activity at a hypothetical Marcellus-like hydraulic fracturing site: a pre-drilling steady state, the injection of fluids, a shut-in period, production, and the continued migration of hydraulic fracturing fluids after the well is plugged and abandoned. They quantified how much hydraulic fracturing fluid flows back up the well after fracturing, how much reaches overlying aquifers, and how much is permanently sequestered by capillary imbibition (which is treated as a sink term). Their results affirmed that, without a pathway such as a permeable fault or leaky wellbore, it is very unlikely that hydraulic fracturing fluid from a deep shale could reach an overlying aquifer. However, the study did indicate that upward migration on the order of 328 ft (100 m) could occur through relatively low-permeability overburden, even if no discrete, permeable pathway exists.

6.3.2.2 Fracture Overgrowth out of the Production Zone

Fractures extending out of the intended production zone into another formation, or into an unintended zone within the same formation, could provide a potential fluid migration pathway into drinking water resources (Jackson et al., 2013d). This migration could occur either through the fractures themselves or in connection with other permeable subsurface features or formations (Figure 6-7). Such “out-of-zone fracturing” is undesirable from a production standpoint and may occur as a result of inadequate reservoir characterization or fracture treatment design (Eisner et al., 2006). Some researchers have noted that fractures growing out of the targeted production zone could potentially contact other formations, such as higher conductivity sandstones or conventional hydrocarbon reservoirs, which may create an additional pathway for migration into a drinking water resource (Reagan et al., 2015). In addition, fractures growing out of the production zone could potentially intercept natural, preexisting fractures (discussed in Section 6.3.2.4) or active or abandoned wells near the well where hydraulic fracturing is performed (discussed in Section 6.3.2.3).

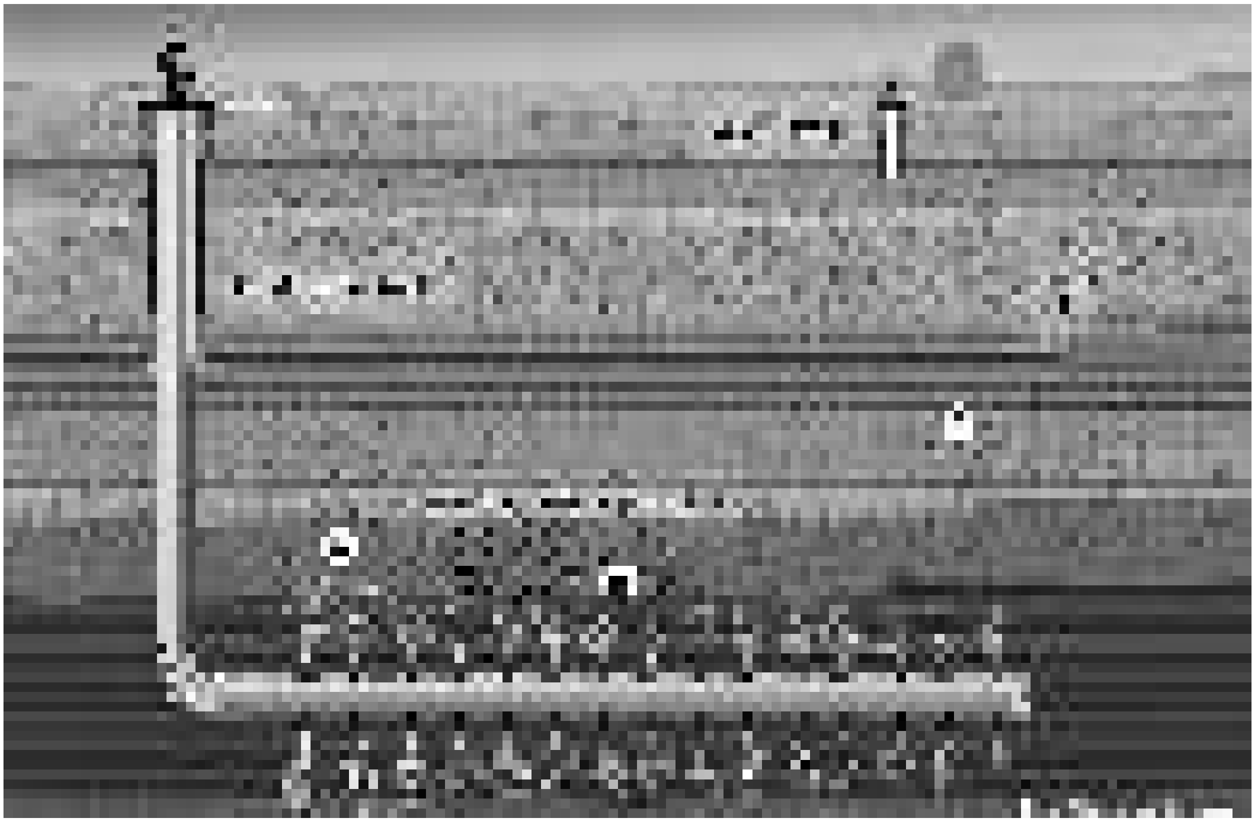

Figure 6-7. Conceptualized depiction of potential pathways for fluid movement out of the production zone: (a) induced fracture overgrowth into over- or underlying formations; (b) induced fractures intersecting natural fractures; and (c) induced fractures intersecting a permeable fault.

The fracture's geometry (Section 6.3.1) affects its potential to extend beyond the intended zone and serve as a pathway to drinking water resources. Vertical heights of fractures created during hydraulic fracturing operations have been measured in several U.S. shale plays, including the Barnett, Woodford, Marcellus, and Eagle Ford, using microseismic monitoring and tiltmeters (Fisher and Warpinski, 2012). These data indicate typical fracture heights extending from tens to hundreds of feet.[1] Davies et al. (2012) analyzed this data set and found that the maximum fracture height was 1,929 ft (588 m) and that 1% of the fractures had a height greater than 1,148 ft (350 m). This may raise some questions about fractures being contained within the producing formation, as some Marcellus fractures were found to extend vertically for at least 1,500 ft (460 m), while the maximum thickness of the formation is generally 350 ft (110 m) or less (MCOR, 2012). However, the majority of fractures within the Marcellus were found to have heights less than 328 ft (100 m), suggesting limited possibilities for fracture overgrowth exceeding the separation between shale reservoirs and shallow aquifers (Davies et al., 2012). This is consistent with modeling results found by Kim and Moridis (2015) and others, as described below. Where the producing formation is not

[1] As described in Section 6.3.1, microseismic data represent the small amounts of seismic energy generated during subsurface fracturing. The Fisher and Warpinski dataset includes the top and bottom depths of mapped fracture treatments in the four shale plays mentioned, giving the maximum propagation length.

continuous horizontally, the lateral extent of fractures may also become important. For example, in the Fisher and Warpinski (2012) data set, fractures were found to extend to horizontal lengths greater than 1,000 ft (300 m).

Results of National Energy Technology Laboratory (NETL) research in Greene County, Pennsylvania, are generally consistent with those reported in the Fisher and Warpinski (2012) data set. Microseismic monitoring was used at six horizontal Marcellus Shale wells to identify the maximum upward extent of brittle deformation (i.e., rock breakage) caused by hydraulic fracturing (Hammack et al., 2014). At three of the six wells, fractures extending between 1,000 and 1,900 ft (300 and 580 m) above the Marcellus Shale were identified. Overall, approximately 40% of the microseismic events occurred above the Tully Limestone, the formation overlying the Marcellus Shale. The microseismic data suggest that fracture propagation occurs above the Tully Limestone, which is sometimes referred to as an upper barrier to hydraulic fracture growth (Hammack et al., 2014). However, all microseismic events were at least 5,000 ft (2,000 m) below drinking water aquifers, as the Marcellus Shale is one of the deepest shale plays (Table 6-3), and no impacts to drinking water resources or another local gas-producing interval were identified. See Text Box 6-6 for more information on the Greene County site.

Text Box 6-6. Monitoring at the Greene County, Pennsylvania, Hydraulic Fracturing Test Site.

Monitoring performed at the Marcellus Shale test site in Greene County, Pennsylvania, evaluated fracture height growth and zonal isolation during and after hydraulic fracturing operations (Hammack et al., 2014). The site has six horizontally drilled wells and two vertical wells that were completed into the Marcellus Shale. Pre-fracturing studies of the site included a 3D seismic survey to identify faults, pressure measurements, and baseline sampling for isotopes; drilling logs were also run. Hydraulic fracturing occurred April 24 to May 6, 2012, and June 4 to 11, 2012. Monitoring at the site included the following:

- **Microseismic monitoring** was conducted during four of the six hydraulic fracturing jobs on the site, using geophones placed in the two vertical Marcellus Shale wells. These data were used to monitor fracture height growth above the six horizontal Marcellus Shale wells during hydraulic fracturing.
- **Pressure and production data** were collected from a set of existing vertical gas wells completed in Upper Devonian/Lower Mississippian zones 3,800 to 6,100 ft (1,200 to 1,900 m) above the Marcellus. Data were collected during and after the hydraulic fracturing jobs and used to identify any communication between the fractured areas and the Upper Devonian/Lower Mississippian rocks.
- **Chemical and isotopic analyses** were conducted on gas and water produced from the Upper Devonian/Lower Mississippian wells. Samples were analyzed for stable isotope signatures of hydrogen, carbon, and strontium and for the presence of perfluorocarbon tracers used in 10 stages of one of the hydraulic fracturing jobs to identify possible gas or fluid migration to overlying zones (Sharma et al., 2014a; Sharma et al., 2014b).

As of September 2014, no evidence was found of gas or brine migration from the Marcellus Shale (Hammack et al., 2014), although longer-term monitoring is necessary to confirm that no impacts to overlying zones have occurred (Zhang et al., 2014a).

Similarly, in Dunn County, North Dakota, there is evidence suggestive of out-of-zone fracturing in the Bakken Shale (U.S. EPA, 2015i). At the Killdeer site (Section 6.2.2.1), hydraulic fracturing fluids and produced water were released during a rupture of the casing at the Franchuk 44-20 SWH well. Water quality characteristics at two monitoring wells located immediately downgradient of the Franchuk well reflected a mixing of local Killdeer Aquifer water with deep formation brine. Ion and isotope ratios used for brine fingerprinting suggest that Madison Group formations (which directly overlie the Bakken in the Williston Basin) were the source of the brine observed in the Killdeer Aquifer, and the authors concluded that this provides evidence for out-of-zone fracturing (U.S. EPA, 2015i). Industry experience also indicates that out-of-zone fracturing could be fairly common in the Bakken and that produced water from many Bakken wells has Madison Group chemical signatures (Arkadakskiy and Rostron, 2013; Arkadakskiy and Rostron, 2012; Peterman et al., 2012).

Fracture growth from a deep formation to a near-surface aquifer is generally considered to be limited by layered geological environments and other physical constraints (Fisher and Warpinski, 2012; Daneshy, 2009). For example, differences in in-situ stresses in layers above and below the production zone can restrict fracture height growth in sedimentary basins (Fisher and Warpinski, 2012). High-permeability layers near hydrocarbon-producing zones can reduce fracture growth by acting as a "thief zone" into which fluids can migrate, or by inducing a large compressive stress that acts on the fracture (de Pater and Dong, 2009, as cited in Fisher and Warpinski, 2012). Although thief zones may prevent fractures from reaching shallower formations or growing to extreme vertical lengths, they do allow fluids to migrate out of the production zone into receiving formations, which could (depending on site-specific conditions) potentially contain drinking water resources. A volumetric argument has also been used to discuss limits of vertical fracture growth; that is, the volumes of fluid needed to sustain fracture growth beyond a certain height would be unrealistic (Fisher and Warpinski, 2012). However, as described in Section 6.3.1, fracture volume can be greater than the volume of injected fluid due to the effects of pressurized water combined with the effects of gas during injection (Kim and Moridis, 2015). Nevertheless, some numerical investigations suggest that, unless unrealistically high pressures and injection rates are applied to an extremely weak and homogeneous formation that extends up to the near surface, hydraulic fracturing generally induces stable and finite fracture growth in a Marcellus-type environment and fractures are unlikely to extend into drinking water resources (Kim and Moridis, 2015).

Modeling studies have identified other factors that can affect the containment of fractures within the producing formation. As discussed above, additional numerical analysis of fracture propagation during hydraulic fracturing has demonstrated that contrasts in the geomechanical properties of rock formations can affect fracture height containment (Gu and Siebrits, 2008) and that geological layers present within shale gas reservoirs can limit vertical fracture propagation (Kim and Moridis, 2015). In another modeling study, Myshakin et al. (2015) applied a multi-layered geologic model to study whether fracture growth can extend upward through overlying strata and reach drinking water resources in a Marcellus Shale-type environment. Most fractures were predicted either to extend upward to the overlying layer (about 46%) or to remain in the Marcellus Shale (about 34%). About 20% of the fractures were predicted to extend further upward into or above the overlying limestone. These model results are consistent with microseismic events observed above the Tully Limestone in Greene County, Pennsylvania (Hammack et al., 2014), where the fracture heights ranged from 0 to 700 ft (0 to 200 m) and most of the fractures terminated less than 100 ft (31 m) above the top of the Marcellus.

If fractures were to propagate from the production zone to drinking water resources, other factors would need to be in place for fluid migration to occur. Using a numerical simulation, Reagan et al. (2015) investigated potential short-term migration of gas and water between a shale or tight gas formation and a shallower groundwater unit, assuming that a permeable pathway already exists between the two formations. Note that, for the purposes of this study, the pathway was assumed to be pre-existing, and Reagan et al. (2015) did not model the hydraulic fracturing process itself.

The subsurface system evaluated in the Reagan et al. (2015) modeling investigation included a horizontal well used for hydraulic fracturing and gas production, a connecting pathway between the producing formation and the aquifer, and a shallow vertical water well in the aquifer (Figure 6-7). The parameters and scenarios used in the study are shown in Table 6-4; two vertical separation distances between the producing formation and the aquifer were investigated, along with a range of production zone permeabilities and other variables used to describe four production scenarios. The horizontal well was assigned a constant bottomhole pressure of half the initial pressure of the target reservoir, not accounting for any over-pressurization from hydraulic fracturing. (As noted in Section 6.3.2.1, over-pressurization during hydraulic fracturing can create an additional driving force for upward migration.) In the simulation, migration was assessed immediately after hydraulic fracturing and for up to a 2-year simulation period representing the production stage.

Results of this modeling investigation indicate a generally downward water flow within the connecting fracture (i.e., flow from the aquifer through the connecting fracture into the hydraulically induced fractures in the production zone) with some upward migration of gas (Reagan et al., 2015). In certain simulated cases, gas breakthrough (the appearance of gas at the base of the drinking water aquifer) was also observed. The key parameter affecting migration of gas into the aquifer was the production regime, particularly whether gas production (which drives migration toward the production well) was occurring in the reservoir. Simulations that included a producing gas well showed only a few instances of breakthrough, while simulations without gas production (i.e., that assumed the well was shut-in) tended to result in breakthrough. When gas breakthrough did occur, the breakthrough times ranged from minutes to 20 days. However, in all cases, the gas escape was limited in duration and scope, because the amount of gas available for immediate migration toward the shallow aquifer was limited to that initially stored in the hydraulically induced fractures after the stimulation process and prior to production. These simulations indicate that the target reservoir may not be able to replenish the gas that was available for migration prior to production.

Based on the results of the Reagan et al. (2015) modeling study, gas production from the reservoir appears likely to mitigate gas migration, both by reducing the amount of available gas and depressurizing the induced fractures (which counters the buoyancy of any gas that may escape from the production zone into the connecting fracture). Production at the gas well also creates pressure gradients that drive a downward flow of water from the aquifer via the fracture into the producing formation, increasing the amount of water produced at the gas well. Furthermore, the effective permeability of the connecting feature is reduced during water (downward) and gas (upward) counter-flow within the fracture, further retarding the upward movement of gas or allowing gas to dissolve into the downward flow. However, Reagan et al. (2015) did find an increased potential for gas release from the producing formation in cases where there is no gas production following hydraulic fracturing. The potential for gas migration during shut-in periods following hydraulic fracturing and prior to production may be more significant, especially when out-of-zone fractures are formed. Without the effects of production, gas can rise via buoyancy, with any downward-flowing water from the aquifer displacing the upward-flowing gas.

Reagan et al. (2015) also found that the permeability of a connecting fault or fracture may be an important factor affecting the potential upward migration of gas (although not as significant as the production regime). For the cases where gas escaped from the production zone, the maximum volume of migrating gas depended upon the permeability of the connecting feature: the higher the permeability, the larger the volume. The modeling results also showed that lower permeabilities delay the downward flow of water from the aquifer, allowing the trace amount of gas that entered into the fracture early in the modeled period to reach the aquifer, which was otherwise predicted to dissolve in the water flowing downward in the feature. Similarly, the permeabilities of the target reservoir, fracture volume, and the separation distance were found to affect gas migration, because they affected the initial amount of gas stored in the hydraulically induced fractures. In contrast, the permeability of the drinking water aquifer was not found to be a significant factor in the assessment.

Table 6-4. Modeling parameters and scenarios investigated by Reagan et al. (2015).
This table illustrates the range of parameters included in the Reagan et al. (2015) modeling study. See Figure 6-7, Figure 6-8, and Figure 6-9 for conceptualized illustrations of these scenarios.

Model parameter or variable	Values investigated in model scenarios
All scenarios	
Lateral distance from connecting feature to water well	328 ft (100 m)
Vertical separation distance between producing formation and drinking water aquifer	656 ft (200 m); 2,625 ft (800 m)
Producing formation permeability range	1 nD (1 x 10^{-21} m^2); 100 nD (1 x 10^{-19} m^2); 1 µD (1 x 10^{-18} m^2)
Drinking water aquifer permeability	0.1 D (1 x 10^{-13} m^2); 1 D (1 x 10^{-12} m^2)
Initial conditions	Hydrostatic
Production well bottom hole pressure	Half of the initial pressure of the producing formation (not accounting for over-pressurization from hydraulic fracturing)
Production regime	Production at both the water well and the gas well; Production at only the water well; Production at only the gas well; No production

Model parameter or variable	Values investigated in model scenarios
Fracture pathway scenarios	
Connecting feature permeability	1 D (1 x 10^{-12} m^2); 10 D (1 x 10^{-11} m^2); 1,000 D (1 x 10^{-9} m^2)
Offset well pathway scenarios	
Lateral distance from production well to offset well	33 ft (10 m)
Cement permeability of offset well	1 µD (1 x 10^{-18} m^2); 1 mD (1 x 10^{-15} m^2); 1 D (1 x 10^{-12} m^2); 1,000 D (1 x 10^{-9} m^2)

6.3.2.3 Migration via Fractures Intersecting with Offset Wells and Other Artificial Structures

Another potential pathway for fluid migration is one in which hydraulic fracturing fluids or displaced subsurface fluids move through newly created fractures into an offset well or its fracture network, resulting in a process called well communication (Jackson et al., 2013d). The offset well can be an abandoned (i.e., plugged), inactive, or actively producing well. In addition, if the offset well has also been used for hydraulic fracturing, the fracture networks of the two wells might intersect. The situation where hydraulic fractures propagate to (and inject fluid into and/or cause pressure increases in) other existing wells or hydraulic fractures is referred to as a "frac hit" and is known to occur in areas with a high density of wells (Jackson et al., 2013a).

Frac hits can be more common in unconventional production settings compared to conventional production settings, due to the closer/denser well spacing (King and Valencia, 2016). Figure 6-8 provides a schematic to illustrate fractures that intercept an offset well, and Figure 6-9 depicts (in a simplified illustration) how the fracture networks of two such wells might intersect. This can be a particular concern in shallower formations, where the local least principal stress is vertical (resulting in more horizontal fracture propagation), and in situations where there are drinking water wells in the same formation as wells used for hydraulic fracturing.

Instances of well communication have been known to occur and are described in well records and the oil and gas literature. For example, an analysis of operator data collected by the New Mexico Oil Conservation Division (NM OCD) in 2013−2014 identified 120 instances of well communication in the San Juan Basin between 2007 and 2013 (Vaidyanathan, 2014). In some cases, well communication incidents have led to documented production and/or environmental problems. A study in the Barnett Shale noted two cases of well communication, one with a well 1,100 ft (340 m) away and the other with a well 2,500 ft (760 m) away from the initiating well; ultimately, one of the offset wells had to be re-fractured because the well communication halted production (Craig et al., 2012). In some cases, the fluids that intersect the offset well flow up the wellbore and spill onto the surface. In its report *Review of State and Industry Spill Data: Characterization of Hydraulic Fracturing-Related Spills*, the EPA (2015m) recorded 10 incidents in which fluid spills were attributed to well communication events (see Text Box 5-10 for more information on this effort).[1] The Well File Review (U.S. EPA, 2016c) reports that 1% of the wells (an estimated 280 wells) represented in the study reported a frac hit, where the hydraulic fracturing operation documented in the Well File Review led to communication with a nearby well.[2] (It was not possible to determine whether fluids reached protected groundwater resources during these frac hits based on information in the well files.) While the subsurface effects of frac hits have not been extensively studied, these cases demonstrate the possibility of fluid migration via communication with other wells and/or their fracture networks. More generally, well communication events can indicate fracture behavior that was not intended by the treatment design.

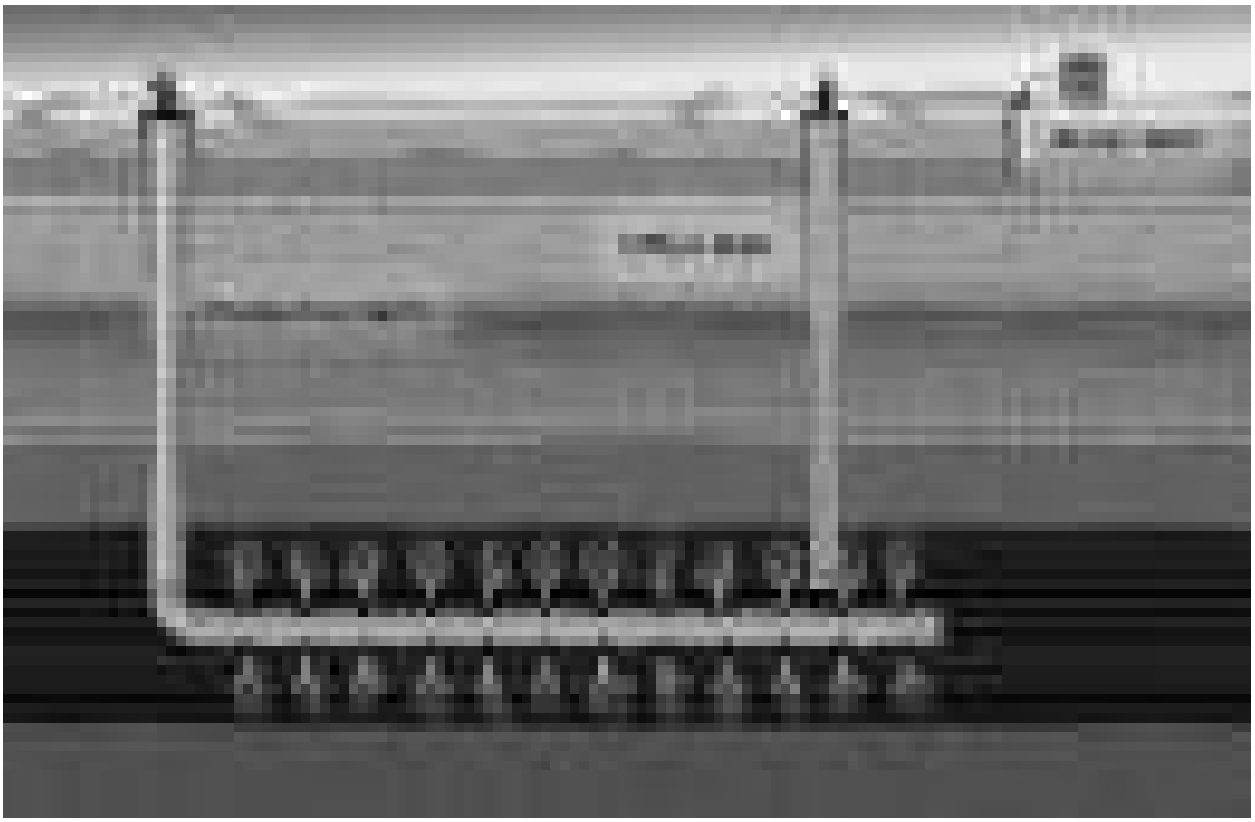

Figure 6-8. Induced fractures intersecting an offset well (in a production zone, as shown, or in overlying formations into which fracture growth may have occurred).

This image shows a conceptualized depiction of potential pathways for fluid movement out of the production zone (not to scale).

[1] These spills are represented by line numbers 163, 236, 265, 271, 286, 287, 375, 376, 377, and 380 in Appendix B of U.S. EPA (2015m).

[2] 280 wells (95% confidence interval: 240 – 320 wells).

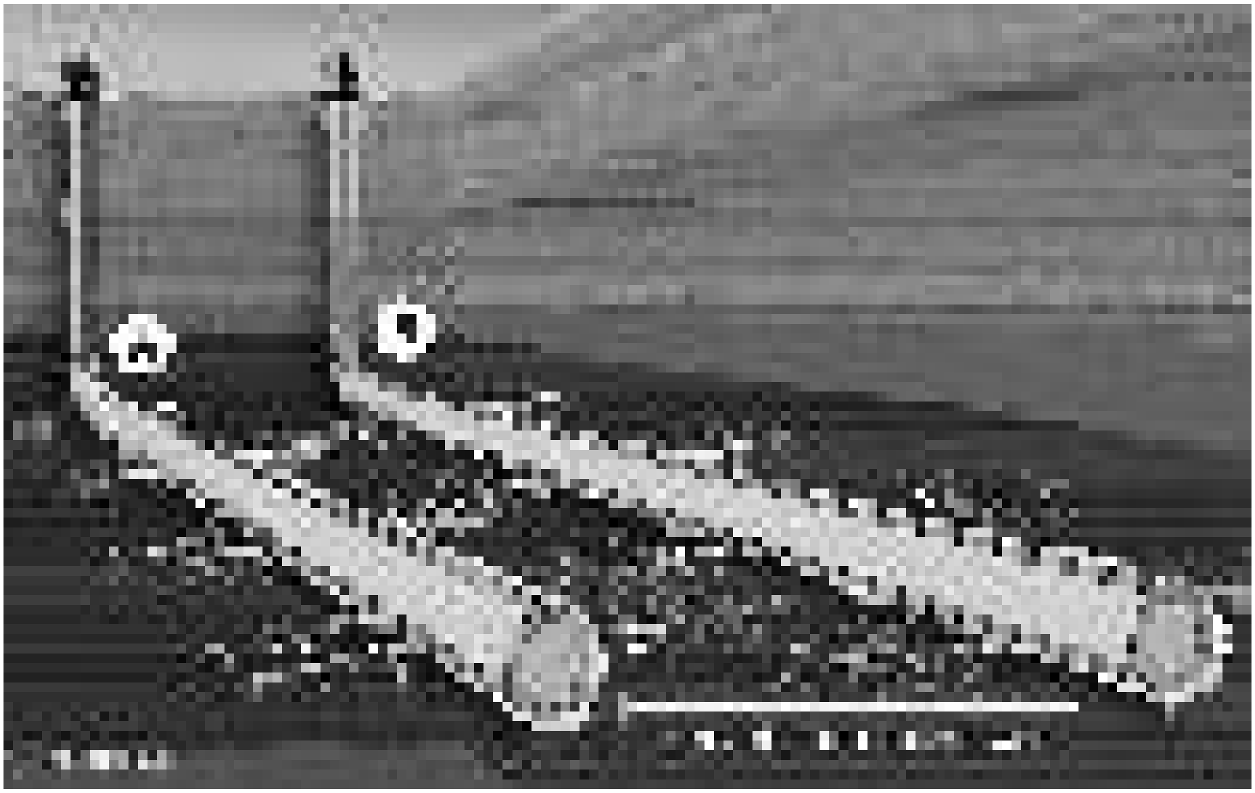

Figure 6-9. Well communication (a frac hit).
This image shows a conceptualized depiction of the fractures of a newly fractured well (Well A) intersecting the existing fracture network created during a previous hydraulic fracturing operation in an offset well (Well B). Evidence of this interaction may be observed in the offset well as a pressure change, lost production, and/or introduction of new fluids. Depending on the condition of the offset well, this can result in fluid being spilled onto the surface, rupturing of cement and/or casing and hydraulic fracturing fluid leaking into subsurface formations, and/or fluid flowing out through existing flaws in the casing and/or cement. (Figure is not to scale.)

A well communication event is usually observed at the offset well as a pressure spike, due to the elevated pressure from the originating well, or as an unexpected drop in the production rate (Lawal et al., 2014; Jackson et al., 2013a). Ajani and Kelkar (2012) performed an analysis of frac hits in the Woodford Shale in Oklahoma, studying 179 wells over a 5-year period. The authors used fracturing records from the newly completed wells and compared them to production records from surrounding wells. The authors assumed that sudden changes in production of gas or water coinciding with fracturing at a nearby well were caused by communication between the two wells, and increased water production at the surrounding wells was assumed to be caused by hydraulic fracturing fluid flowing into these offset wells. The results of the Oklahoma study showed that 24 wells had decreased gas production or increased water production within 60 days of the initial gas production at the nearby fractured well. A total of 38 wells experienced decreased gas or increased water production up to a distance of 7,920 ft (2,410 m), which the study authors defined as the distance between the midpoints of the laterals; 10 wells saw increased water production from as far away as 8,422 ft (2,567 m). In addition, one well showed a slight increase in gas production rather than a decrease.[1]

Other studies of well communication events have relied on similar information. In the NM OCD operator data set, the typical means of detecting a well communication event was through pressure changes at the offset well, production lost at the offset well, and/or fluids found in the offset well. In some instances, well operators determined that a well was producing fluid from two different formations, while in one instance, the operator identified a potential well communication event due to an increase in production from the offset well (Vaidyanathan, 2014). In another study, Jackson et al. (2013a) found that the decrease in production due to well communication events was much greater in lower permeability reservoirs. The authors note an example where two wells 1,000 ft (300 m) apart communicated, reducing production in the offset well by 64%. These results indicate that the subsurface interactions of well networks or complex hydraulics driven by each well at a densely populated (with respect to wells) area are important factors to consider for the design of hydraulic fracturing treatments and other aspects of oil and gas production.

The key factor affecting the likelihood of a well communication event and the impact of a frac hit is the location of the offset well relative to the well where hydraulic fracturing was conducted (Ajani and Kelkar, 2012). In the Ajani and Kelkar (2012) analysis, the likelihood of a communication event was less than 10% in wells more than 4,000 ft (1,000 m) apart, but rose to nearly 50% in wells less than 1,000 ft (300 m) apart. Well communication was also much more likely with wells drilled from the same pad. The affected wells were found to be in the direction of maximum horizontal stress in the field, which correlates with the expected direction of fracture propagation. Modeling work by Myshakin et al. (2015) is generally consistent with these results, indicating that the risk of fluid movement through pre-existing wellbores or open faults is negligible unless hydraulic fractures are located very close to these features.[2]

Statistical modeling by Montague and Pinder (2015) investigated the probability that a hypothetical new well used for hydraulic fracturing within the area of New York underlain by the Marcellus Shale would intersect an existing wellbore. The results indicated that this probability would be from 0 to 3.45%. The model incorporated the depth of the hypothetical new well, the vertical growth of induced fractures, and the depth and locations of existing nearby wells. The model also assumed that the existing wells are vertical and fracture growth is not impacted by nearby wells or existing fractures. However, the authors concluded that the inclusion of horizontal wells within the data set could increase the chance of intersection with induced fractures.

Well communication may be more likely to occur where there is less resistance to fracture growth. Such conditions may be related to existing production operations (e.g., where previous hydrocarbon extraction has reduced the pore pressure, changed stress fields, or affected existing fracture networks) or the existence of high-permeability rock units (Jackson et al., 2013a). As Ajani and Kelkar (2012) found in the Woodford Shale, one of the deepest major shale plays (Table 6-3), induced fractures tend to enter portions of the reservoir that have already been fractured as

[1] The numbers of wells cited in the study reflect separate analyses, and the numbers cited are not additive.

[2] In the Myshakin et al. (2015) paper, the authors do not quantify or explain what is meant by "very close."

opposed to entering previously unfractured rocks, ultimately causing interference in offset wells. Mukherjee et al. (2000) described this tendency for asymmetric fracture growth toward depleted areas in low-permeability gas reservoirs due to pore pressure depletion from production at offset wells. The authors note that pore pressure gradients in depleted zones would affect the subsurface stresses. Therefore, depending on the location of the new well with respect to depleted zone(s) and the orientation of the existing induced fractures, the newly created fracture can be asymmetric, with only one wing of the fracture extending into the depleted area and developing significant length and conductivity (Mukherjee et al., 2000). The extent to which the depleted area affects fracturing depends on factors such as cumulative production, pore volume, hydrocarbon saturation, effective permeability, and the original reservoir or pore pressure (Mukherjee et al., 2000). Similarly, high-permeability rock types acting as thief zones may also cause preferential fracturing due to a higher leakoff rate into these layers (Jackson et al., 2013a).

In addition to location, the potential for impact on a drinking water resource also depends on the condition of the offset well. (See Section 6.2 for information on the mechanical integrity of well components.) In their analysis, Ajani and Kelkar (2012) found a correlation between well communication and well age: older wells were more likely to be affected. If the cement in the annulus between the casing and the formation is intact and the well components can withstand the stress exerted by the pressure of the fluid, nothing more than an increase in pressure and extra production of fluids would occur during a well communication event. However, if the offset well is not able to withstand the pressure of the hydraulic fracturing fluid, well components could fail (Figure 6-4), allowing fluid to migrate out of the well.

The highest pressures most hydraulic fracturing wells will face during their life spans occur during the process of fracturing (Section 3.3). In some cases, temporary equipment is installed in wells during fracturing to protect the well against the increased pressure. Therefore, many producing wells may not be designed to withstand pressures typical of hydraulic fracturing (Enform, 2013) and can experience problems when fracturing occurs in nearby wells. Depending on the location of the weakest point in the offset well, this could result in fluid being spilled onto the surface; rupturing of cement and/or casing and hydraulic fracturing fluid leaking into subsurface formations; and/or fluid flowing out through existing flaws in the casing and/or cement. (See Chapters 5 and 7 for additional information on how such spills can affect drinking water resources.) For example, a documented well communication event near Innisfail, Alberta, Canada (Text Box 6-7) occurred when several well components failed, because they were not rated to handle the increased pressure caused by the well communication (ERCB, 2012). In addition, if the fractures were to intersect an uncemented portion of the wellbore, the fluids could potentially migrate into formations that are uncemented along the wellbore.

In older wells near a hydraulic fracturing operation, plugs and cement can degrade over time; in some cases, abandoned wells may never have been plugged properly. Before the 1950s, most well plugging efforts were focused on preventing water from the surface from entering oil fields. As a result, many wells from that period were abandoned with little or no cement (NPC, 2011b). This can be a significant issue in areas with legacy (i.e., historic) oil and gas exploration and when wells are re-entered and hydraulically fractured (or re-fractured) to increase production in a reservoir. In one study, 18 of 29 plugged and abandoned wells in Quebec were found to show signs of leakage (Council of Canadian Academies, 2014). Similarly, a PA DEP report cited three cases where migration of natural gas had been caused by well communication events with old, abandoned wells, including one case where private drinking water wells were affected (PA DEP, 2009c). In Tioga County, Pennsylvania, following hydraulic fracturing of a shale gas well, an abandoned well nearby produced a 30 ft (9 m) geyser of brine and gas for more than a week (Dilmore et al., 2015).

Text Box 6-7. Well Communication at a Horizontal Well near Innisfail, Alberta, Canada.

In most cases, well communication during fracturing results in a pressure surge accompanied by a drop in gas production and additional flow of produced water or hydraulic fracturing fluid at an offset well. However, if the offset well is not capable of withstanding the high pressures of fracturing, more significant damage can occur.

In January 2012, fracturing at a horizontal well near Innisfail in Alberta, Canada, caused a surface spill of fracturing and formation fluids at a nearby operating vertical oil well. According to the investigation report by the Alberta Energy Resources Conservation Board (ERCB, 2012), pressure began rising at the vertical well less than two hours after fracturing ended at the horizontal well.

Several components of the vertical well facility—including surface piping, discharge hoses, fuel gas lines, and the pressure relief valve associated with compression at the well—were not rated to handle the increased pressure and failed. Ultimately, the spill released, in addition to gas, an estimated 19,816 gal (75,012 L^3) of hydraulic fracturing fluid, brine, and oil covering an area of approximately 656 ft by 738 ft (200 m by 225 m).

The ERCB determined that the lateral of the horizontal well passed within 423 ft (129 m) of the vertical well at a depth of approximately 6,070 ft (1,850 m) below the surface in the same formation. The operating company had estimated a fracture half-length of 262 to 295 ft (80 to 90 m) based on a general fracture model for the field.[1] While there were no regulatory requirements for spacing hydraulic fracturing operations in place at the time, the 423 ft (129 m) distance was out of compliance with the company's internal policy to space fractures from adjacent wells at least 1.5 times the predicted half-length. The company also did not notify the operators of the vertical well of the hydraulic fracturing operations. The incident prompted the ERCB to issue *Bulletin 2012-02—Hydraulic Fracturing: Interwellbore Communication between Energy Wells*, which outlines expectations for avoiding well communication events and preventing adverse effects on offset wells.

Various studies estimate the number of abandoned wells in the United States to be significant. The Interstate Oil and Gas Compact Commission (IOGCC, 2008) estimates that over one million wells were drilled in the United States prior to the enactment of state oil and gas regulations, and the status and location of many of these wells are unknown. A recent estimate of wells completed before the adoption of statewide well abandonment criteria in 1957 in Pennsylvania placed the range at 305,000 to 390,000 wells in the state, with more than 176,000 of those wells likely abandoned pre-1957 (Dilmore et al., 2015). As of 2000, PA DEP's well plugging program reported that it had documented 44,700 wells that had been plugged and 8,000 that were in need of plugging, and approximately 184,000 additional wells with an unknown location and status (PA

[1] The fracture half-length is the radial distance from a wellbore to the outer tip of a fracture propagated from that well (Schlumberger, 2014).

DEP, 2000). A similar evaluation from New York State found that the number of unplugged wells was growing in the state despite an active well plugging program (Bishop, 2013). In the Midwest, Sminchak et al. (2014) examined two areas of historical oil and gas exploration as part of an investigation of potential carbon dioxide sequestration sites. They found that a 4.3 mi by 4.3 mi (6.9 km by 6.9 km) square area in Michigan contained 22 abandoned oil and gas wells and a 9.3 mi by 9.3 mi (15.0 km by 15.0 km) square area in Ohio contained 359 abandoned oil and gas wells.

Various state programs exist to plug identified orphaned wells, but they face the challenge of identifying and addressing a large number of wells.[1] In some cases, remote sensing technologies can be used to identify wells for which no records exist. For example, an NETL study in Pennsylvania found that helicopter-based high-resolution magnetic surveys can be used to accurately locate wells with steel casing; wells with no steel casing exhibit weak or no magnetic anomaly and are not detected by such surveys (Veloski et al., 2015). Chapter 10 includes a discussion of factors and practices, including those related to active and abandoned wells near hydraulic fracturing operations, that can reduce the frequency of impacts to drinking water quality.

The Reagan et al. (2015) numerical modeling study included an assessment of migration via an offset well as part of its investigation of potential fluid migration from a producing formation into a shallower groundwater unit (Section 6.3.2.2). For the offset well pathway, it was assumed that the hydraulically induced fractures intercepted an older offset well with deteriorated components. (This assessment can also be applicable to cases where potential migration may occur via the production well-related pathways discussed in Section 6.2) The highest permeability value tested for the connecting feature represented a case with an open wellbore. A key assumption for this investigation was that the offset well was already directly connected to a permeable feature in the reservoir or within the overburden.

Similar to the cases for permeable faults or fractures discussed in Section 6.3.2.2, the study investigated the effect of multiple well- and formation-related variables on potential fluid migration (Table 6-4). Based on the simulation results, an offset well pathway can have a greater potential for gas release from the production zone into a shallower groundwater unit than the fracture pathway discussed in Section 6.3.2.2 (Reagan et al., 2015). This difference is primarily due to the total pore volume of the connecting pathway within the offset well; if the offset well pathway has a significantly lower pore volume compared to the fracture pathway, this would reduce possible gas storage in the connecting feature and increase the speed of buoyancy-dependent migration. However, as with the fracture scenario, the gas available for migration in this case is still limited to the gas that is initially stored in the hydraulically induced fractures. Accordingly, any incidents of gas breakthrough in the model results were limited in both duration and magnitude.

In their modeling study, Reagan et al. (2015) found that production at the gas well (the well used for hydraulic fracturing) also affects the potential upward migration of gas and its arrival times at the drinking water formation due to its effect on the driving forces (e.g., pressure gradient). Similar to the fracture cases described in Section 6.3.2.2, production in the target reservoir appears to mitigate upward gas migration, both by reducing the amount of gas that might otherwise be

[1] An orphaned well is an inactive oil or gas well with no known (or financially solvent) owner.

available for upward migration and by creating a pressure gradient toward the production well. Only scenarios without the mitigating feature of gas production result in upward migration into the aquifer. This assessment also found a generally downward water flow within the connecting well pathway, which is more pronounced when the production well is operating and there is de-pressurization within the fractures. The producing formation and aquifer permeabilities appear not to be significant factors for upward gas migration via this pathway. Instead, Reagan et al. (2015) found the permeability of the connecting well to be the key factor affecting the migration of gas to the aquifer and the water well. Very low permeabilities (less than 1 mD, or 1×10^{-15} m^2) for the connecting well lead to no migration of gas into the aquifer regardless of the vertical separation distance, whereas larger permeabilities presented a greater potential for gas breakthrough.

Brownlow et al. (2016) also modeled communication with an abandoned well. The modeling exercise was based on operator data from the Eagle Ford Shale. Two types of cases were modeled: cases with an open (unplugged) abandoned well (which the authors note are known to occur in Texas) and cases with an abandoned well that was converted into a water well after the lower portion of the well had been filled with drilling mud (a practice allowed in Texas until 1967). The modeling results indicated that fluid could potentially migrate up both types of abandoned wells, with relatively greater flow rates in open abandoned wells and in abandoned wells closer to the well used for hydraulic fracturing. Similar to the Reagan et al. (2015) study, the production regime was also a key factor; when production and flowback were included in the simulation, they were found to inhibit upward migration. Modeled flow rates through the mud-filled well were comparable to those found by Reagan et al. (2015) with higher flows predicted through the open well.

A similar study was conducted by Nowamooz et al. (2015), who modeled a hypothetical well in the Utica Shale in Quebec. They assumed a 7.9 in (200 mm) wellbore with an approximately 2 in (51 mm) annulus space filled with intact cement. The researchers varied the permeability of the cement from 1 μD (1×10^{-19} m^2) to 1 mD (1×10^{-15} m^2). The results indicated that, at the highest permeability of 1 mD, a flow of methane of 1.02×10^{-2} ft^3/day (2.9×10^{-4} m^3/d) was possible. This was two orders of magnitude higher than the flow when the cement permeability was 1 μD (1×10^{-19} m^2). The wellbore permeabilities used by Nowamooz et al. (2015) appear to be consistent with actual permeabilities observed in the field, which can vary widely. For example, a study of 31 abandoned oil and gas wells in Pennsylvania found effective permeability values along the wellbores in the range of 10^{-6} to 10^2 mD (1×10^{-21} to 1×10^{-13} m^2) (Kang et al., 2015).

In the same way that fractures can propagate to intersect offset wells, they can also potentially intersect other artificial subsurface structures including mine shafts or solution mining sites. No known incidents of this type of migration have been documented. However, the Bureau of Land Management (BLM) has identified over 48,000 abandoned mines in the United States and is adding new mines to its inventory every year (BLM, 2015). In addition, the Well File Review identified an estimated 800 cases where wells used for hydraulic fracturing were drilled through mining voids, and an additional 90 cases of drilling through gas storage zones or wastewater disposal zones (U.S.

EPA, 2015n).[1,2] The analysis suggests emplacing cement within such zones can be challenging, which, in turn, could lead to a loss of zonal isolation (as described in Section 6.2) and create a pathway for fluid migration.

6.3.2.4 Migration via Fractures Intersecting Geologic Features

Potential fluid migration via natural, permeable fault or fracture zones in conjunction with hydraulic fracturing has been recognized as a potential contamination hazard for several decades (Harrison, 1983). Natural fracture systems have a strong influence on the success of a fracture treatment, and the topic has been studied extensively from the perspective of optimizing treatment design (e.g., Dahi Taleghani and Olson, 2011; Weng et al., 2011; Vulgamore et al., 2007). While porous flow in unfractured shale or tight sand formations is assumed to be negligible due to very low formation permeabilities (as discussed in Section 6.3.2.1), the presence of small natural fractures known as "microfractures" within tight sand or shale formations is widely recognized, and these fractures affect fluid flow and production strategies. Naturally occurring permeable faults and larger-scale fractures within or between formations can potentially allow for more significant flow pathways out of the production zone (Jackson et al., 2013d). Figure 6-7 illustrates the concept of induced fractures intersecting with permeable faults or fractures extending out of the target reservoir.[3]

The specific effects of natural fractures on fluid migration, and the mechanisms by which these effects occur, are not completely understood. While naturally occurring microfractures can impact the growth of induced fractures (e.g., by affecting the tensile strength of a shale layer), studies based on modeling and monitoring data generally do not indicate that they contribute to fracture growth in a way that could affect the frequency or severity of impacts. Microfractures could affect fluid flow patterns near the induced fractures by increasing the effective contact area. Conversely, these microfractures could act as capillary traps for the hydraulic fracturing fluid during treatment (contributing to fluid leakoff) and potentially hinder hydrocarbon flow due to lower gas relative permeabilities (Dahi Taleghani et al., 2013). Ryan et al. (2015) suggested that some natural fracture processes/patterns (such as the presence of two subvertical fracture sets) can contribute to upward gas migration, while others (such as small fracture sets with low connectivity that are confined to individual geologic layers) can preclude it.

In some areas, larger-scale geologic features may affect potential fluid flow pathways. As discussed in Text Box 6-3, baseline measurements taken before shale gas development show evidence of thermogenic methane in some shallow aquifers, suggesting that, in some cases, natural subsurface pathways exist and might allow for naturally occurring migration of gas over geologic time (Robertson et al., 2012). There is also evidence demonstrating that gas undergoes mixing in

[1] 800 wells (95% confidence interval: 10 – 1,900 wells).

[2] 90 wells (95% confidence interval: 50 – 100 wells).

[3] Faults and fractures can exhibit a range of permeabilities. For example, permeable (also referred to as "transmissive" or "conductive") faults or fault segments have enough permeability to allow fluids to flow along or across them, while others are relatively impermeable and can serve as barriers to flow. These differences in permeability are associated with geologic conditions such as rock type, depth, and stress regime. Generally, when researchers refer to the potential for migration via natural geologic features, it is assumed that these features are sufficiently permeable to serve as a pathway.

subsurface pathways (Baldassare et al., 2014; Molofsky et al., 2013; Fountain and Jacobi, 2000). Warner et al. (2012) compared recent sampling results to data published in the 1980s and found geochemical evidence for migration of fluids through natural pathways between deep underlying formations and shallow aquifers—pathways that the authors suggest could lead to contamination from hydraulic fracturing activities. In northeastern Pennsylvania, there is evidence that brine from deep saline formations has migrated into shallow aquifers over geologic time, preferentially following certain geologic structures (Llewellyn, 2014). However, this depends on local geologic characteristics and does not appear to happen in all locations; for example, in the Monongahela River Basin in West Virginia, shallow groundwater samples did not show evidence of mixing with deep brines (Boothroyd et al., 2016). As described in Chapter 7, karst features (created by the dissolution of soluble rock) can also serve as a potential pathway of fluid movement on a faster time scale.

Monitoring data show that the presence of natural faults and fractures can affect both the height and width of induced hydraulic fractures. When faults are present, relatively larger microseismic responses are seen and larger fracture growth can occur, as described below. Rutledge and Phillips (2003) suggested that, for a hydraulic fracturing operation in East Texas, pressurizing existing fractures (rather than creating new hydraulic fractures) was the primary process that controlled enhanced permeability and fracture network conductivity at the site. Salehi and Ciezobka (2013) used microseismic data to investigate the effects of natural fractures in the Marcellus Shale and concluded that fracture treatments are more efficient in areas with clusters or “swarms” of small natural fractures, while areas without these fracture swarms require more thorough stimulation. These microseismic data show that swarms of natural fractures within a shale formation can result in a fracture network with a larger width-to-height ratio (i.e., a shorter and wider network) than would be expected in a zone with a low degree of natural fracturing.

A few studies have used monitoring data to specifically investigate the effect of natural faults and fractures on the vertical extent of induced fractures. A statistical analysis of microseismic data by Shapiro et al. (2011) found that fault rupture (movement along a fault) from hydraulic fracturing is limited by the extent of the stimulated rock volume and is unlikely to extend beyond the fracture network. However, as demonstrated by microseismic data presented by Vulgamore et al. (2007), in some settings, the fracture network—and, in this case, the possibility of fault rupture—could extend laterally for thousands of feet. In the Fisher and Warpinski (2012) data set (Section 6.3.2.2), the greatest fracture heights occurred when the hydraulic fractures intersected pre-existing faults. Similarly, Hammack et al. (2014) reported that fracture growth seen above the Marcellus Shale is consistent with the inferred extent of pre-existing faults at the Greene County, Pennsylvania, research site (Section 6.3.2.2 and Text Box 6-6). The authors suggested that clusters of microseismic events may have occurred where preexisting small faults or natural fractures were present above the Marcellus Shale. Viñal (2015) used time-lapse multi-component seismic monitoring to monitor the overburden of the Montney Shale during a hydraulic fracturing operation in Alberta, Canada. The researchers found increases in the anisotropy in the overburden, which they interpreted as fractures being propagated along natural faults out of the shale and into the overburden. At a site in Ohio, Skoumal et al. (2015) found that hydraulic fracturing induced a rupture along a pre-existing fault approximately 0.6 mi (1 km) from the hydraulic fracturing operation. Using a new monitoring method known as tomographic fracturing imaging, Lacazette and Geiser (2013) also found vertical hydraulic fracturing fluid movement from a production well into a natural fracture network for distances of up to 0.6 mi (1.0 km). However, Davies et al. (2013) questioned whether this technique actually measures hydraulic fracturing fluid movement.

Modeling studies have also investigated whether hydraulic fracturing operations are likely to reactivate faults and create a potential fluid migration pathway into shallow aquifers. Results from one study suggest that, under specific circumstances, interaction with a permeable fault could result in fluid migration to the surface but only on relatively long (ca. 1,000 year) time scales (Gassiat et al., 2013). These findings have been disputed in the literature due to certain suggested limitations of the study, including the model setup, assumptions, and calibration; unrealistic fault representation; lack of constraints on fluid overpressure; and exclusion of the capillary imbibition effect (Birdsell et al., 2015b; Flewelling and Sharma, 2015). In response to these critiques, the authors stated that their work was a parametric study in which the model geometry, parameter, and boundary conditions were defined based on data collected from multiple shale gas basins, and the objective of the study was not to calibrate results to a specific site (Lefebvre et al., 2015). Other researchers reject the notion that open, permeable faults coexist with hydrocarbon accumulation (Flewelling et al., 2013). However, it is unclear whether the existence of faults in low permeability reservoirs affects the accumulation of hydrocarbons because, under natural conditions, the flow of gas may be limited due to capillary tension.

Like the other pathways discussed in this section, other conditions in addition to the physical presence of a permeable fault or fracture would need to exist for fluid migration to a drinking water resource to occur. The modeling study conducted by Reagan et al. (2015) and discussed in Section 6.3.2.2 indicates that, if such a permeable feature exists, the transport of gas and fluid flow would strongly depend upon the production regime and, to a lesser degree, the features' permeability and the separation between the reservoir and the aquifer. In addition, the pressure distribution within the reservoir (e.g., over-pressurized vs. hydrostatic conditions) will affect the fluid flow through fractures/faults. As a result, the presence of multiple geologic and well-related factors can increase the potential for fluid migration into drinking water resources. For example, in the Mamm Creek area of Colorado (Section 6.2.2.4), mechanical integrity and drilling-related problems likely acted in concert with natural fracture systems to result in a gas seep into surface water and shallow groundwater (Crescent, 2011). A similar situation occurred in southeastern Bradford County, Pennsylvania (discussed in Section 6.2), where natural fractures intersected an uncemented casing annulus and allowed gas to flow from the annulus into nearby domestic wells and a stream (Llewellyn et al., 2015).

Other modeling studies investigating the potential of fluid migration related to existing faults and fractures have given mixed results. Pfunt et al. (2016) performed modeling based on conditions in the North German Basin, i.e., deep geological settings where undisturbed cap rocks are present between the fractured formation and shallow aquifers. Their modeling indicated that the hydraulic fracturing fluid did not reach the near-surface area either during hydraulic fracturing operations or in the long-term in the presence of highly permeable pathways (fault zones, fractures). Like previous modeling studies, the authors found that the injection pressure and permeability of the connecting fault are two important factors that control upward fluid migration.

Rutqvist et al. (2013) found that, while somewhat larger microseismic events are possible in the presence of faults, repeated events and a seismic slip would amount to a total rupture length of 164 ft (50 m) or less along a fault, not far enough to allow fluid migration between a deep gas reservoir (approximately 6,562 ft or 2,000 m deep) and a shallow aquifer. A follow-up study using more sophisticated three-dimensional modeling techniques also found that deep hydraulic fracturing is unlikely to create a direct flow path into a shallow aquifer, even when hydraulic fracturing fluid is injected directly into a fault (Rutqvist et al., 2015). Similarly, a modeling study that investigated potential fluid migration from hydraulic fracturing in Germany found potential vertical fluid migration up to 164 ft (50 m) in a scenario with high fault zone permeability, although the authors note this is likely an overestimate because their goal was to "assess an upper margin of the risk" associated with fluid transport (Lange et al., 2013). More generally, results from Rutqvist et al. (2013) indicate that fracturing along an initially impermeable fault (as is expected in a shale gas formation) would result in numerous small microseismic events that act to prevent larger events from occurring (and, therefore, prevent the creation of more extensive potential pathways).

Schwartz (2015) modeled methane flow through a hypothetical permeable fault at a well in Germany. Methane flow was modeled through a permeable leakage zone that was 0.1 ft by 13 ft (0.03 m by 4 m) with an assumed permeability in the range of approximately 100 D to of 10,000 D (1×10^{-10} m^2 to 1×10^{-8} m^2). The model indicated that methane could reach a drinking water aquifer approximately 2,953 ft (900 m) above the gas zone in about a half a day and reach a maximum flow after two days. According to the model results, methane entering the aquifer led to an increase in pH, the release of negatively charged constituents such as chromium, and the adsorption of positively charged ions such as arsenic. Decreasing the permeability of the leakage zone by a factor of 100 increased the travel time by a factor of four. In another study, Myshakin et al. (2015) modeled brine migration through a natural and induced fracture network. Their results indicated that the main pathway for vertical migration of hydraulic fracturing fluid to overlying layers is through the induced fractures, and not the natural fractures. The location of hydraulic fractures relative to each other affects the extent of brine migration into overburden layers; compared to single fractures separated by large distances, closely spaced fractures were associated with higher pressures in—and, consequently, more brine migration into—overlying layers.

6.4 Synthesis

In the injection stage of the hydraulic fracturing water cycle, operators inject hydraulic fracturing fluids into a well under pressure that is high enough to fracture the production zone. These fluids flow through the well and then out into the surrounding formation, where they create fractures in the rock, allowing hydrocarbons to flow through the fractures, to the well, and then up the production string.

The production well and the surrounding geologic features function as a system that is often designed with multiple elements that can isolate hydrocarbon-bearing zones and water-bearing zones, including groundwater resources, from each other. This physical isolation optimizes oil and gas production and can protect drinking water resources via isolation within the well (by the casing and cement) and/or through the presence of multiple layers of subsurface rock between the target formations where hydraulic fracturing occurs and drinking water aquifers.

6.4.1 Summary of Findings

In this chapter, we consider impacts to drinking water resources to occur if hydraulic fracturing fluids or other subsurface fluids affected by hydraulic fracturing enter and adversely impact the quality of groundwater resources. Potential pathways for fluid movement to drinking water resources may be linked to one or more components of the well and/or features of the subsurface geologic system. If present, these potential pathways can, in combination with the high pressures under which fluids are injected and pressure changes within the subsurface due to hydraulic fracturing, result in the subsurface movement of fluids to drinking water resources.

The potential for these pathways to exist or form has been investigated through modeling studies that simulate subsurface responses to hydraulic fracturing, and demonstrated via case studies and other monitoring efforts. In addition, the development of some of these pathways—and fluid movement along them—has been documented. It is important to note that, if multiple barriers afforded by the well design and the presence of subsurface rock formations are present, the development of a pathway within this system does not necessarily result in an impact on a drinking water resource.

6.4.1.1 Fluid Movement via the Well

A production well undergoing hydraulic fracturing is subject to higher stresses during the relatively brief hydraulic fracturing phase than during any other period of activity in the life of the well. If the well cannot withstand the stresses experienced during hydraulic fracturing operations, pathways associated with the casing and cement can form that can result in the unintended movement of fluids into the surrounding environment (Section 6.2).

Multiple barriers within the well, including casing, cement, and a completion assembly can, if present, isolate hydrocarbon-bearing formations from drinking water resources located at a different depth. However, inadequate construction, defects in or degradation of the casing or cement, and/or the absence of redundancies such as multiple layers of casing and proper emplacement of cement can allow fluid movement into drinking water resources. Various studies of wells in the Marcellus Shale showed failure rates between 3 and 10%, depending on the type of failure studied (contamination of drinking water resources may or may not have occurred at these wells). The EPA's Well File Review found that 3% of all hydraulic fracturing jobs involved a downhole mechanical integrity failure, which generally resulted in hydraulic fracturing fluid entering the annular space between the casing and formation or between two casing strings.

Ensuring proper well design and mechanical integrity—particularly proper cement placement and quality—are important actions for preventing unintended fluid migration along the wellbore. While not all of the mechanical integrity failures described above resulted in fluid movement to—or contamination of—a drinking water resource, aspects of well design that lead to increased failure rates have the potential to increase the frequency or severity of impacts to drinking water quality associated with hydraulic fracturing operations.

6.4.1.2 Fluid Movement within Subsurface Geologic Formations

Potential subsurface pathways for fluid migration to drinking water resources include flow of fluids out of the production zone into formations above or below it, fractures extending out of the production zone or into other induced fracture networks, intersections of fractures with abandoned or active wells, and hydraulically induced fractures intersecting with faults or natural fractures (Section 6.3).

Vertical separation between the zone where hydraulic fracturing operations occur and drinking water resources reduces the potential for fluid migration to impact the quality of drinking water resources. However, not all hydraulic fracturing operations are characterized by large vertical distances between the production zone and drinking water resources. In coalbed methane plays, which are typically shallower than shale gas plays, these separation distances can be smaller than in other types of formations. Also, in certain areas, hydraulic fracturing is known to take place in formations containing water that meets the salinity threshold that is used in some definitions of a drinking water resource.

Lateral separation between wells undergoing hydraulic fracturing and other wells (including active and abandoned wells) also reduces the potential for fluid migration to impact drinking water resources. While some operators design fracturing treatments to communicate with the fractures of another well and optimize oil and gas production, unintended communication between two wells or their fracture systems can lead to spills in an offset well, which is an indicator of hydraulic fracturing treatments extending beyond their planned design. These well communication incidents, or “frac hits,” have been reported in New Mexico, Oklahoma, and a few other locations. Surface spills from well communication incidents have also been documented. Based on the available information, frac hits most commonly occur on multi-well pads and when wells are spaced less than 1,100 ft (340 m) apart, but they have been observed at wells up to 8,422 ft (2,567 m) away from a well undergoing hydraulic fracturing.

6.4.1.3 Impacts to Drinking Water Resources

We identified some example cases in the literature where the pathways associated with hydraulic fracturing resulted in an impact on the quality of drinking water resources.

One of these cases took place in Bainbridge Township, Ohio, in 2007. Failure to cement over-pressured formations through which a production well passed—and proceeding with the hydraulic fracturing operation without adequate cement and an extended period during which the well was shut in—led to a buildup of natural gas within the well annulus and high pressures within the well. This ultimately resulted in movement of gas from the production zone into local drinking water aquifers (Section 6.2.2.2). Twenty-six domestic drinking water wells were taken off-line and the houses were connected to a public water system after the incident due to elevated methane levels.

Casings at a production well near Killdeer, North Dakota, ruptured in 2010 following a pressure spike during hydraulic fracturing, allowing fluids to escape to the surface. Brine and tert-butyl alcohol were detected in two nearby monitoring wells. Following an analysis of potential sources, the only source consistent with the conditions observed in the two impacted water wells was the well that ruptured during hydraulic fracturing. There is also evidence that out-of-zone fracturing occurred at the well (Sections 6.2.2.1 and 6.3.2.2).

There are other cases where contamination of or changes to the quality of drinking water resources near hydraulic fracturing operations were identified. Hydraulic fracturing remains a potential contributing cause in these cases. For example:

- Migration of stray gas into drinking water resources involves many potential routes, including poorly constructed casing and naturally existing or induced fractures in subsurface formations. Multiple pathways for fluid movement may have worked in concert in northeastern Pennsylvania (possibly due to cement issues or sustained casing pressure), the Raton Basin in Colorado (where fluid migration may have occurred along natural rock features or faulty well seals), and the Wattenberg field in Colorado (where the surface casing depth and the presence of uncemented gas zones are major factors in determining the likelihood of mechanical integrity failures and contamination). While the sources of methane identified in drinking water wells in each study area could be determined with varying degrees of certainty, attempts to definitively identify the pathways of migration have generally been inconclusive (Text Box 6-3).
- At the East Mamm Creek drilling area in Colorado, inadequate placement of cement allowed the migration of methane through natural faults and fractures in the area. This case illustrates how construction issues, sustained casing pressure, and the presence of natural faults and fractures, in conjunction with elevated pressures associated with hydraulic fracturing, can work together to create a pathway for fluids to migrate toward drinking water resources (Sections 6.2.2.2 and 6.3.2.4).

Additionally, there are places in the subsurface where oil and gas resources and drinking water resources co-exist in the same formation. Evidence we examined indicates that some hydraulic fracturing for oil and gas occurs within formations where the groundwater has a salinity of less than 10,000 mg/L TDS. By definition, this results in the introduction of hydraulic fracturing fluids into formations that meet both the Safe Drinking Water Act's salinity-based definition of an underground source of drinking water and the broader definition of a drinking water resource developed for this assessment. According to the data we examined, these formations are generally in the western United States, e.g., near Pavillion, Wyoming. Hydraulic fracturing in a drinking water resource may be of concern in the short-term (where people are currently using these zones as a drinking water supply) or the long-term (if drought or other conditions necessitate the future use of these zones for drinking water).

There are other cases in which production wells associated with hydraulic fracturing are alleged to have caused contamination of drinking water resources. Data limitations in most of those cases (including the unavailability of information in litigation settlements resulting in sealed documents) make it difficult to assess whether or not hydraulic fracturing was a cause of the contamination.

6.4.2 Factors Affecting Frequency or Severity of Impacts

The multiple barriers within the hydraulic fracturing well and the presence of subsurface low-permeability geologic formations between the production zone and drinking water resources isolate fluids from drinking water resources. Because of this, any factors that affect the integrity of the system comprised of the well and the surrounding geology have the potential to affect the frequency or severity of impacts on drinking water quality. The primary factors that can affect the frequency or severity of impacts are: (1) the construction and condition of the well that is being hydraulically fractured, (2) the amount of vertical separation between the production zone and formations that contain drinking water resources, and (3) the location, depth, and condition of nearby wells or natural faults or fractures.

The presence and condition of the well's casing and cement are key factors that affect the frequency or severity of impacts to drinking water resources. Even in wells where there is substantial vertical separation (e.g., thousands of feet), defects in the well can, in theory, allow fluid movement over significant vertical distance. For example, fully cemented surface casing that extends through the base of drinking water resources is a key protective component of the well. Risk evaluation studies of a limited number of injection wells show that, if the surface casing is not set deeper than the bottom of the drinking water resource, the risk of aquifer contamination increases a thousand-fold. A review of wells that were hydraulically fractured in the Wattenberg field in Colorado showed that wells with fewer casing and cementing barriers across gas-bearing zones exhibited higher rates of failures. Most, but not all, wells used in hydraulic fracturing operations have fully cemented surface casing.

The absence of or defects in casing or cement can be the result of inadequate design or construction, including fewer layers of protective casing or when cement is incomplete (i.e., not present across all oil-gas- or water-bearing formations), of inadequate quality, or improperly emplaced. Wells that were constructed pursuant to older, less stringent requirements have a greater likelihood of exhibiting mechanical integrity problems associated with inadequate design and/or construction.

Deviated and horizontal wells may exhibit more casing and cement problems compared to vertical wells. Some (but not all) studies have shown that sustained casing pressure—a buildup of pressure within the well annulus that can indicate the presence of leaks—occurs more frequently in deviated and horizontal wells compared to vertical wells. Cement integrity problems can arise as a result of challenges in centering the casing and placing the cement in these wells. Absent efforts to ensure the emplacement of sufficient cement that is of adequate integrity, the increased use of these wells in hydraulic fracturing operations has the potential to increase the frequency at which associated cementing problems occur. This, in turn, has the potential to increase the frequency of impacts to the quality of drinking water resources.

Even in optimally designed wells, degradation of the casing and cement as they age or due to the cumulative effects of formation or operational stresses exerted on the well over time (e.g., cyclic stresses in multi-stage fractures) can impact the mechanical integrity of the well and affect the frequency of impacts to drinking water quality. Older wells exhibit more mechanical integrity problems compared to newer wells when hydraulically fractured or re-fractured. If mechanical integrity issues exist but are not detected and subsequently addressed, hydraulic fracturing fluids or other fluids can move into drinking water resources and the concentrations of contaminants in those drinking water resources—and therefore the severity of the impact—can increase.

In areas where there is little or no vertical separation between the production zone and drinking water resources, there is a greater potential to increase the frequency or severity of impacts to drinking water quality. For example, when the vertical separation is relatively small and other subsurface pathways (e.g., artificial penetrations) are present, the potential for these pathways to provide a more direct link between the production zone and a drinking water resource is greater than if there is a large separation. As described above, there are places where hydraulic fracturing operations occur in formations meeting the salinity threshold that is used in some definitions of a drinking water resource. The practice of injecting hydraulic fracturing fluids into a formation that also contains a drinking water resource can affect the quality of that water, because it is likely some of that fluid remains in the formation following hydraulic fracturing. The properties (e.g., chemical composition, toxicity, etc.) of hydraulic fracturing fluids or naturally occurring fluids that migrate to drinking water resources can affect the severity of the impact on the quality of those resources (see Chapter 9 for more information on the chemicals used in hydraulic fracturing fluids).

Where the separation between the production zone and drinking water resources is small, and where natural or induced fractures that transect the layers between these formations are present, there is a potential for increased frequency of impacts to drinking water quality via induced or natural fractures or faults. (Impacts via well-related pathways can also be a concern in these situations, as described above.)

Research shows that fractures created during hydraulic fracturing can extend out of the production zone, and that the vertical component of fracture growth is generally greater in deeper formations than shallow formations. Out-of-zone fracturing could be a concern in deeper formations if there is little vertical separation between the production zone and a deep drinking water resource and fractures propagate to unintended vertical heights. If out-of-zone fracturing is not detected (e.g., via monitoring) and subsequently addressed, the impacts to the quality of drinking water resources associated with fluid movement via these induced fractures have the potential to become more severe.

Regardless of the extent of the vertical separation between the production zone and drinking water resources, the presence of active or abandoned wells near hydraulic fracturing operations can increase the potential for hydraulic fracturing fluids to move to drinking water resources. For example, a deficiency in the construction of a nearby well (or degradation of the well's components), can provide a pathway for movement of hydraulic fracturing fluids, methane, or brines that might affect drinking water quality. If the fractures intersect an uncemented portion of a nearby wellbore, the fluids can potentially migrate along that wellbore into any formations where the well is not cemented.

The frequency of impacts to the quality of drinking water resources may increase where wells are densely spaced (particularly in shallow hydraulic fracturing operations where more fracture propagation is expected to be in the horizontal direction). The frequency of impacts may also be higher in mature oil and gas fields that pre-date the use of construction/plugging methods that can withstand the stresses associated with hydraulic fracturing operations. In these mature fields, wells tend to be older so degradation is a concern, and the location or condition of abandoned wells may not be documented. Based on the information presented in this chapter, the increased use of hydraulic fracturing in horizontal wells and in multiple wells on a single pad can increase the likelihood that these pathways could develop. This, in turn, could increase the frequency at which impacts on drinking water quality occur.

See Chapter 10 for a discussion of factors and practices that can reduce the frequency or severity of impacts to drinking water quality.

6.4.3 Uncertainties

Generally, less is known about the occurrence of (or potential for) impacts of injection-related pathways in the subsurface than for other components of the hydraulic fracturing water cycle, which tend to be easier to observe and measure. Furthermore, while there is a large amount of information available on production wells in general, there is little information that is both specific to hydraulic fracturing operations and readily accessible across the states to form a national picture.

6.4.3.1 Limited Availability of Information Specific to Hydraulic Fracturing Operations

There is extensive information available on the design goals for hydraulically fractured oil and gas wells (i.e., to address the stresses imposed by high-pressure, high-volume injection), including from industry-developed best practices documents. Additionally, many studies have documented how production wells have historically been constructed, how they perform, and the rates at which they experience problems that can lead to pathways for fluid movement. However, because of possible differences in well construction and operational practices, it is unknown how historical well performance studies apply to wells used in hydraulic fracturing operations.

Because wells that have been hydraulically fractured must withstand many of the same downhole stresses as other production wells, we consider studies of the pathways for impacts to drinking water quality in production wells to be relevant to identifying the potential pathways relevant to hydraulic fracturing operations. However, without specific data on the as-built construction of wells used in hydraulic fracturing operations, we cannot definitively state whether these wells are consistently constructed to withstand the stresses they may encounter.

There is also, in general, very limited information available on the monitoring and performance of wells used in hydraulic fracturing operations. Published information is sparse regarding mechanical integrity tests (MITs) performed during and after hydraulic fracturing, the frequency at which mechanical integrity issues arise in wells used for hydraulic fracturing, and the degree and speed with which identified issues are addressed. There is also little information available regarding MIT results for the original hydraulic fracturing event in wells built for that purpose, for wells that are later re-fractured, or for existing, older wells not initially constructed for hydraulic fracturing but repurposed for that use.

These limitations on hydraulic fracturing-specific information make it difficult to provide definitive estimates of the rate at which wells used in hydraulic fracturing operations experience the types of mechanical integrity problems that can contribute to the movement of hydraulic fracturing fluids or other fluids to drinking water resources.

There is also a limited number of peer-reviewed published studies based on groundwater sampling that provide evidence to assess whether formation brines, hydraulic fracturing fluids, or gas move in unintended ways through the subsurface during and after hydraulic fracturing. Subsurface monitoring data (i.e., data that characterize the presence, migration, or transformation of fluids within subsurface formations related to hydraulic fracturing operations) are scarce relative to the tens of thousands of oil and gas wells that are estimated to be hydraulically fractured across the country each year (see Chapter 3 for more information on the occurrence of hydraulic fracturing in the United States).

Information on fluid movement within the subsurface and the extent of fractures that develop during hydraulic fracturing operations is also limited. For example, limited information is available in the published literature on how flow regimes or other subsurface processes change at sites where hydraulic fracturing is conducted. Instead, much of the available research, and therefore the literature, addresses how hydraulic fracturing and other production technologies perform to optimize hydrocarbon production. In addition, much of the published data on fracture propagation are for shale formations, and no large-scale data sets on fracture growth in other unconventional formations exist or are publicly available.

These limitations on hydraulic fracturing-specific information make it difficult to provide definitive estimates of the rate at which wells used in hydraulic fracturing operations experience the types of mechanical integrity problems that can contribute to unintended fluid movement.

6.4.3.2 Limited Systematic, Accessible Data on Well Performance or Subsurface Movement

While the oil and gas industry generates a large amount of information on well performance as part of operations, most of this is proprietary, or otherwise not readily available to the public in a compiled or summary manner. Therefore, no national or readily accessible way exists to evaluate the design and performance of individual wells or wells in a region, particularly in the context of local geology or the presence of other wells and/or hydraulic fracturing operations. Many states have large amounts of operator-submitted data, but information about construction practices or the performance of individual wells is typically not in a searchable or aggregated form that would enable assessments of well performance under varying settings, conditions, or timeframes. Although it is collected in some cases, there is no collection, reporting, or publishing of baseline (pre-drilling and/or pre-fracturing) and post-fracturing monitoring data on a national basis that could indicate the presence or absence of hydraulic fracturing-related fluids in shallow zones and whether or not migration of those fluids has occurred. (See Chapter 10 for additional discussion of data limitations.) Ideally, data from groundwater monitoring are needed to complement theories and modeling on potential pathways and fluid migration.

While some of the types of impacts described above can occur quickly (i.e., on the scale of days or weeks, as with mechanical integrity problems or well communication events), other impacts (e.g., in slow-moving, deep groundwater) may be detectable only on much longer timescales. Without comprehensive collection and review of information about how hydraulic fracturing operations perform, fluid movement could occur without early detection, which could, in turn, increase the severity of any resultant impacts to drinking water quality. For example, testing the mechanical integrity of wells, monitoring the extent of the fractures that form, and conducting pre- and post-hydraulic fracturing water quality monitoring can detect fluid movement (or the potential for fluid movement) and provide opportunities to mitigate or minimize the severity of impacts associated with unforeseen events.

The limited amount of available information also hinders our ability to evaluate how frequently drinking water impacts are occurring, the probability that these impacts occur, or to what extent they are tied to specific well construction, operation, and maintenance practices. This also significantly limits our ability to evaluate the aggregate potential for hydraulic fracturing operations to affect drinking water resources or to identify the potential cause of drinking water contamination in areas where hydraulic fracturing occurs. The absence of this information greatly limits the ability to make quantitative statements about the frequency or severity of these impacts.

6.4.4 Conclusions

The production well and the surrounding geologic features function as a system that provides multiple barriers that can isolate hydrocarbon-bearing zones and water-bearing zones, including drinking water resources. Because of this, factors affecting the integrity of any of these barriers have the potential to adversely affect the quality of drinking water resources.

We have identified a number of pathways by which hydraulic fracturing fluids can reach and affect the quality of drinking water resources. These pathways include migration via inadequate casing and/or cement in the hydraulic fracturing well, fluid movement in the subsurface via fractures extending out of the target zone, or vertical fluid movement via other natural or artificial structures.

The primary factors affecting the frequency or severity of impacts to drinking water quality associated with hydraulic fracturing operations include the condition of the casing and cement of the production well and their placement relative to drinking water resources, the extent of the vertical separation between the production zone and drinking water resources, and the presence and condition of offset wells or natural faults or fractures near the hydraulic fracturing operation.

There is evidence that, in some cases highlighted in the literature, these pathways have formed and the quality of drinking water resources has been impacted. We do not know the frequency of such impacts associated with the injection stage of the hydraulic fracturing water cycle, however. This is related to the following: the subsurface environment is geologically complex, the relevant production processes cannot be directly observed, and publicly available data that can support an evaluation of the impacts of hydraulic fracturing on the quality of drinking water resources is, in general, very limited.

Chapter 7. Produced Water Handling

Abstract

Produced water is a byproduct of hydrocarbon production and flows to the surface through the production well, along with oil and gas. Operators must store and dispose of (or in some cases treat) large amounts of non-potable produced water, either on site or off site, and spills or releases of produced water have the potential to impact drinking water resources. Unlike produced water from conventional oil and gas production, produced water generated following hydraulic fracturing initially contains returned hydraulic fracturing fluids. Much of the hydraulic fracturing fluid remains below ground; the median amount of fluid returned to the surface is 30% or less. Up to several million gallons of water can be produced from each well, with production generally decreasing with time.

Produced water contains several classes of constituents: salts, metals, radioactive materials, dissolved organic compounds, and hydraulic fracturing chemicals and their transformation products (the result of reactions of these chemicals in the subsurface). The concentrations of these constituents change with time, as the initially returning hydraulic fracturing fluid blends with formation water. Typically, this means that the produced water becomes more saline with time. Produced water composition and volume vary from well to well, both among different formations and within formations. A large number of organic compounds have been identified in produced water, many of which are naturally occurring petroleum hydrocarbons; some are known hydraulic fracturing chemicals. Only a few transformation products have been identified, and they include chlorinated organics.

Spills and releases of produced water with a variety of causes have been documented at different steps in the production process. The causes include human error, equipment or container failure (for instance, pipeline, tank or storage pit leaks), accidents, and storms. Unauthorized discharges may account for some releases as well. An estimated half of the spills are less than 1,000 gal (3,800 L). A small number of much larger spills has been documented, including a spill of 2.9 million gal (11 million L). Both short- and long-term impacts to soil, groundwater, and surface from spills have occurred. For many spills, however, the impacts are unknown. The potential of spills of produced water to affect drinking water resources depends upon the release volume, duration, and composition, as well as watershed and water body characteristics.

Data are lacking to characterize the severity and frequency of impacts on a nationwide scale. Suspected local-scale impacts often require an extensive multiple lines-of-evidence investigation to determine their cause. Further, when investigations do take place, the lack of baseline water quality data can make it difficult to determine the cause and severity of the impact. In such cases, additional data are necessary to determine the full extent of the impact of releases of produced water.

7. Produced Water Handling

7.1 Introduction

Water is a byproduct of oil and gas production. After the hydraulic fracturing of the formation is completed, the injection pressure is reduced, and a possible inactive period where the well is "shut in" is completed, water is allowed to flow back from the well to prepare for oil or gas production.[1] This return-flow water may contain chemicals injected as part of the hydraulic fracturing fluid, chemicals naturally occurring in the formation, or the products of reactions that take place in the formation. Initially this water, sometimes called flowback, is mostly hydraulic fracturing fluid, but as time goes on, water chemistry becomes more similar to water associated with the formation. For formations containing saline water (brine), the salinity of the returned water increases as time passes as the result of increased contact time between the hydraulic fracturing fluid and the formation and inclusion of an increased portion of formation water. For this assessment, and consistent with industry practice, the term produced water is used to refer to any water flowing from the oil or gas well.

Produced water is piped directly to an injection well or stored and accumulated at the surface for eventual management by injection into disposal wells, transport to wastewater treatment plants, reuse, or in some cases, placement in evaporation pits or permitted direct discharge. See Text Box ES-11 and Section 8.4 for discussion of these management practices.

Produced water spills and releases can occur due to several causes, including events associated with pipelines, transportation, blowouts, and storage. Impacts to drinking water resources can occur if this released water enters surface water bodies or reaches groundwater. Such impacts may result in the water becoming unfit for consumption, either through obvious taste and odor considerations or the constituents in the water exceeding hazard levels (Chapter 9). Once released to the environment, transport of chemical constituents depends on the characteristics of the:

- Spill (volume, duration, concentration);
- Fluid (density as influenced by salinity);
- Chemicals (volatility, sorption, solubility); and
- Site-specific environmental characteristics (surface topography and location of surface water bodies, the type of the soil and aquifer materials, layering and heterogeneity of rocks, and the presence of dissolved oxygen and other factors needed to support biodegradation, and the presence of inorganic species that affect metal transport).

This chapter provides characterization of produced water and also provides background information for the coverage of wastewater disposal and reuse in Chapter 8. Chapter 7 addresses the characteristics of produced water including per-well generation of produced water. Chapter 8 considers management of this water, now called wastewater, at an aggregate level, and thus

[1] There can be no shut-in period at all or it can last several weeks (Stepan et al., 2010).

discusses state, regional, and national estimates of treatment volumes. While Chapter 7 considers impacts from several types of unintentional releases, Chapter 8 focuses on impacts that are associated with wastewater management practices. One specific issue, leakage from pits and impoundments, is introduced in Chapter 7 as one of several avenues for accidental releases, with a more detailed exploration of the use of pits in wastewater management presented in Chapter 8.

Chapter 7 begins with a review of definitions for flowback and produced water in Section 7.1.1. Definitions are followed by a discussion in Section 7.2 of water volumes per well, first presenting data on the volume and percent of hydraulic fracturing fluid returned to the surface and then presenting data on the volume of water returned during production. These data all represent the response of individual wells. Because of the need to have aggregated volumes for estimating wastewater treatment loadings, estimates of total volumes are given in Section 8.2.

Chapter 7 continues with discussion of the chemical composition of produced water (Section 7.3). Because the composition of produced water is only known through analysis of samples, laboratory methods and their limitations are described in Section 7.3.1. Time-dependent changes in composition are discussed via three specific examples in Section 7.3.3, followed by discussion of five types of constituents: salts, metals, radioactive materials, organics, and known hydraulic fracturing additives in Section 7.3.4. The chemical and geological processes controlling the chemical composition of produced water are described in Appendix E. Spatial and temporal trends in the composition of produced water are illustrated with examples from the literature and data compiled for this report (Section 7.3.5).

The potential for impacts on drinking water resources of produced water releases and spills are described based on reported spill incidents (Section 7.4), and examples of spills from specific sources and data compilation studies are given in Section 7.4.2. The potential for impacts is described using contaminant transport principles in Section 7.6. The chapter concludes with a discussion of uncertainties and knowledge gaps, factors that influence the severity of impacts, and major findings (Section 7.7).

7.1.1 Definitions

Multiple definitions exist for the terms flowback and produced water. Appendix Section E.1 gives examples of definitions used by different organizations. These differing definitions reflect differing usage of the terms among various groups and that produced water reflects the continuously varying mixture between returning injection fluid and formation water. The majority of produced water definitions are fundamentally similar. The following definition is used in this report for produced water: any type of water that flows from the subsurface through oil and gas wells to the surface as a by-product of oil and gas production. Thus produced water can variously refer to returned hydraulic fracturing fluid, formation water alone, or a mixture of the two.

The term flowback has two major meanings. First is the process used to prepare the well for production by allowing excess liquids and proppant to return to the surface. The second use of the term is to refer to fluids predominantly containing hydraulic fracturing fluid that return to the surface. Because formation water can contact and mix with injection fluids, the distinction between returning hydraulic fracturing fluid and formation water is not clear. Definitions of flowback are operational in the sense that they include some characteristic of the oil and gas operation (i.e., fluids returning within 30 days). These reflect that during the early phases of operation, a higher concentration of chemical additives is expected and later, water is characteristic of the formation. Because we use existing literature in our review, we do not introduce a preferred definition of flowback, and describe all water flowing from the well as produced water.

7.2 Volume of Hydraulic Fracturing Flowback and Produced Water

Veil (2015) estimated that, in 2012, all types (i.e., from conventional and unconventional reservoirs) of U.S. onshore and offshore oil and gas production generated 8.90 x 10^{11} gal (3.37 x 10^{12} L) of produced water. More details and state-level estimates are given in Section 8.2. This section presents information on flowback and produced water volume over various time scales, and where possible, on a per-well and per-formation basis, because characteristics and volume of flowback and produced water vary by well, formation, and time.

The amount of produced water from a well varies and depends on several factors, including production, formation, and operational factors. Production factors include the amount of fluid injected, the type of hydrocarbon produced (gas or liquid), and the location within the formation. Formation factors include the formation pressure, the interaction between the formation and injected fluid (capillary forces), and reactions within the reservoir. Operational factors include the volume of the fractured production zone that includes the length of well segments and the height and width of the fractures. Certain types of problems also influence water production, including possible loss of mechanical integrity and subsurface communication between wells, both of which can result in an unexpected increase in water production (U.S. GAO, 2012; Byrnes, 2011; DOE, 2011a; GWPC and ALL Consulting, 2009; Reynolds and Kiker, 2003).

The processes that allow gas and liquids to flow are related to the conditions along the faces of fractures. Byrnes (2011) conceptualized fluid flow across the fracture face as being composed of three phases. The first is characterized by forced imbibition of fluid into the reservoir and occurs during and immediately following fracture stimulation.[1] Second is fluid redistribution within the reservoir rock, due to capillary forces. Estimates have shown that 50% or more of fracturing fluid could be captured within the Marcellus shale if imbibition drives water 2 to 6 in (5 to 15 cm) into the formation (Engelder, 2012; Byrnes, 2011; He, 2011). In the last phase, water flows out of the formation when the well is opened and pressure is reduced in the wellbore and fractures. The purpose of this phase is to recover as much of the injected fluid as possible (Byrnes, 2011) to allow higher oil or gas flow rates. The length of the last phase and, consequently, the amount of water removed, depends on factors such as the amount of injected fluid, the permeability and relative permeability of the reservoir, capillary pressure properties of the reservoir rock, and the pressure near the fracture faces.[2] The well can be shut in for varying time periods depending on operator scheduling, surface facility construction and connection thereto, or other reasons.

[1] The displacement of a non-wet fluid (i.e., gas) by a wet fluid (typically water). Adapted from Dake (1978).

[2] When multiple fluids (water, oil, gas) occupy portions of the pore space, the permeability to each fluid depends on the fraction of the pore space occupied by the fluid and the fluid's properties. As defined by Dake (1978), when this effective permeability is normalized by the absolute permeability, the resulting relationship is known as the relative permeability.

7.2.1 Flowback of Injected Hydraulic Fracturing Fluid

The amount of water produced by wells within the first few days following fracturing varies from formation to formation. Wells in the Mississippi Lime and Permian Basin can produce 1 million gal (3.8 million L) in the first 10 days of production. Wells in the Barnett, Eagle Ford, Granite Wash, Cleveland/Tonkawa Sand, Niobrara, Marcellus, and Utica Shales can produce 300,000 to 1 million gal (1.14 to 3.78 million L) within the first 10 days. Haynesville wells produce less, about 250,000 gal (950,000 L) (Mantell, 2013). Data show that the rate of water produced during the flowback period decreases as time passes (Ziemkiewicz et al., 2014; Hansen et al., 2013; Hayes, 2009).

It is not possible to specify precisely the amount of injected fluids that return in the flowback, because there is not a clear distinction between flowback and produced water, and the indicators (e.g., salinity and radioactivity, to name two) are not routinely monitored (GWPC and ALL Consulting, 2009). Rather, flowback estimates usually relate the amount of produced water measured at a given time after fracturing as a percentage of the total amount of injected fluid. Estimates of the fraction of injected hydraulic fracturing fluid that returns as flowback are highly variable (U.S. EPA, 2016d; Vengosh et al., 2014; Mantell, 2013; Vidic et al., 2013; Minnich, 2011; Xu et al., 2011). The maxima are less than 85% in all but one of the examples given in Table 7-1, Table 7-2, and Table 7-3, and most of the median values are less than 30%. In some cases, the amount of flowback is greater than the amount of injected hydraulic fracturing fluid, and the additional water comes from the formation (Nicot et al., 2014) or from a conductive pathway from an adjacent formation (Arkadakskiy and Rostron, 2013). See Appendix Section E.2.1 for more details.

Table 7-1. Data from one company's operations indicating approximate total water use and approximate produced water volumes within 10 days after completion of wells.
From Mantell (2013).

Formation	Approx. total average water use per well (million gal)	Produced water (flowback) within the first 10 days after completion		Produced water as a percentage of average water use per well	
		Low estimate (million gal)	High or only estimate (million gal)	Low estimate (% of total water use)	High or only estimate (% of total water use)
Gas shale plays (primarily dry gas)					
Barnett[a]	3.4	0.3	1.0	9%	29%
Marcellus[a]	4.5	0.3	1.0	7%	22%
Haynesville	5.4	--	0.25	--	5%
Liquid plays (gas, oil, condensate)					
Mississippi Lime	2.1	--	1.0	--	48%

Formation	Approx. total average water use per well (million gal)	Produced water (flowback) within the first 10 days after completion		Produced water as a percentage of average water use per well	
		Low estimate (million gal)	High or only estimate (million gal)	Low estimate (% of total water use)	High or only estimate (% of total water use)
Cleveland/ Tonkawa	2.7	0.3	1.0	11%	37%
Niobrara	3.7	0.3	1.0	8%	27%
Utica	3.8	0.3	1.0	8%	26%
Granite Wash	4.8	0.3	1.0	6%	21%
Eagle Ford	4.9	0.3	1.0	6%	20%

[a] Mantell (2011) reported produced water for the first 10 days at 500,000 to 600,000 gal for the Barnett, Fayetteville and Marcellus Shales.

Table 7-2. Additional short-, medium-, and long-term produced water estimates.

Location–formation	Produced water as percentage of injected fluid	Reference	Comment
Estimates without reference to a specific data set			
Unspecified Shale	5% – 35%	Hayes (2011)	
Marcellus Shale	10% – 25%	Minnich (2011)	Initial flowback
ND–Bakken	25%	EERC (2013)	
Estimates with reference to specific data evaluation			
Short duration			
Marcellus Shale	10%	Clark et al. (2013)	0 – 10 days
TX—Barnett	20%	Clark et al. (2013)	0 – 10 days
TX—Haynesville	5%	Clark et al. (2013)	0 – 10 days
AR—Fayetteville	10%	Clark et al. (2013)	0 – 10 days
Medium duration			
WV—Marcellus	8%	Hansen et al. (2013)	30 days
Marcellus Shale	24%	Hayes (2011, 2009)	Average from 19 wells, 90 days

Location–formation	Produced water as percentage of injected fluid	Reference	Comment
Long duration

Resource type	Well type	Fracturing fluid (million gal)			Flowback (percent of fracturing fluid returned)		
		Weighted average	Range	Data points	Weighted average	Range	Data points
Shale	Horizontal	4.2	0.091–24	80,388	7%	0%–580%	7,377
	Directional	1.4	0.037–20	340	33%	1%–57%	36
	Vertical	1.1	0.015–19	5,197	96%	2%–581%	57
Tight	Horizontal	3.4	0.069–12	7,301	12%	0%–60%	75
	Directional	0.05	0.046–4	3,581	10%	0%–60%	342
	Vertical	1	0.016–4	10,852	4%	0%–60%	130

7.2.2 Produced Water Volumes

Mantell (2013, 2011) described the amount of produced water over the long term as high, moderate, or low for several formations. Wells in the Barnett Shale, Cleveland/Tonkawa Sand, Mississippi Lime, and the Permian Basin can produce more than 1,000 gal (3,800 L) of water per million cubic feet (MMCF) of gas. The most water-productive of these can be as high as 5,000 gal (19,000 L) per MMCF of gas. As a specific example, a high water producing formation in the western United States was described as producing 4,200 gal (16,000 L) per MMCF of gas for the life of the well (McElreath, 2011). The well was fractured and stimulated with about 4 million gal (15 million L) of water and returned 60,000 gal (230,000 L) per day in the first 10 days, followed by 8,400 gal (32,000 L) per day in the remainder of the first year. The Niobrara, Granite Wash, Eagle Ford, Haynesville, and Fayetteville Shales are relatively dry formations (with small amounts of naturally occurring formation water) and produce between 500 and 2,000 gal (1,900 to 7,600 L) of produced water per MMCF of gas (Mantell, 2013). The Utica and Marcellus Shales are viewed as drier still and produce less than 200 gal (760 L) per MMCF of gas.

Wells producing in various formation show high produced water volume variability, including the Barnett Shale, which was attributed by Nicot et al. (2014) to a few wells with exceptionally high water production. Some of these wells produced more than the amount of injected fracturing fluid.

Wells in conventional and unconventional reservoirs produce differing amounts of water. Individual hydraulically fractured wells producing gas from the Marcellus Shale produced more water than hydraulically fractured wells in conventional wells in Pennsylvania (Lutz et al., 2013). However, on a per-unit of gas produced basis, wells producing from the Marcellus Shale generate less water (35%), than those in the conventional formations.

The EPA (2016d) reported characteristics of long-term produced water for hydraulically fractured shale and tight formations (Table 7-4). For shale, horizontal wells produced more water (1,100 gal/day; 4,200 L/day) than vertical wells (500 gal/day; 1,900 L/day). Typically, this would be attributed to the longer length of the production zone in horizontal laterals than in vertical wells.

Table 7-4. Long-term produced water generation rates (gal/day per well) for wells in unconventional reservoirs.

Source: U.S. EPA (2016d). The formation-level data used to develop Tables 7-3 and 7-4 appear in Appendix Table E-1.

Resource type	Well type	Long-Term Produced Water Generation Rates (gal per day per well)		
		Weighted average	Range	Data points
Shale	Horizontal	1,100	0–29,000	43,893
	Directional	820	0.83–12,000	1,493
	Vertical	500	4.8–51,000	12,551
Tight	Horizontal	980	10–120,000	4,692
	Directional	390	15–8,200	10,784
	Vertical	650	0.71–2100	34,624

In an example from the Pennsylvania Marcellus Shale, the EPA determined that, for vertical wells in unconventional reservoirs, 6% of water came from drilling, 35% from flowback, and 59% from long-term produced water; for horizontal wells, the corresponding numbers were 9%, 33%, and 58% (U.S. EPA, 2016d). This result agrees with the U.S. Department of Energy (DOE, 2011a) who concluded that the characteristic small amount of produced water from the Marcellus Shale was due either to its low water saturation or low relative permeability to water (see Section 6.3.2.1). For these dry formations, low shale permeability and high capillarity cause water to imbibe into the formation, where some is retained permanently.

7.2.2.1 Time Trends

High rates of water production (flowback) typically occur in the first few months after hydraulic fracturing, followed by rates reduced by an order of magnitude (e.g., Nicot et al., 2014). In many cases half of the total produced water from a well is generated in the first year. Similarly, the EPA (2016d) reported a general rule of thumb that, for unconventional reservoirs, the volume of flowback (which occurs over a short period of time) is roughly equal to the volume of long-term produced water. These trends in produced water volumes occur within the timeline of hydraulic fracturing activities (Section 3.3), and show that the large, initial return volumes of flowback last for several weeks, whereas the lower-rate produced water phase can last for years (Figure 7-1).

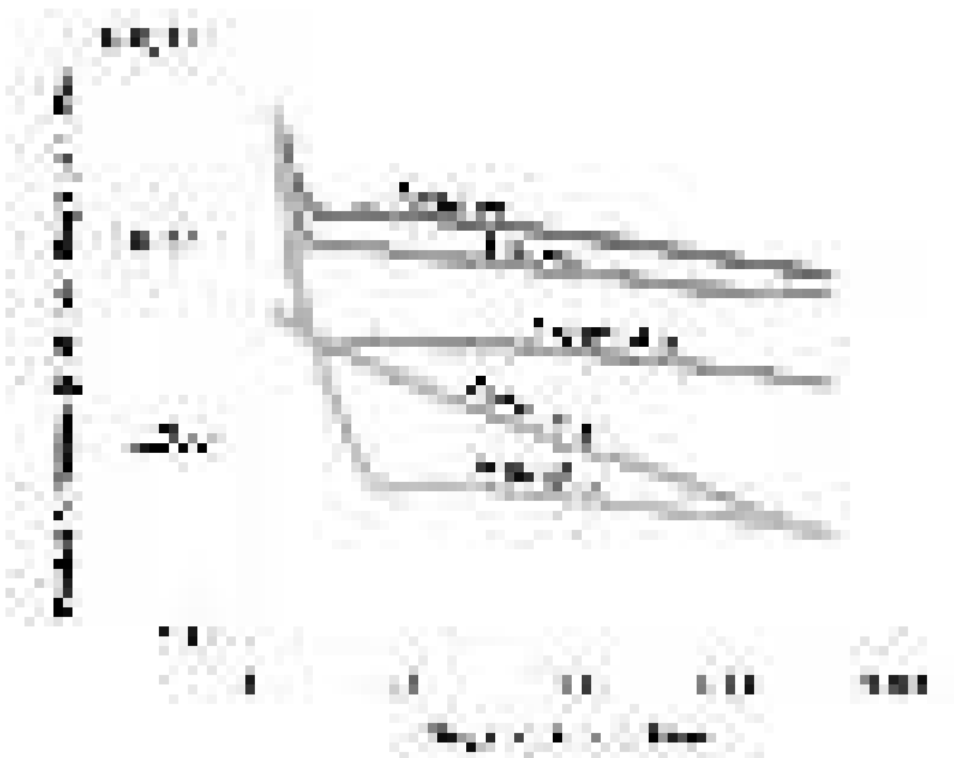

Figure 7-1. Generalized examples of produced water flow from five formations.
Actual produced water flows vary by location, play, basin, and amount of water used for hydraulic fracturing (EWI, 2015). Figure used with permission.

7.2.2.2 Coalbed Methane

Water is pumped from coal seams to reduce pressure so that gas adsorbed to the surface of the coal can flow to the production well (Guerra et al., 2011). Consequently, CBM tends to produce large volumes of water early on: more than conventional gas-bearing formations (U.S. GAO, 2012) (Figure 7-2). Within producing CBM formations, water production can vary for unknown reasons (U.S. GAO, 2012). As an example, data show that CBM production in the Powder River Basin produces 16 times more water than that in the San Juan Basin (U.S. GAO, 2012).

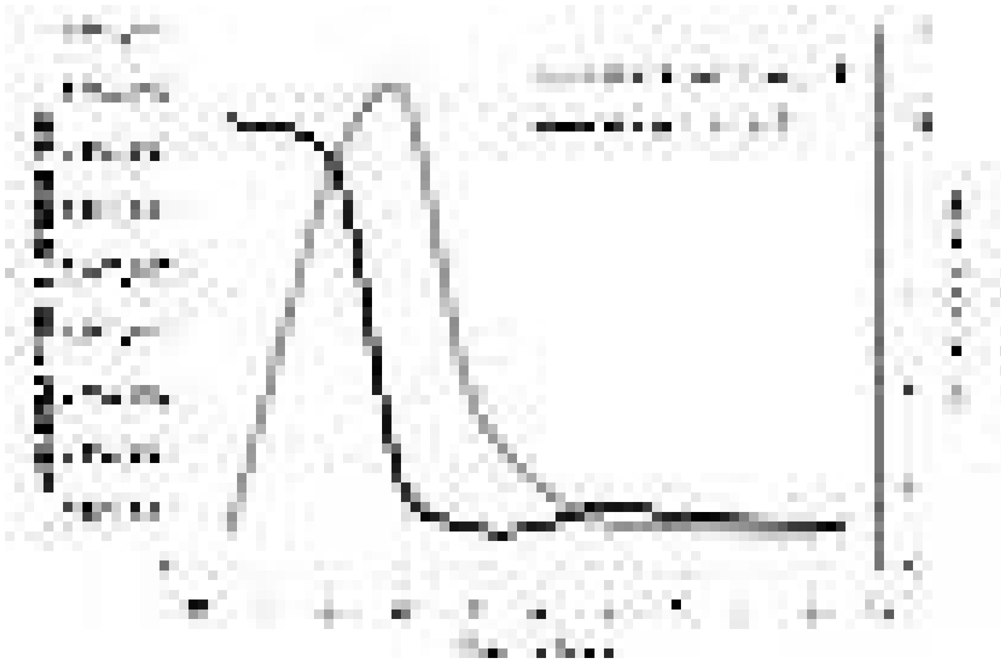

Figure 7-2. Typical produced water volume for a coal bed methane well in the western United States.
Source: Guerra et al. (2011).

7.3 Chemical Composition of Produced Water

For hydraulically fractured wells, the chemical composition of produced water changes from being similar to the injected hydraulic fracturing fluid to reflecting a mixture of hydraulic fracturing fluids, naturally occurring hydrocarbons, transformation products, and formation water. Initial produced water data show continuous changes in chemical composition and reflect processes occurring in the formation (Section 7.3.3). The data presented on longer-term produced water represent water that is primarily associated with the formation, rather than the hydraulic fracturing fluid (Section 7.3.4). Unlike the hydraulic fracturing fluid, the composition of which may be disclosed, compositional data on produced water comes from laboratory analysis of samples. Because of this reliance, we first discuss sampling and analysis of produced water, and especially note the limitations of existing analytical methods for organic chemicals and radionuclides.[1] It is important to note that the analytical methods can differ depending on the purpose of the analysis. Specifically, advanced laboratory methods have been used to identify unknown organic constituents of produced water (Section 7.3.1), routine methods are used for pre-drilling sampling, and a combination of methods may be needed for assessing environmental impacts (Section 7.4.2.5).

7.3.1 Determination of Produced Water Composition

Recent advances in analytical methods for produced water have allowed detection and quantification of a broad range of organic compounds, including those associated with hydraulic

[1] Chemical components of produced water are described below.

fracturing fluid (Section 7.3.4.7 and Appendix E.3.5.). These studies make clear that standard analytical methods are not adequate for detecting and quantifying the numerous organic chemicals, both naturally occurring and anthropogenic, that are now known to occur in produced water (Lester et al., 2015; Maguire-Boyle and Barron, 2014; Thurman et al., 2014). Similarly, methods commonly applied for the analysis of radionuclides in drinking water may suffer from analytical interferences that result in poor data quality (Maxwell et al., 2016; Ying et al., 2015; Zhang et al., 2015b; Nelson et al., 2014; U.S. EPA, 2014i, 2004b). In these instances, alternative methods that have been developed to support the nuclear materials production and waste industry provide more reliable approaches to ensure adequate detection limits and avoid sample matrix interferences that are anticipated for the high salinity and concentrations of organic constituents that may be present in produced water samples.[1] Development of advanced or non-routine methods for both organics and inorganics (especially radium) suggests that data generated from earlier methods may be less reliable that those developed by the new methods (Nelson et al., 2014), and that advanced analytical techniques are needed to detect or quantify some analytes.

The compositional data that follow in this chapter and Appendix E rely on the analytical procedures used in measurement and were summarized as noted from numerous produced water studies or compilations, such as the U.S. Geological Survey (USGS) produced water database (Blondes et al., 2014).

7.3.2 Factors Influencing Produced Water Composition

Several interacting factors influence the chemical composition of produced water: (1) the composition of injected hydraulic fracturing fluids, (2) the targeted geological formation and associated hydrocarbon products, (3) the stratigraphic environment, and (4) subsurface processes and residence time (Barbot et al., 2013; Chapman et al., 2012; Dahm et al., 2011; Blauch et al., 2009).

The mineralogy and structure of a formation are determined initially by deposition, when rock grains settle out of their transporting medium (Marshak, 2004). Generally, shale forms from clays that were deposited in deep, oxygen-poor marine environments, and sandstone can form from sand deposited in shallow marine environments (Ali et al., 2010; U.S. EPA, 2004a). Coal forms when carbon-rich plant matter collects in shallow peat swamps. In the United States, coal formed in both freshwater (northern Rocky Mountains) and marginal-marine environments (Alabama's Black Warrior formation) (NRC, 2010; Horsey, 1981). Consequently, shale and sandstone produced water are expected to be saline, and CBM water may be much less so.

7.3.3 Produced Water Composition During the Flowback Period

The chemistry of produced water changes over time, especially during the first days or weeks after hydraulic fracturing. Generally, produced water concentrations of cations, anions, metals, naturally occurring radioactive material (NORM), and organics increase as time goes on (Barbot et al., 2013; Haluszczak et al., 2013; Chapman et al., 2012; Davis et al., 2012; Gregory et al., 2011; Blauch et al.,

[1] For guidance in planning, implementing, and assessing projects that require laboratory analysis of radionuclides, see U.S. EPA (2004b).

2009). The causes include precipitation and dissolution of salts, carbonates, sulfates, and silicates; pyrite oxidation; leaching and biotransformation of organic compounds; and mobilization of NORM and trace elements. Concurrent precipitation of sulfates (e.g., $BaSO_4$) and carbonates (e.g., $CaCO_3$) alongside decreases in pH, alkalinity, dissolved carbon, and microbial abundance and diversity occur over time after hydraulic fracturing (Orem et al., 2014; Barbot et al., 2013; Murali Mohan et al., 2013; Davis et al., 2012; Blauch et al., 2009; Brinck and Frost, 2007). Leaching of organics appears to be a result of injected and formation fluids associating with shale and coal strata (Orem et al., 2014). Concentrations of organics in CBM produced water decrease with time, possibly due to the depletion of coal-associated water through formation pumping (Orem et al., 2007).

7.3.3.1 Total Dissolved Solids

Produced water total dissolved solids concentrations (TDS) increase by varying degrees because of the formation's geological origin. As an example, TDS concentrations increased to upper bound values in samples from four Marcellus Shale gas wells (Chapman et al., 2012) (Figure 7-3). The increased TDS was composed of increased sodium, calcium, and chloride (Chapman et al., 2012; Blauch et al., 2009). Similarly, TDS in flowback from the Westmoreland County wells started low and exceeded that of typical seawater (35,000 mg/L) within three days (Chapman et al., 2012). In a similar study, wells with hydraulic fracturing fluid containing less than 1,000 mg/L saw TDS concentrations increase above a median value of 200,000 mg/L within 90 days (Hayes, 2009).

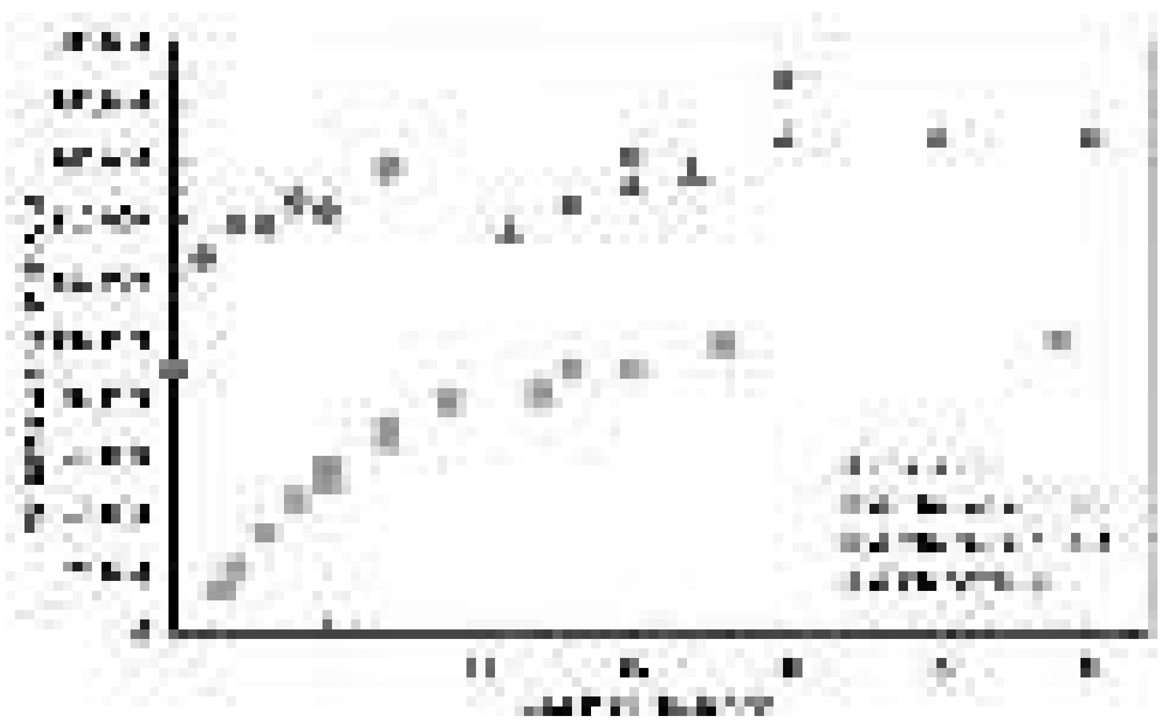

Figure 7-3. TDS concentrations measured through time for injected fluid (at 0 days), and produced water samples from four Marcellus Shale gas wells in three southwest Pennsylvania counties.
Data from Chapman et al. (2012).

7.3.3.2 Radionuclides

Shales and sandstones naturally contain various radionuclides (Sturchio et al., 2001).[1] Radium in pore waters or adsorbed onto clay particles and grain coatings can dissolve and return in produced water (Langmuir and Riese, 1985). Available data indicate that radium and TDS concentrations in produced water are positively correlated (Rowan et al., 2011; Fisher, 1998), likely because radium remains adsorbed to mineral surfaces when salinity is low, and then desorbs into solution with increased salinity (Sturchio et al., 2001). As an example, over the course of 20 days, radium concentration in flowback from a Marcellus Shale gas well increased by almost a factor of four (Chapman et al., 2012; Rowan et al., 2011) (Figure 7-4).

Figure 7-4. Total radium and TDS concentrations measured through time for injected (day 0), and produced water samples Greene County, PA, Marcellus Shale gas wells.
Data from Rowan et al. (2011) and Chapman et al. (2012).

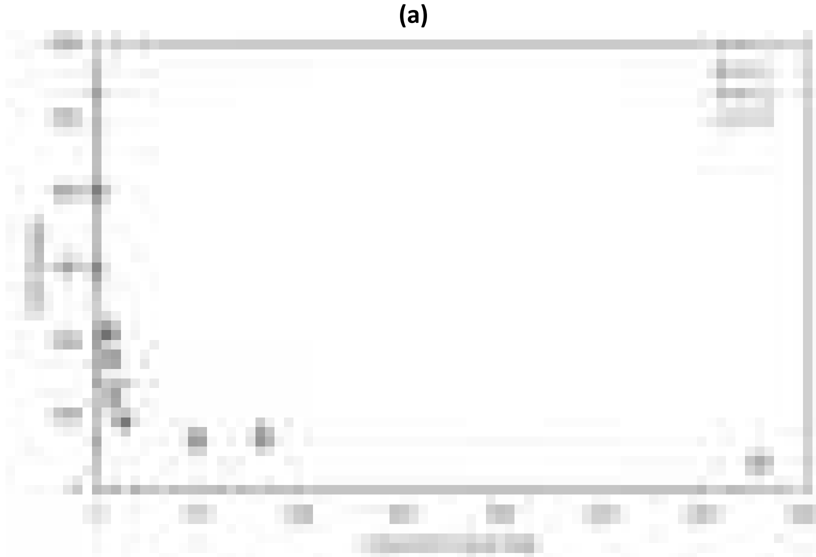
7.3.3.3 Dissolved Organic Carbon

Dissolved organic carbon (DOC) concentrations decrease from initial levels in shales and coalbeds (Murali Mohan et al., 2013; Orem et al., 2007). This occurs while TDS and chloride concentrations are increasing (Barbot et al., 2013; Chapman et al., 2012). DOC sorption, dilution with injected or formation water, biochemical reactions, and microbial transformation may all cause decreased concentrations of DOC during flowback. Injected organics can include gel polymer formulations, namely guar gum; petroleum distillates; and ethyl and ether glycol formulations, which can serve as food sources for microbes. (Wuchter et al., 2013; Arthur et al., 2009b; Hayes, 2009). In coalbeds,

[1] Hydraulic fracturing fluids typically do not contain radioactive material (Rowan et al., 2011). However, reusing produced water can introduce radioactive material into hydraulic fracturing fluid. See Section 7.3.4.6 and PA DEP (2015b).

water contacting the coal may become depleted in DOC to the degree that when outside water of lower DOC is produced, the resulting DOC concentrations in the produced water are reduced (Orem et al., 2014).

(a)



(b)

Figure 7-5. (a) Increasing chloride (Cl) and (b) decreasing DOC concentrations measured through time for samples from three Marcellus Shale gas wells on a single well pad in Greene County, PA.

Data from Cluff et al. (2014). Reprinted with permission from Cluff, M; Hartsock, A; Macrae, J; Carter, K; Mouser, PJ. (2014). Temporal changes in microbial ecology and geochemistry in produced water from hydraulically fractured Marcellus Shale Gas Wells. Environ Sci Technol 48: 6508-6517. Copyright 2014 American Chemical Society.

As an example, produced water DOC concentrations decreased from their initial levels twofold from the hydraulic fracturing fluid and initial samples (Figure 7-5b) followed by a decrease of 11-fold over nearly 11 months. The DOC leveled off several months after hydraulic fracturing, presumably as a result of in situ attenuation processes (Cluff et al., 2014). As DOC was decreasing, chloride concentrations increased five- to six-fold. These chloride concentrations increased linearly during the first two weeks (Cluff et al., 2014) and then later approached higher levels (Figure 7-5a). The pattern in the DOC and chloride levels reflected the changing composition of the produced water—initially high in DOC from hydraulic fracturing additives and low in salinity, then higher in salinity and lower in DOC reflecting the chemistry of formation water. The changing composition of produced water suggests that the potential concern for produced water spills also changes: initially the produced water may contain more hydraulic fracturing chemicals, and later the concern may shift to the impact of high salinity water.

7.3.4 Produced Water Composition

The chemical composition of produced water continues to change after the initial flowback period. Produced water may contain a range of constituents, but in widely varying amounts. Generally, these can include:

- Salts, including those composed from chloride, bromide, sulfate, sodium, magnesium and calcium;
- Metals including barium, manganese, iron, and strontium;
- Radioactive materials including radium (radium-226 and radium-228);
- Oil and grease, and dissolved organics (including BTEX);[1]
- Hydraulic fracturing chemicals, including tracers and their transformation products; and
- Produced water treatment chemicals.[2]

We discuss these groups of chemicals and then conclude by discussing variability within formation types and within production zones.

7.3.4.1 Similarity of Produced Water from Conventional and Unconventional Reservoirs

Produced water generated from unconventional reservoirs is reported to be similar to produced water from conventional reservoirs in terms of TDS, pH, alkalinity, oil and grease, TOC, and other organics and inorganics (Wilson, 2014; Haluszczak et al., 2013; Alley et al., 2011; Hayes, 2009; Sirivedhin and Dallbauman, 2004). Although produced water salinity varies within and among shales and tight formations, produced water is typically characterized as saline (Lee and Neff, 2011; Blauch et al., 2009). Produced water from coalbeds may have low TDS if the coal source bed was formed in freshwater. Saline produced water is also enriched in major anions (e.g., chloride, bicarbonate, sulfate); cations (e.g., sodium, calcium, magnesium); metals (e.g., barium, strontium);

[1] BTEX is an acronym representing benzene, toluene, ethylbenzene, and xylenes.

[2] Some chemicals are added to produced water for the purpose of oil/water separation, improved pipeline flow, or equipment maintenance, including prevention of corrosion and scaling in equipment (Cal/EPA, 2016). Generally the chemicals serve as clarifiers, emulsifiers, emulsion breakers, floating agents, and oxygen scavengers. Among proprietary formulations, a few specific chemicals have been disclosed including low concentrations of benzene, toluene, and inorganics (acetic acid, ammonium chloride, cupric sulfate, sodium hypochlorite).

naturally occurring radionuclides (e.g., radium-226, radium-228) (Chapman et al., 2012; Rowan et al., 2011); and organics (e.g., hydrocarbons) (Orem et al., 2007; Sirivedhin and Dallbauman, 2004).

7.3.4.2 Variability in Produced Water Composition Among Unconventional Reservoirs

Alley et al. (2011) compared geochemical parameters of shale gas, tight gas, and CBM produced water. This comparison aggregated data on produced water from original analyses, peer-reviewed literature, and public and confidential government and industry sources and determined the statistical significance of the results.

As shown in Table 7-5, Alley et al. (2011) found that of the constituents of interest common to all three types of produced water from unconventional reservoirs (calcium, chloride, potassium, magnesium, manganese, sodium, and zinc):

1. Shale gas produced water had significantly different concentrations from those of CBM;
2. Shale gas produced water constituent concentrations were significantly similar to those of tight gas, except for potassium and magnesium; and
3. Five tight gas produced water constituent concentrations (calcium, chloride, potassium, magnesium, and sodium) were significantly similar to those of CBM (Alley et al., 2011).

The degree of variability between produced waters of these three resource types is consistent with the degree of mineralogical and geochemical similarity between shale and sandstone formations, and the lack of the same between shale and coalbed formations (Marshak, 2004). Compared to the others, shale gas produced water tends to be more acidic, as well as enriched in strontium, barium, and bromide. CBM produced water is alkaline, and it contains relatively low concentrations of TDS (one to two orders of magnitude lower than in shale and sandstone). It also contains lower levels of sulfate, calcium, magnesium, DOC, sodium, bicarbonate, and oil and grease than typically observed in shale and sandstone produced waters (Alley et al., 2011; Dahm et al., 2011; Benko and Drewes, 2008; Van Voast, 2003).[1]

[d] SU = standard units.

7.3.4.3 General Water Quality Parameters

Data characterizing the content of produced water from unconventional reservoirs in 12 shale and tight formations and CBM basins were evaluated for this assessment. These reservoirs and basins include parts of 18 states, but the data do not allow for comparison of trends over time.

For most reservoirs, the amount of available general water quality parameter data is variable (see Appendix Table E-2 for an example). Average pH levels range from 5.87 to 8.19, with typically lower values for shales. Larger variations in average specific conductivity are seen among unconventional reservoirs and range from 213 microsiemens (μS)/cm in the Bakken Shale to 184,800 μS/cm in Devonian sandstones (Appendix Table E-2). Shale and tight formation produced waters are enriched in suspended solids, as reported concentrations for total suspended solids and turbidity exceed those of coalbeds by one to two orders of magnitude.

The average dissolved oxygen (DO) concentrations of CBM produced water range from 0.39-1.07 mg/L (Appendix Table E-3). By comparison, well-oxygenated surface water can contain up to 10 mg/L DO at 59 °F (15 °C) (U.S. EPA, 2012a). Thus, coalbed produced water is either hypoxic (less than 2 mg/L DO) or anoxic (less than 0.5 mg/L DO) and, if released to surface waters, could contribute to aquatic organism stress (USGS, 2010; NSTC, 2000).

7.3.4.4 Salinity and Inorganics

The TDS profile of produced water from unconventional reservoirs is dominated by sodium and chloride, with large contributions to the profile from mono- and divalent cations (Sun et al., 2013; Guerra et al., 2011). Shale and sandstone produced waters tend to be characterized as sodium-chloride-calcium water types, whereas CBM produced water tends to be characterized as sodium chloride or sodium bicarbonate water types (Dahm et al., 2011). Elevated levels of bromide, sulfate, and bicarbonate are also present (Sun et al., 2013). Elevated strontium and barium levels are characteristic of Marcellus Shale produced water (Barbot et al., 2013; Haluszczak et al., 2013; Chapman et al., 2012). Data representing shales and tight formations are presented in Appendix Table E-4.

Marcellus Shale produced water salinities range from less than 1,500 mg/L to over 300,000 mg/L, as shown by Rowan et al. (2011). By comparison, the average salinity concentration for seawater is 35,000 mg/L.

Of the CBM data presented in Appendix Table E-5, differences are evident between the Black Warrior and the three western formations (Powder River, Raton, and San Juan). The Black Warrior is higher in average chloride, specific conductivity, TDS, TOC, and total suspended solids, and lower in alkalinity and bicarbonate than the other three. These differences are due to the saline or brackish conditions during deposition in the Black Warrior, and its older geologic age that contrasts with the freshwater conditions for the younger western basins. The TDS concentration of CBM produced water can range from 170 mg/L to nearly 43,000 mg/L (range composited from Dahm et al. (2011) and Benko and Drewes (2008); see also Van Voast (2003)).[1]

7.3.4.5 Metals

The metals content of produced water from unconventional reservoirs varies by well and site lithology. Levels of iron, magnesium, and boron were within ranges known for conventional produced water (Hayes, 2009). Produced water from unconventional reservoirs may also contain low levels of heavy metals (e.g., chromium, copper, nickel, zinc, cadmium, lead, arsenic, and mercury as found by Hayes). Data illustrating metal concentrations in produced water appear in Appendix Tables E-6 and E-7.

7.3.4.6 Naturally Occurring Radioactive Material (NORM) and Technologically Enhanced Naturally Occurring Radioactive Material (TENORM)

Geologic environments contain naturally occurring radioactive material (NORM). Radioactive materials commonly present in shale and sandstone sedimentary environments include uranium, thorium, radium, and their decay products. Elevated formation uranium levels have been used to identify potential areas of natural gas production for decades (Fertl and Chilingar, 1988). Shales that contain significant levels of uranium include the Barnett in Texas, the Woodford in Oklahoma, the New Albany in the Illinois Basin, the Chattanooga Shale in the southeastern United States, and a group of black shales in Kansas and Oklahoma (Swanson, 1955).[2] When exposed to the environment in produced water, NORM is called *technologically enhanced* naturally occurring radioactive material (TENORM).[3] Water soluble forms of TENORM are present in most produced water from unconventional reservoirs, but particularly so in Marcellus Shale produced water (Rowan et al., 2011; Fisher, 1998).

Due to insolubility under prevailing reducing conditions encountered within shale formations, only low levels of uranium and thorium are found in produced water, typically in the concentrated form of mineral phases or organic matter (Nelson et al., 2014; Sturchio et al., 2001). Conversely, radium, a decay product of uranium and thorium, is known to be relatively soluble within the redox range encountered in subsurface environments (Sturchio et al., 2001; Langmuir and Riese, 1985). As noted in Section 7.3.3.2, radium and TDS produced water concentrations are positively correlated (Rowan et al., 2011; Fisher, 1998); therefore, in formations containing radium, increasing TDS concentration indicates likely increasing radium concentration.

---

[1] From a similar dataset, Dahm et al. (2011) report TDS concentrations from a composite CBM produced water database (n = 3,255) for western basins that often are less than 5,000 mg/L (85% of samples).

[2] Marine black shales are estimated to contain an average of 15–60 ppm uranium depending on depositional conditions (Fertl and Chilingar, 1988).

[3] The U.S. EPA Office of Air and Radiation's website (https://www.epa.gov/radiation/technologically-enhanced-naturally-occurring-radioactive-materials-tenorm) states that TENORM is produced when activities such as uranium mining or sewage sludge treatment concentrate or expose radioactive materials that occur naturally in ores, soils, water, or other natural materials. Formation water containing radioactive materials contains NORM, because it is not exposed; produced water contains TENORM, because it has been exposed to the environment.

Median values of total radium in the Marcellus Shale ranged from about 1,000 pCi/L to less than 6,000 pCi/L, which are values far exceeding the industrial discharge limit of 60 pCi/L (Rowan et al., 2011) (Figure 7-6). In the Marcellus Shale, TENORM levels in produced water from unconventional reservoirs exceeded levels from conventional reservoirs levels by factors of 4 to 26 (PA DEP, 2015b) (Appendix Table E-8). The individual median concentrations in produced water from unconventional reservoirs of 11,300 pCi/L gross alpha, 3,445 pCi/L gross beta, and total radium of 7,180 pCi/L (Appendix Table E-8). TENORM has been identified in hydraulic fracturing fluid, presumably due to the reuse of produced water at levels from 2 to 4.5 times lower than produced water from unconventional reservoirs (PA DEP, 2015b) (Appendix Table E-8).

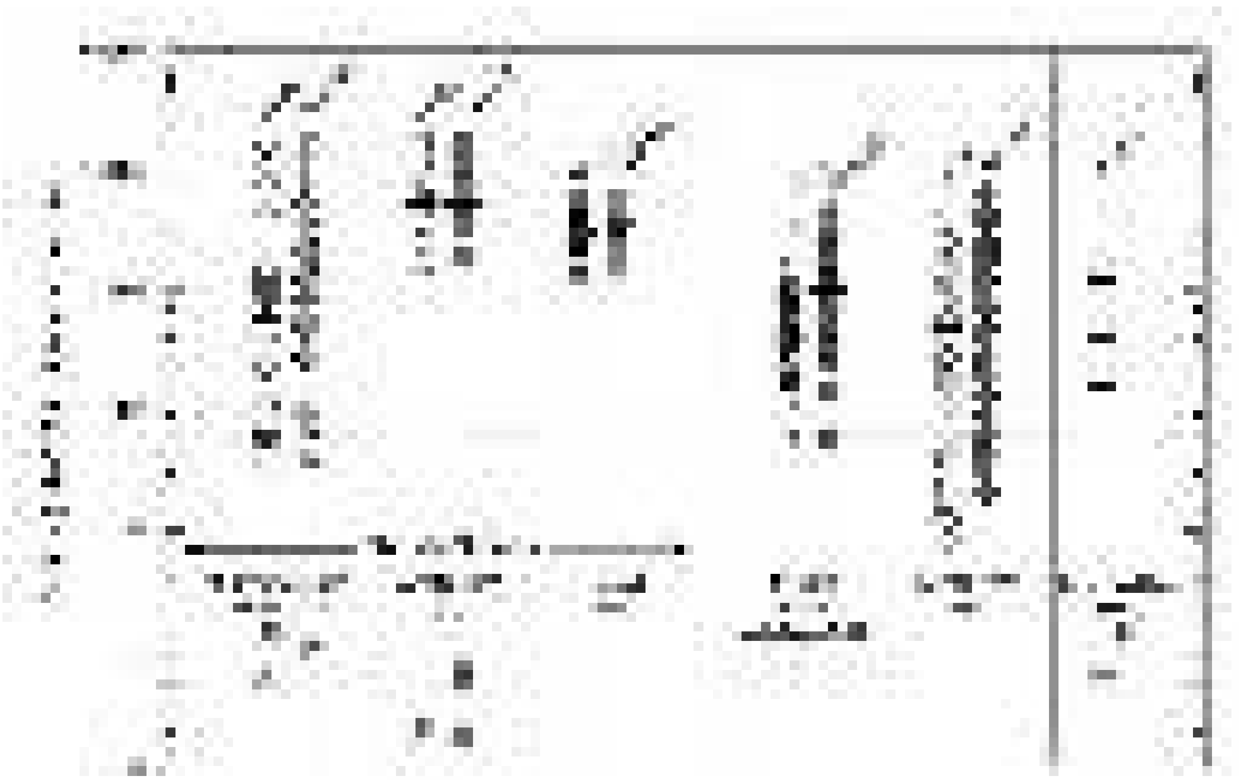

Figure 7-6. Data on radium 226 (open symbols) and total radium (filled symbols) for Marcellus Shale wells (leftmost three columns) and other formations (rightmost three columns).
Source: Rowan et al. (2011). The dashed line represents the industrial effluent discharge limit of 60 pCi/L set by the Nuclear Regulatory Commission. The black lines indicate the median concentrations, and the number of points in each dataset are shown in parentheses. Citations within the figure are provided in Rowan et al. (2011).

7.3.4.7 Organics

The organic content of produced water varies by well and lithology, but consists of naturally occurring and injected organic compounds (Lee and Neff, 2011). Of the organics detected by either routine or advanced analytical methods (Section 7.3.1), the majority are naturally occurring constituents of petroleum (Appendix Tables H-4 and H-5). These organics may be dissolved in water or, in the case of oil production, in the form of a separate or emulsified phase. Several classes of organic chemicals have been found in shale gas and CBM produced water, including aromatics, polyaromatic hydrocarbons, heterocyclic compounds, aromatic amines, phenols, phthalates, aliphatic alcohols, fatty acids, and nonaromatic compounds (list from Orem et al. (2014), see also: Hayes (2009), Benko and Drewes (2008), Orem et al. (2007), and Sirivedhin and Dallbauman (2004)). Compounds found in CBM waters included pyrene, phenanthrenone, alkyl phthalates, C_{12} through C_{18} fatty acids, and others. Similarly, compounds found in shale gas produced water included pyrene and perylene, ethylene glycol, diethylene glycol monododecyl ether, 2-(2-butoxyethoxy) ethanol, and others (Orem et al., 2014). Biomarkers—organic molecules characteristically produced by life forms, and unique to shale formations—have recently been suggested to fingerprint produced water (Hoelzer et al., 2016). More representative examples from five coal bed and two shale gas formations with reported concentrations are given in Appendix Tables E-9, E-11, and E-12, and the complete list of chemicals with CAS registry numbers identified by the EPA for this assessment appears in Appendix H. (See Appendix Table H-4 for chemicals with EPA-identified CAS numbers and Appendix Table H-5 for chemicals without.) Appendix Table E-13 lists concentrations of organic chemicals that were identified in three specific studies (Khan et al., 2016; Lester et al., 2015; Orem et al., 2007).

7.3.4.8 Hydraulic Fracturing Fluid Additives

Several chemicals used in hydraulic fracturing fluids have been identified in produced water. (Examples are shown in Table 7-6, Appendix Table E-10, and Appendix Tables H-4 and H-5.) Many of these chemicals were identified through advanced analytical procedures and equipment, and would not be expected to be found by routine analyses. Of note is that phthalates do not occur naturally. Their presence in produced water is due to either their use in hydraulic fracturing fluids; polyvinyl chloride (PVC) in well adhesives, valves, or fittings; or coatings on laboratory sample bottles (Orem et al., 2007).[1] Phthalates can also be used in drilling fluids, as breaker additives, or as plasticizers (Maguire-Boyle and Barron, 2014; Hayes and Severin, 2012a).[2] One of the produced water phthalates has been identified as a component of hydraulic fracturing fluid (di(2-ethylhexyl) phthalate) (Appendix Table H-2), while others have not, and those may originate from laboratory or field equipment.

Table 7-6. Examples of compounds identified in produced water that can be components of hydraulic fracturing fluid.

Appendix Tables H-4 and H-5 list chemicals identified in produced water and indicates those also identified as constituents of hydraulic fracturing fluid. Chemical or class designation in this table is taken directly from the text of the cited references except where noted, and may or may not reflect the chemical names from the Distributed Structure-Searchable Toxicity Database (DSSTox) show in Appendix Table H-4 or other chemicals listed in Appendix Table H-5.

Chemical or class	Use	Reference
2-Butanone	Solvent; microbial degradation product	Lester et al. (2015)

[1] Examples include di(2-ethylhexyl) phthalate, diisodecyl phthalate, and diisononyl phthalate (Orem et al., 2007).

Acetone	Solvent; microbial degradation product	Lester et al. (2015)
Cocamidopropyl dimethylamine (C-7)	Foaming and lubrication enhancer	Lester et al. (2015)
Di(2-ethylhexyl) phthalate[a]	Derivative of polyvinyl chloride used in adhesives, valves, fittings or coatings of sample bottles	Orem et al. (2007)
Diethylene glycol monododecyl ether	Antifreeze, scale inhibitor, friction reducer	Orem et al. (2014)
Dioctadecyl ester of phosphate phosphoric acid	Common lubricant	Maguire-Boyle and Barron (2014)
Ethylene glycol	Antifreeze, scale inhibitor, friction reducer	Orem et al. (2014)
Fatty acid phthalate esters	(Related to) use in drilling fluids and breakers	Maguire-Boyle and Barron (2014)
Fluorocarbons	Tracers	Maguire-Boyle and Barron (2014)
Hexahydro-1,3,5-trimethyl-1,3,5-triazine-2-thione	Biocide	Orem et al. (2014)
Linear alkyl ethoxylates (C-4 to C-8, C-11 to C-14)	Enhancer of surfactant properties	Lester et al. (2015); Thurman et al. (2014)
Polyethylene glycol carboxylates (PEG-C-EO2 to PEG-C-EO10)	Friction reducer, clay stabilizer, surfactants	Thurman et al. (2016)
Polyethylene glycols (PEG-EO4 to PEG-EO10)	Friction reducer, clay stabilizer, surfactants	Thurman et al. (2016)
Polypropylene glycols (PPG-PO2 to PPG PO10)	Friction reducer, clay stabilizer, surfactants	Thurman et al. (2016)
Toluene	Solvent, scale inhibitor	Thacker et al. (2015)
Triethylene glycol monododecyl ether	Antifreeze, scale inhibitor, friction reducer	Orem et al. (2014)
Xylenes	Solvent, scale inhibitor	Thacker et al. (2015)

[a] Di(2-ethylhexyl) phthalate was named di-2-ethyl hexyl phthalate in Maguire-Boyle and Barron (2014).

7.3.4.9 Reactions within Formations

The introduction of hydraulic fracturing fluids into the target formation induces a number of changes to formation solids and fluids that influence the chemical evolution and composition of produced water. These changes can result from physical processes (e.g., rock fracturing and fluid mixing); geochemical processes (e.g., introducing oxygenated fluids of composition unlike that of the formation); and down hole conditions (elevated temperature, salinity, and pressure) that mobilize trace or major constituents into solution.

The creation of fractures exposes new formation surfaces to interactions involving hydraulic fracturing fluids and existing formation fluids. Formations in unconventional reservoirs targeted for development are composed of detrital, cement, and organic fractions. For example, elements potentially available for mobilization when exposed via fracturing include calcium, magnesium, manganese, and strontium in cement fractions, and silver, chromium, copper, molybdenum, niobium, vanadium, and zinc in organic fractions.

From organic compounds identified in five flowback samples and one produced water sample from the Fayetteville Shale, three possible types of reactions were identified by Hoelzer et al. (2016): hydrolysis of delayed acids, oxidant-caused halogenation reactions, and transformation of disclosed additives. First, delayed acids are used to "break" gel structures and would be intentionally introduced for their ability to cause in-formation reactions. Second, strong oxidants or other compounds introduced as breakers, along with elevated temperature and salinity, can trigger reactions between halogens (chloride, bromide, and iodide) and methane, acetone and pyrane resulting in halomethane compounds. A similar suggestion was made by Maguire-Boyle and Barron (2014). Low pH was found to promote oxidation of additives (Tasker et al., 2016). Third, known additives may react to form byproducts. Hoelzer et al. (2016) postulate examples from several types of compounds, two of these are the formation of benzyl alcohol from the hydraulic fracturing additive benzyl chloride, and abiotic and biotic reactions of phenols. In a study that used synthetic fracturing fluid, Tasker et al. (2016) reported that surfactants were recalcitrant to degradation under high pressure and temperature, which may explain the presence of the surfactant glycols in produced water as reported by Thurman et al. (2016) (Table 7-6), and the oxidation of other additives (gelling and some friction reducers (Table 5-1)) may explain their absence.

7.3.5 Spatial Trends in Produced Water Composition

As was reported for the volume of produced water (Section 7.2.2), the composition of produced water varies spatially on a regional to local scale according to the geographic and stratigraphic locations of each well within a hydraulically fractured production zone (Bibby et al., 2013; Lee and Neff, 2011). Spatial variability of produced water content occurs: (1) between plays of different rock sources (e.g., coal vs. sandstone); (2) between plays of the same rock type (e.g., Barnett Shale vs. Bakken Shale); and (3) within formations of the same source rock (e.g., northeastern vs. southwestern Marcellus Shale) (Barbot et al., 2013; Alley et al., 2011; Breit, 2002).

Geographic variability in produced water content has been established at a regional scale for conventional produced water. As an example, Benko and Drewes (2008) demonstrate TDS variability in conventional produced water among fourteen western geologic basins (e.g., Williston, San Juan, and Permian Basins). Median TDS in these basins range from as low as 4,900 mg/L in the Big Horn Basin to as high as 132,400 mg/L in the Williston Basin based on over 133,000 produced water samples from fourteen basins (Benko and Drewes, 2008).[1]

Average or median TDS of more than 100,000 mg/L has been reported for the Bakken (North Dakota, Montana) and Marcellus (Pennsylvania) formations; between 50,000 mg/L and 100,000 mg/L for the Barnett (Texas), and less than 50,000 mg/L for the Fayetteville (Arkansas) shale formations.[2] In tight formations, the average TDS was above 100,000 mg/L for the Devonian Sandstone (Pennsylvania) and Cotton Valley Group (Louisiana, Texas), between 50,000 mg/L and 100,000 mg/L for the Oswego (Oklahoma), and less than 50,000 mg/L for the Mesaverde Formation (Colorado, New Mexico, Utah, Wyoming). Maximum concentrations above 200,000 mg/L have been reported for the Marcellus, Bakken, Cotton Valley Group and Devonian Sandstone (Appendix Table E-2).

CBM produced waters had average TDS of less than 5,000 mg/L in the Powder River (Montana, Wyoming), Raton (Colorado, New Mexico), and San Juan (Arizona, Colorado, New Mexico, Utah) basins; while above 10,000 mg/L in the Black Warrior Basin (Alabama, Mississippi), which as noted above are due to the depositional history of these basins (Appendix Table E-3, Section 7.3.2).

Data further illustrating variability within both shale and tight gas reservoirs, as well as coalbed methane fields, at both the formation and local scales are presented and discussed in Appendix Section E.3.

7.4 Spill and Release Impacts on Drinking Water Resources

Surface spills of produced water from oil and gas production have occurred across the country and, in some cases, have caused impacts to drinking water resources. Released fluids can flow into nearby surface waters, if not contained on-site, or infiltrate into groundwater via soil. In this section, we first briefly describe the potential for spills from produced water handling equipment. Next, we address individually reported spill events. These have originated from pipeline leaks, well blowouts, well communication events, and leaking pits and impoundments. We then summarize several studies of aggregated spill data, which are based on state agency spill reports.

7.4.1 Produced Water Handling and Spill Potential

Throughout the production phase at oil and certain wet gas production facilities, produced water is stored in containers and pits that can contain free phase, dissolved phase, and emulsified crude oil. Since the crude oil is not efficiently separated out by the flow-through process vessels (such as

[1] Data were drawn from the USGS National Produced Water Geochemical Database v2.0. Published updates made in October 2014 to the database (v2.1) are not reflected in this document.

[2] Because publications we are comparing may report either average or median values (but not uniformly both), we combine average and medians in this paragraph.

three-phase separators, heater treaters, or gun barrels), this crude oil can remain present in the produced water container or pit.

Produced water can be transferred to surface pits for long-term storage and evaporation. Surface pits are typically uncovered, earthen pits that may or may not be lined.[1] Unlined pits can lead to contamination of groundwater, especially shallow alluvial systems. Recovered fluids can overflow or leak from surface pits due to improper pit design and weather events.

Produced water that is to be treated or disposed of off-site is typically stored in storage tanks or pits until it can be loaded into transport trucks for removal (Gilmore et al., 2013). Tank storage systems are typically closed loop systems in which produced water is transported from the wellhead to aboveground storage tanks through interconnecting pipelines (GWPC and IOGCC, 2014). Failure of connections and lines during the transfer process or the failure of a storage tank can result in a surface release of fluids.

Depending on its characteristics, produced water can be recycled and reused on-site. It can be directly reused without treatment (after blending with freshwater), or it can be treated on-site prior to reuse (Boschee, 2014). As with other produced water management options, these systems also can spill during transfer of fluids.

7.4.2 Spills of Produced Water

7.4.2.1 Pipeline Leaks

Produced water is typically transported from the wellhead through a series of pipes or flowlines to on-site storage or treatment units (GWPC and IOGCC, 2014), or nearby injection wells. Faulty connections at either end of the transfer process or leaks or ruptures in the lines carrying the fluid can result in surface spills. A field report from PA DEP (2009b) described a leak from a 90-degree bend in an overland pipe carrying a mixture of produced water and freshwater between two pits. The impact included a "dull sheen" on the water and measured chloride concentration of 11,000 mg/L. The leak impacted a 0.4 mi (0.6 km) length of a stream, and fish and salamanders were killed. Beyond a confluence at 0.4 mi (0.6 km) with a creek, no additional dead fish were found. The release was estimated at 11,000 gal (42,000 L). In response to the incident, the pipeline was shut off, a dam was constructed for recovering the water, water was vacuumed from the stream, and the stream was flushed with fresh water (PA DEP, 2009b).

Another example of a pipeline release occurred in January 2015, when 70,000 bbls (2,940,000 gal or 11,130,000 L) of produced water containing petroleum hydrocarbons (North Dakota Department of Health, 2015) were released from a broken pipeline that crosses Blacktail Creek in Williams County, ND. The response included placing absorbent booms in the creek, excavating contaminated soil, removing oil-coated ice, and removing produced water from the creek. The electrical conductivity and chloride concentration in the water along the creek, the Little Muddy River, and Missouri River were found to be elevated above background levels, as were samples

[1] The use of the terms "impoundments" and "pits" varies and is described in Chapter 8. For the purposes of this section, the term "pits" will be generally used to cover all below-grade storage (but not above ground closed or open tanks).

taken from groundwater recovery trenches. Remediation work on this site continues as of the date of this writing (August, 2016).

7.4.2.2 Well Blowouts

Spills of produced water have occurred as a result of well blowouts. Fingerprinting of water from two monitoring wells in Killdeer, ND, was used to determine that brine contamination in the two wells resulted from a well blowout during a hydraulic fracturing operation. See the discussion in Section 6.2.2.1 for more information.

Another example of a well blowout associated with a hydraulic fracturing operation occurred in Clearfield County, PA. The well blew out, resulting in an uncontrolled flow of approximately 35,000 gal (132,000 L) of brine and fracturing fluid; some of the liquids reportedly reached a nearby stream (Barnes, 2010). The blowout occurred during drilling of plugs that were used to isolate fracture stages from each other. An independent investigation found that the primary cause of the incident was that the sole blowout preventer on the well had not been properly tested. In addition, the company did not have certified well control experts on hand or a written pressure control procedure (Vittitow, 2010).

In North Dakota, a blowout preventer failed, causing a release of between 50 and 70 bbls per day (2,100 gal/day or 7,900 L/day and 2,940 gal/day or 11,100 L/day) of produced water and oil (Reuters, 2014). Frozen droplets of oil and water sprayed on a nearby frozen creek. Liquid flowing from the well was collected and trucked offsite. A 3-ft (0.9-m) berm was placed around the well for containment. Multiple well communication events have also led to produced water spills ranging from around 700 to 35,000 gal (2,600 L to 130,000 L) (Vaidyanathan, 2013a). Well communication is described in Section 6.3.2.3.

The Chesapeake Energy ATGAS 2H well, located in Leroy Township, Bradford County, PA, experienced a wellhead flange failure on April 19, 2011, during hydraulic fracturing operations. Approximately 10,000 gal (38,000 L) of produced water spilled into an unnamed tributary of Towanda Creek, a state-designated trout stock fishery and a tributary of the Susquehanna River (USGS, 2013b; SAIC and GES, 2011). Chesapeake conducted post-spill surface water and groundwater monitoring (SAIC and GES, 2011).

Chesapeake concluded that there were short-term impacts to surface waters of a farm pond within the vicinity of the well pad, the unnamed tributary, and Towanda Creek following the event (SAIC and GES, 2011). The lower 500 ft (200 m) of the unnamed tributary exhibited elevated chloride, TDS, and specific conductance, which returned to background levels in less than a week. Towanda Creek experienced these same elevations in concentration, but only at its confluence with the unnamed tributary; elevated chloride, TDS, and specific conductance returned to background levels the day after the blowout (SAIC and GES, 2011).

7.4.2.3 Leaks from Pits and Impoundments

Leaks of produced water from on-site pits have caused releases as large as 57,000 gal (220,000 L) and have caused surface water and groundwater impacts (Vaidyanathan, 2013b; Levis, 2011; 2010c; PADEP, 2010). VOCs have been measured in groundwater near the Duncan Oil Field in New Mexico downgradient of an unlined pit storing produced water. More example releases from pits are described in Section 8.4.5.

Two of EPA's retrospective case studies evaluated potential impacts from produced water pits. The EPA retrospective case studies were designed to determine whether multiple lines of evidence might be found that could specifically link constituent(s) found in drinking water to hydraulic fracturing activities using the tiered assessment framework presented in Appendix Section E.6. A multiple-lines-of-evidence approach was used to evaluate potential cause-and-effect relationships between hydraulic fracturing activities and contaminant presence in groundwater. Such an approach is needed, because the presence of a constituent in groundwater that is also found in hydraulic fracturing fluids or produced water does not necessarily implicate hydraulic fracturing activities as the cause. This is because some constituents of hydraulic fracturing fluids or produced water are ubiquitous in society (i.e., BTEX), and some constituents of produced water can be present in groundwater as background constituents (i.e., methane, iron, and manganese).

Elements of the assessment framework include gathering background information, including pre-drilling sample results; developing a conceptual model of the site; and assessing multiple analytes to develop lines of evidence. Development of these requires adherence to sampling and quality assurance protocols to generate defensible data. Among many other quality assurance requirements, proper well purging and analyses of field and laboratory blanks are needed (Appendix Table E-17 and Figure E-15).

In the EPA's *Retrospective Case Study in Southwestern Pennsylvania: Study of the Potential Impacts of Hydraulic Fracturing on Drinking Water Resources* (U.S. EPA, 2015j), elevated chloride concentrations and their timing relative to historical data suggested a recent groundwater impact on a private water well occurred near a pit. The water quality trends suggested that the chloride anomaly was related to the pit, but site-specific data were not available to provide a definitive assessment of the cause(s) and the longevity of the impact. Evaluation of other water quality parameters did not provide clear evidence of produced water impacts.

In the EPA's *Retrospective Case Study in Wise County, Texas: Study of the Potential Impacts of Hydraulic Fracturing on Drinking Water Resources* (U.S. EPA, 2015l), impacts to two water wells were attributed to brine, but the data collected for the study were not sufficient to distinguish among multiple possible brine sources, including reserve pits, migration from underlying formations along wellbores, migration from underlying formation along natural fractures and a nearby brine injection well.

To aid in assessing impacts, a number of geochemical indicators and isotopic tracers for identifying oil and gas produced water have been identified. These include (Lauer et al., 2016; Warner et al., 2014a, b):

- Common ion ratios, including bromide/chloride and lithium/chloride;
- Isotope ratios, especially Strontium isotope ratios ($^{87}Sr/^{86}Sr$); and

- Enrichment of certain isotopes: $\delta^{18}O$, $\delta^{2}H$, $\delta^{7}Li$, $\delta^{13}C$-DIC, $\delta^{11}B$.[1]

For the case study, twelve geochemical indicators, including the bromine/chlorine (Br/Cl) and strontium isotope ratios, were considered for the well-water samples.[2] The results were used to assess whether the likelihood that the observed values originated with produced water (the aforementioned sources of brine), sea water, road salt, landfill leachate, sewage/septic tank leachate, and animal waste. In each sample evaluated, it was found that the water could have originated with one or more of the six sources. Thus these lines of evidence did not allow identification of neither a specific source nor a hydraulic fracturing source (Appendix Table E-18). A third well experienced similar impacts, and a landfill leachate source could not be ruled out in that case.

The case studies illustrate how multiple lines of evidence were needed to assess suspected impacts and that no single constituent or parameter could be used alone to assess potential impacts.

7.4.2.4 Other Sources

In the EPA's *Retrospective Case Study in Northeastern Pennsylvania: Study of the Potential Impacts of Hydraulic Fracturing on Drinking Water Resources* (U.S. EPA, 2014f), a pond was found to be impacted due to elevated chloride and TDS, along with strontium ratios ($^{87}Sr/^{86}Sr$) characteristic of Marcellus Shale produced water. Here, the suspected source of the impact was a well pad which had a hydrochloric acid spill, a possible produced water spill and been used for temporary storage of drill cuttings. The same mulidence fracturing impacts from constituents characteristic of produced water (TDS, chloride, sodium, barium, strontium and radium) found in three domestic wells located in an area with naturally occurring saline groundwater. Conversely, at a spring with organic chemical contamination but no associated chloride or TDS impacts, hydraulic fracturing activities were also ruled out.

An estimated 6,300 to 57,373 gal (24,000 to 217,280 L) of Marcellus Shale produced water was discharged through an open valve that drained a tank at XTO Energy Inc.'s Marquardt pad and flowed into a tributary of the Susquehanna River in November 2010 (U.S. EPA, 2016e; PA DEP, 2011c). Overland and subsurface flow of released fluids impacted surface water, a subsurface spring, and soil. Five hundred tons of contaminated soil were excavated, and an estimated 8,000 gal (30,000 L) of produced water was recovered (Science Applications International Corporation, 2010). Elevated levels of TDS, chloride, bromide, barium and strontium that indicated a release of produced water were present in the surface stream and a spring for roughly 65 days (U.S. EPA, 2016e). At that time the chloride concentration in the spring dropped below the state surface water standard of 250 mg/L. The impact extended a distance of approximately 1,400 ft (440 m) to the spring from the release point. Samples were taken in the tributary roughly 500 ft downstream from the spring, where chloride concentrations remained below the 250 mg/L standard throughout the sampling period, but were above the upstream concentrations (PA DEP, 2011c; Schmidley and Smith, 2011). Similarly, the total barium, total and dissolved iron, manganese and alkalinity concentrations remained below the Pennsylvania surface water quality standards at the downstream monitoring location throughout the monitoring period (Schmidley and Smith, 2011).

[1] DIC is dissolved inorganic carbon.
[2] The full list was: Br vs. B, Cl vs. Mg, Cl vs. Br, Cl vs. HCO_3,Cl vs. Ca, Cl vs. K, Cl vs. Na, Cl vs. SO_4, Cl/Br, Cl/I, K/Rb, $^{87}Sr/^{86}Sr$.

In Pennsylvania, discharges of brine were made into a storm drain that itself discharges to a tributary of the Mahoning River in Ohio. Analyses of the brine and drill cuttings that were discharged indicated the presence of contaminants, including benzene and toluene (U.S. Department of Justice, 2014). In California, an oil production company periodically discharged hydraulic fracturing wastewaters to an unlined sump for 12 days. It was concluded by the prosecution that the discharge posed a threat to groundwater quality (Bacher, 2013). These unauthorized discharges represent both documented and potential impacts on drinking water resources. However, data do not exist to evaluate whether such episodes are uncommon or whether they happen on a more frequent basis and remain largely undetected. Other cases of unpermitted discharges have been reported by various sources (Caniglia, 2014; Paterra, 2011).[1]

7.4.2.5 Data Compilation Studies

Three datasets were examined for produced water spill data. These included two published studies: a review of spills in Oklahoma that occurred prior to the onset of widespread high-volume hydraulic fracturing (Fisher and Sublette, 2005), and an EPA study of spills occurring between February 2006 and April 2012 on the well pads of hydraulically fractured wells (U.S. EPA, 2015m). The EPA spills study, *Review of state and industry spill data: characterization of hydraulic fracturing-related spills*, is described in Text Box 5-10. Because of data availability, EPA's study was dominated by data from Pennsylvania (21% of releases) and Colorado (48% of releases). Several difficulties are encountered in compiling and evaluating data on produced water spills and releases. Because states have differing minimum reporting levels, more spills are potentially reported in states with lower reporting limits.[2]

To include data from another state and to give results current to 2015, data from North Dakota were reviewed for this assessment.[3] Details on the procedures and results for non-produced water spills are given in Appendix Section E.5. The North Dakota Department of Health (NDDOH) collects data on environmental incidents and separately compiles oil field incidents; information is made available to the public at http://www.ndhealth.gov/EHS/Spills/. Of these incidents, most describe a release of oil, salt water, or other liquid. Of the remainder, a few describe releases of gas only.

For the period from November 2012 to November 2013, NDDOH reported 552 releases of produced water that were retained within the boundaries of the production or exploration facility and 104 that were not (North Dakota Department of Health, 2011). Thus, 16% of the releases were not contained within facility boundaries and had greater potential for impacting drinking water resources.

[1] Section 8.4 discusses permitted discharges of wastewater.

[2] For example, two agencies in the state of California manage different databases that both store information on spills associated with oil and gas production (CCST, 2015a). CCST (2015a) reported that the databases contain inconsistencies as to the number of spills and the details regarding those spills (e.g., quantity, chemical composition of the wastewater) resulting in uncertainty on the impacts spills have on the environment.

[3] Wirfs-Brock (2015) presented an analysis of North Dakota spill data through 2013.

7.4.2.6 Frequency of Spills and Releases

The EPA analyzed these data and found that, in recent years (2010-2015), there were between five and seven produced water spills per hundred active production wells (Figure 7-7). Spills declined between 2014 and 2015 (from 846 to 609), although the number of production wells increased. A study of 17 states indicated that there was an overall reduction of 8% in spills from 2014 to 2015, and an increase of 9% in Texas (King and Soraghan, 2016). More details on the data analysis are given in Appendix Section E.5, which includes results on North Dakota oil and spills of other types, including hydraulic fracturing fluids (as noted in Chapter 5).

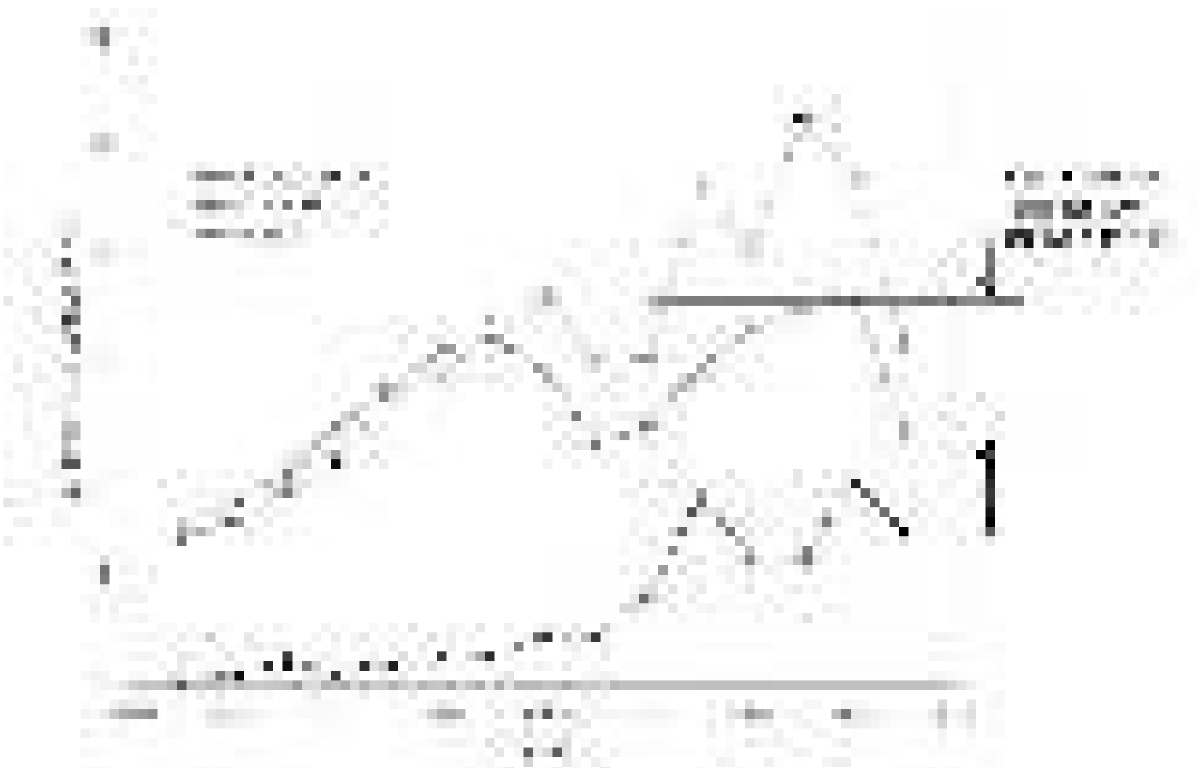

Figure 7-7. Produced water spill rates (spills per active wells) for North Dakota from 2001 to 2015 (Appendix Section E.5).

7.4.2.7 Produced Water Releases—Causes and Sources

The causes and sources identified for releases vary among the three datasets reviewed. North Dakota releases were dominated by leaks from various pieces of equipment, followed by "others," and various overflows (Figure 7-8). While the release rate declined from 2014 to 2015, the causes remained ranked relatively in the same order; notably fewer releases were attributed to "other" and more to equipment failure in 2015. The EPA's spills study found on- or near-well pad releases to be dominated by human error, unknown, and equipment failure (U.S. EPA, 2015m). The earlier

Oklahoma study was dominated by overflows, unpermitted discharges, and storms (Figure 7-9).[1] Storms can cause releases, as was noted after a major flood in northeastern Colorado that caused damage to produced water storage tanks releasing an estimated 43,000 gal (160,000 L) of produced water (COGCC, 2013).

The sources of releases are documented for the Oklahoma and EPA studies (Figure 7-10). The EPA cites storage, unknown, and hoses or lines as the major sources for its 225 well-pad releases. The earlier Oklahoma study cites unclassified, lines, and tanks as major sources of its 8,874 releases.

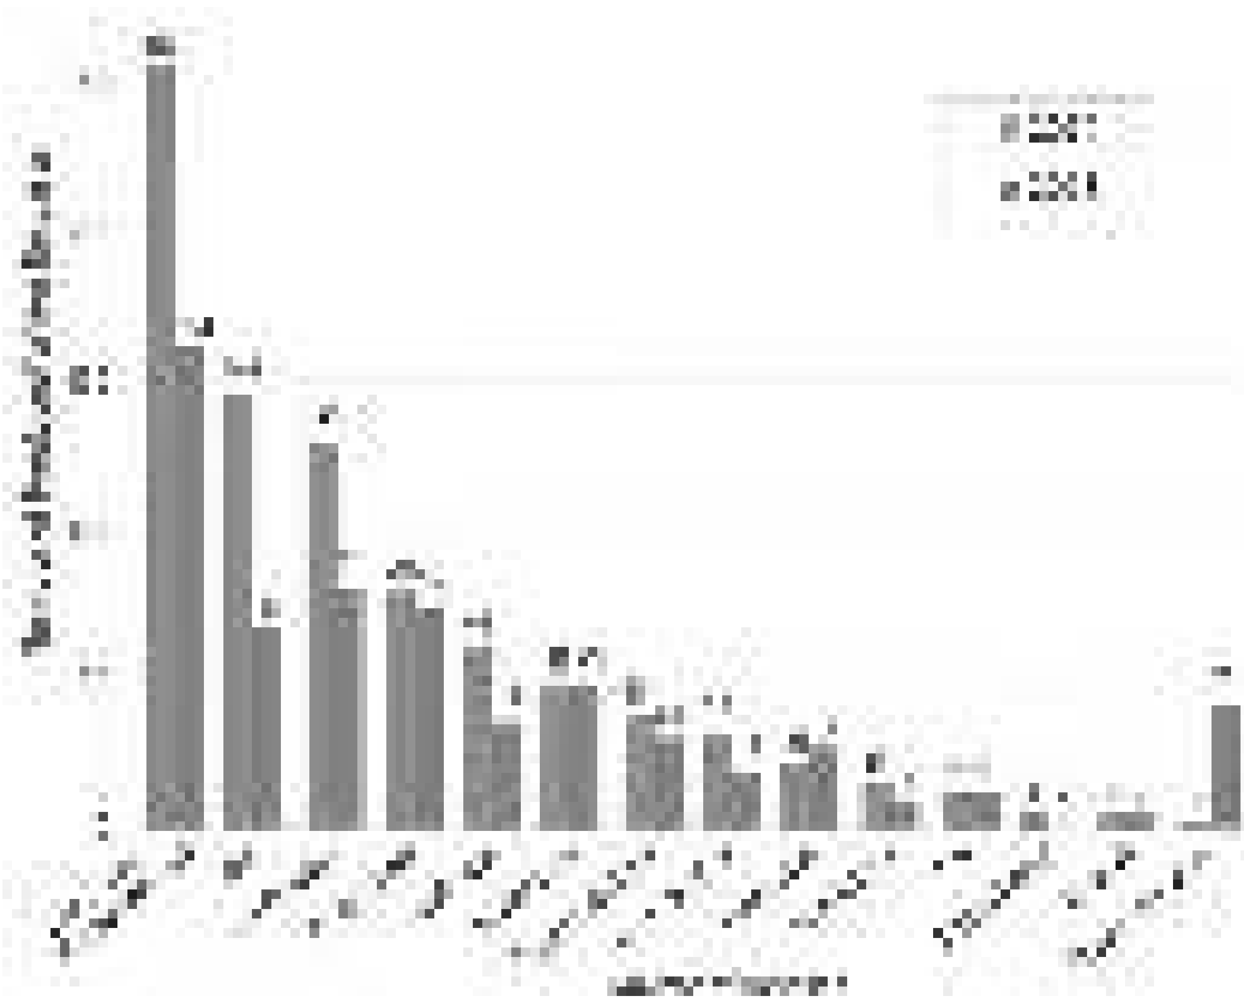

Figure 7-8. Number of produced water releases in North Dakota by cause for 2014 and 2015 (Appendix Section E.5).

[1] Some of the causes in the three studies may be more similar than they appear, because the categorization used in the different studies overlap. For example, the EPA categorized overflows as "human error;" blowouts, vandalism and weather as "other;" and corrosion as "equipment failure," while other studies listed these separately.

Data sources: left, Fisher and Sublette (2005); right, U.S. EPA (2015m).

7.4.2.8 The Volumes of Spilled Produced Water

The 2015 North Dakota spills were ranked from by the median volume, which is the level at which 50% of the spills are below this volume and 50% above (Figure 7-11).[1] Of the North Dakota spills in 2015, the highest median spill volume was caused by a blowout (2,400 gal, 91,000 L, left-most red box). The smallest median volume spill is approximately 10 times lower in volume (84 gal, 320 L). Spills larger than the median are of interest, because of their potential for impacting drinking water resources. The largest volume spill occurred from a pipeline break (2,900,000 gal, 11,000,000 L). The EPA spills study found the highest median volume spill was from equipment failure (1,700 gal, 6400 L), while the highest volume spill was due to container integrity (1,300,000 gal, 4,900,000 L) (Figure 7-12).

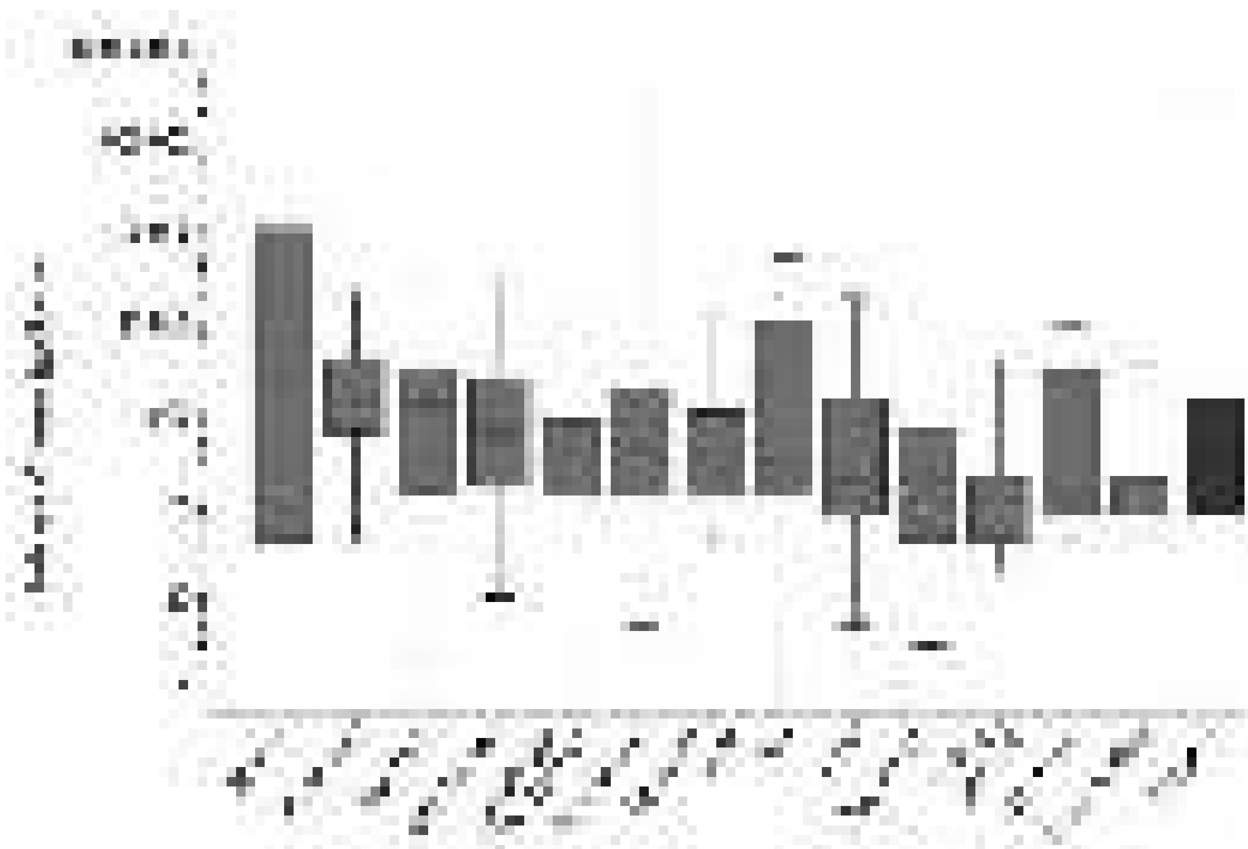

Figure 7-11. Volumes of 2015 North Dakota salt water releases by cause (leftmost 13 boxes in red), and all causes (last box in blue).

[1] These figures are called "box" plots or "box and whisker" plots. The rectangle in the middle represents the range of data from the 25th to 75th percentile. The line across the box represents the 50th percentile, also known as the median. Fifty percent of the data are below the median. The lines extending above and below the boxes represent the range of data from minimum to maximum. These concepts are illustrated in Appendix Figure E-6.

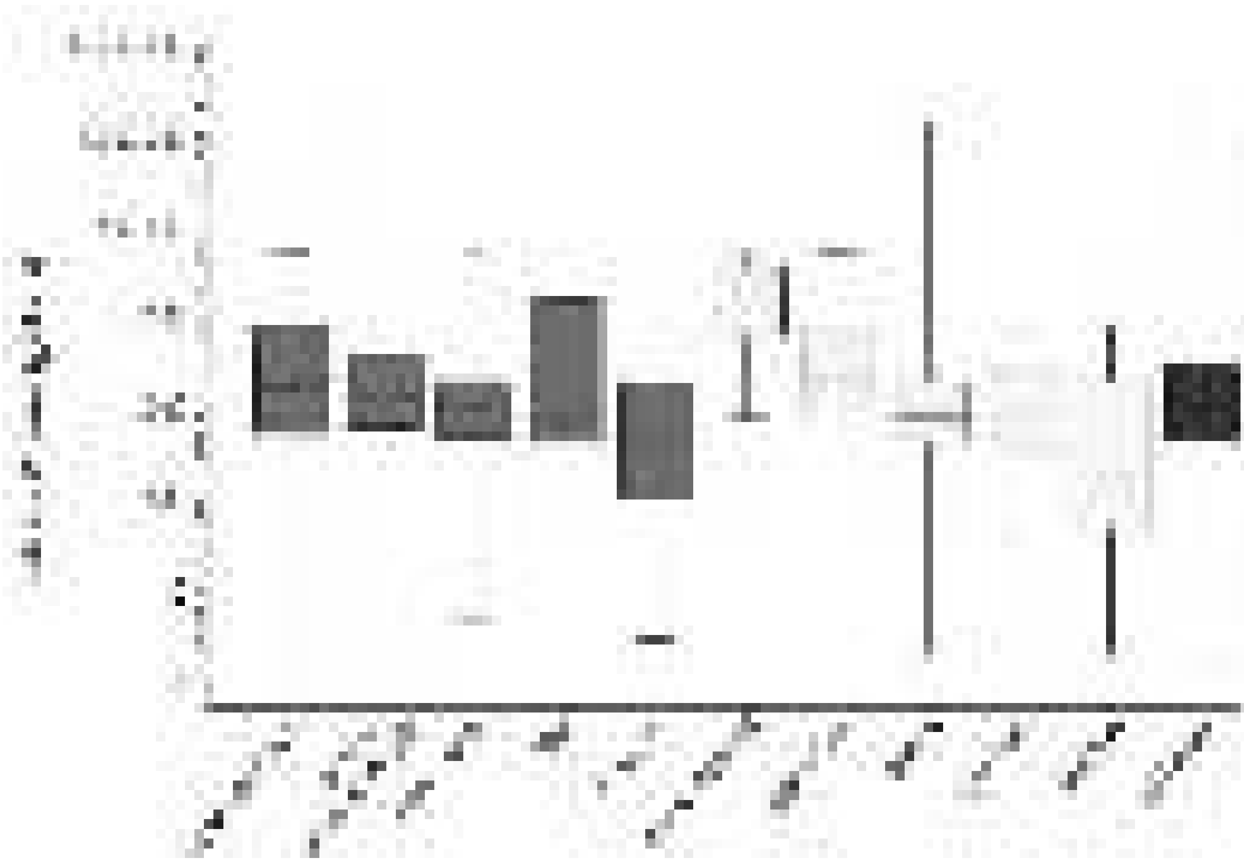

Figure 7-12. Volumes of produced water spills reported by the EPA for 2006 to 2012 by cause (the five left most boxes in red), source (the second five boxes in yellow), and all spills (blue).
Calculated from Appendix B of U.S. EPA (2015m).

From the analyses, half of the spills are less than 1,000 gal (3,800 L) (EPA) and 340 gal (1,300 L) (North Dakota) (Figure 7-12, Figure 7-13, and medians in Table 7-7). The medians for the Oklahoma study were higher (overall 1,700 gal or 6,400 L; see Table 7-7 for yearly values) (Fisher and Sublette, 2005). These occurred in a different state and over an earlier time period, so a direct connection with the recent North Dakota and EPA results has not been made.

The skewed nature of the distributions are noted by the mean values being considerably higher than these medians (see Figure 7-13). In each case, this is caused by a small number of large spills. For 2015 in North Dakota, for example, there were 12 releases of 21,000 gal (79,000 L) or more; 5 of 42,000 gal (160,000 L) or more; and one of greater than 420,000 gal (1,600,000 L) (Appendix Table E-15). The largest spills from these data sets ranged from 1,000,000 gal (3,800,000 L) to 2,900,000 gal (11,000,000 L).

The EPA results give insight into recovery and reuse. Of the volume of spilled produced water, 16% was recovered for on-site use or disposal, 76% was reported as unrecovered, and the rest was unknown. The fewest spills occurred from wells and wellheads, but these spills had the greatest median volumes. Failure of container integrity was responsible for 74% of the volume spilled (U.S. EPA, 2015m).

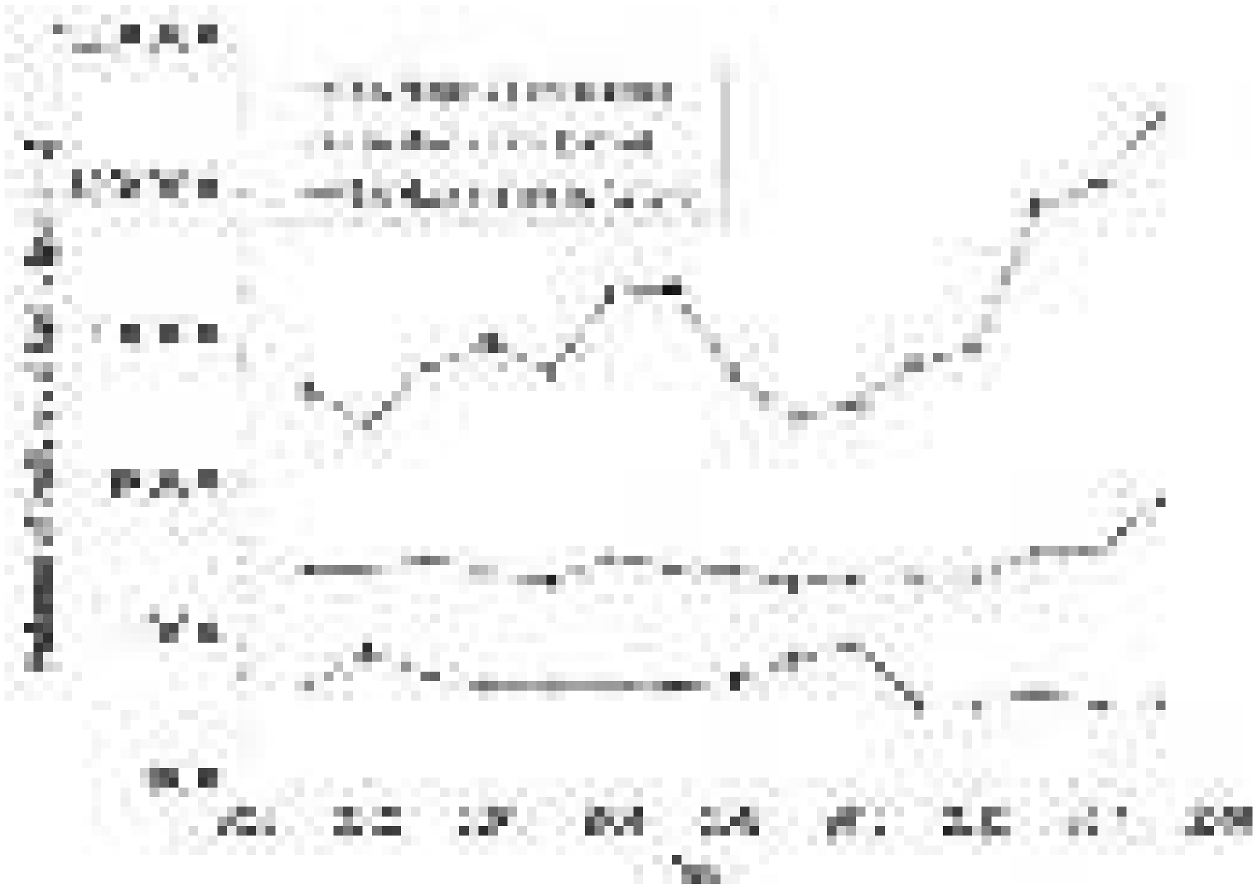

Figure 7-13. Median, mean, and maximum produced water spill volumes for North Dakota from 2001 to 2015.

Table 7-7. Summary of produced water release volumes.

7.4.2.9 Environmental Receptors and Transport

Data from the EPA (U.S. EPA, 2015m) were used to show that some spills were known to impact environmental receptors: soil (141 spills, 340,000 gal, or 1.3 million L); surface water (17 spills, 170,000 gal, or 640,000 L); surface water and soil (13 spills); and groundwater (1 spill, 130 gal, or 490 L).[1] Although 1 spill was identified as reaching groundwater, the possible groundwater impact of 107 of the spills was unknown.

In summary, 18 produced water spills reached surface water or groundwater, accounting for 8% of the 225 cases and accounting for approximately 170,000 gal (640,000 L) of produced water. Spills with known volumes that reached a surface water body ranged from less than 170 gal (640 L) to almost 74,000 gal (280,000 L), with median of 5,900 gal (22,000 L). In 30 cases, it is unknown whether a spill of produced water reached any environmental receptor.

An assessment conducted by the California Council on Science and Technology (CCST, 2015a) states that between January 2009 and December 2014, 575 produced water spills were reported to the California Office of Emergency Services of which nearly 18 percent impacted waterways (CCST, 2015a). These spills occurred in areas where production from both unconventional and conventional reservoirs occurs. Additional studies of spill impacts are presented in Appendix Section E.5.3.

Studies of Environmental Transport of Released Produced Water

The processes that affected the fate and transport of spilled produced water (Figure 7-14) are the same as those processes that impact the fate and transport of spilled chemicals (Section 5.8). Produced water spills differ from the chemical spills as they are always primarily spills of water containing multiple chemicals. Additionally, produced water of high salinity is denser than water and may alter transport and transformation properties of the chemicals and soils.[2] If a spill occurs prior to treatment in an oil and water separator, the produced water can be spilled along with oil. In the environment, oil is transported as a separate phase liquid as it is immiscible with water. The oil phase may become trapped (similarly to how oil is trapped in oil reservoirs) and serve as a slowly dissolving source of hydrocarbons to the environment.

For example, Whittemore (2007) described a site with relatively little infiltration due to moderate to low permeability of silty clay soil and low permeability of underlying shale units. Thus, most, but not all, of the historically surface-disposed produced water at the site flowed into surface drainages. Observed historic levels of chloride in receiving waters resulted from the relative balance of produced water releases and precipitation runoff, with higher concentrations corresponding to low stream flows. Persistent surface water chloride contamination was attributed to slow flushing and discharge of contaminated groundwater.

[1] Quoted volumes.

[2] Appendix Section E.7 describes the estimation of chemical properties for organic chemical constituents of produced water for baseline conditions of low TDS. Elevated salinity, as is common for produced water, would alter these values.

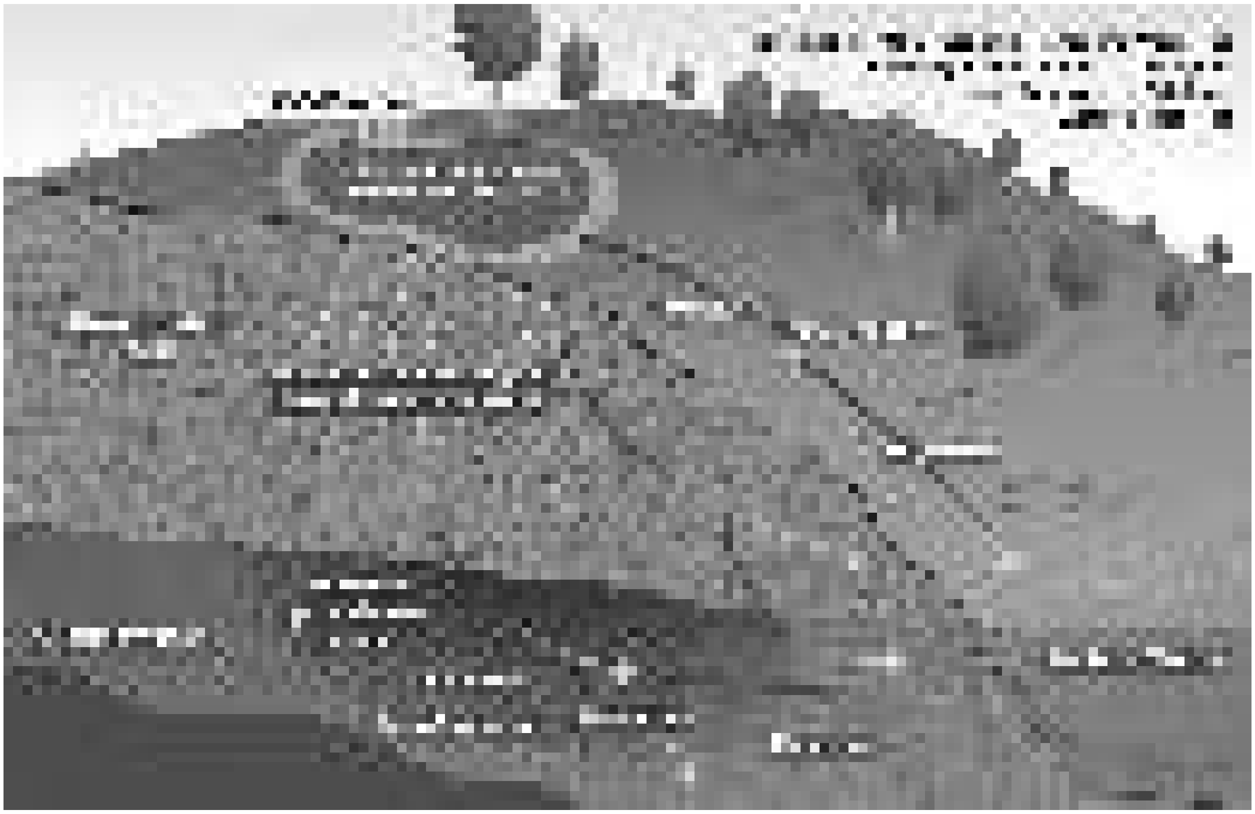

Figure 7-14. Schematic view of transport processes occurring during releases of produced water.

Because it is denser than freshwater, saline produced water can migrate downward through aquifers. Whittemore (2007) reported finding oilfield brine with a chloride concentration of 32,900 mg/L at the base of the High Plains aquifer. Where aquifers discharge to streams, saline stream water has been reported, although at reduced concentrations (Whittemore, 2007), likely due to diffusion within the aquifer and mixing with stream water. The stream flow rate, in part, determines mixing of substances in surface waters. High flows are related to lower chemical concentrations, and vice versa, as demonstrated for bromide in the Allegheny River (States et al., 2013).

7.5 Roadway Transport of Produced Water

Produced water is transported to treatment and disposal sites via pipeline, roadways, or railroad tankers. Accidents during transportation of hydraulic fracturing produced water are a possible mechanism leading to potential impacts to drinking water as truck-related releases have been reported. Nationwide data are not available, however, on the number of such accidents that result in impacts.

Crash rate estimates for Texas showed that commercial motor vehicle (CMV) crashes were correlated with oil and gas development activities over a recent period of increased oil and gas development (Quiroga and Tsapakis, 2015). As an example of the results, the number of new wells in the Permian Basin increased (by 61%) and so did rural CMV crashes (by 52%). For the Barnett Shale region, the number of new wells decreased (by 49%), and so did rural CMV crashes (by 34%). The correlations were strongest for the rural areas with oil and gas development (Permian and Eagle Ford).

Based on scenarios presented in Appendix Section E.8, the EPA estimated for this assessment the number of releases from truck crashes as having a chance of occurrence ranging between 1:110 and 1:13,000 over the lifetime of a producing well. The wide range of these estimates reflects both variable (distance and volume transported) and uncertain (crash rate) quantities. At 5,300 gal (20 m^3) per truckload, the volume from an individual spill would be low relative to the typical volume of water produced from a well. Several limitations are inherent in this analysis, including differing rural road and highway accident rates, differing transport distances, and differing amounts of produced water transported. Further, the estimates present an upper bound on impacts, because not all releases would reach or impact drinking water resources.

As for other types of impacts to drinking water resources, local effects can be significant despite the generally small numbers. For example, a brine-truck spill in Ohio resulted in concern for impacts to a drinking-water-source reservoir (Tucker, 2016).

7.6 Synthesis

Produced water is a by-product of oil and gas production and is that water that comes out of the well after hydraulic fracturing is completed and injection pressure is reduced. Produced water may contain hydraulic fracturing fluid, water from the surrounding formation, and naturally present hydrocarbons. Initially the chemistry of produced water reflects that of the hydraulic fracturing fluid. With time, the chemistry of the produced water becomes more similar to the water in the formation. Produced water is directly re-injected or stored at the surface for eventual reuse or disposal. Impacts to drinking water resources from produced water have been shown where spilled produced water entered surface water bodies or aquifers.

7.6.1 Summary of Findings

The volume and composition of produced water vary geographically, both within and among different production zones and with time and other site-specific factors. In most cases, there are high initial flow rates of produced water that last for a few weeks, followed by lower flow rates throughout the duration of gas production. The amount of fracturing fluid returned to the surface varies, and typically is less than 30%. In some formations (e.g., the Barnett Shale), the ultimate volume of produced water can exceed the volume of hydraulic fracturing fluid because of an inflow of water.

Knowledge of the composition of produced water comes from analysis of samples. Analysis of an individual sample is made much easier if the hydraulic fracturing and any equipment maintenance chemicals have been disclosed. Much of the chemical loading of produced water comes from naturally occurring material, both organic and inorganic, in the formation along with transformation products. As such, knowledge of produced water composition is uniquely dependent on sampling and analysis, which requires appropriate analytical methods. These are methods that can deal especially with high levels of TDS. Recently developed laboratory methods have greatly expanded the knowledge of organic chemicals in shale-gas and CBM produced waters, but these methods rely on advanced equipment and techniques. Routine methods of laboratory analysis do not detect many of the organic constituents of produced water.

The composition of produced water changes with time as the hydraulic fracturing fluid contacts the formation and mixes with the formation water. Typically it becomes more saline and more radioactive, if those constituents are present in the formation, while containing less DOC. The changing composition of produced water suggests that the potential concern for produced water spills also changes: initially the produced water may contain more hydraulic fracturing chemicals, later the concern may shift to the impact of high salinity water. Although varying within and between formations, shale and tight gas produced water typically contains high levels of TDS (salinity) and associated ionic constituents (bromide, calcium, chloride, iron, potassium, manganese, and sodium). Produced water can also contain toxic materials, including barium, cadmium, chromium, lead, mercury, nitrate, selenium, and BTEX. CBM produced water can have lower levels of salinity if its coal source was deposited under fresh water conditions, or if freshwater inflows to coal beds dilutes the formation water (Dahm et al., 2011). Many organic compounds have been identified in produced water. Most of these are naturally occurring constituents of petroleum. With the advent of advanced analytical techniques, more hydraulic fracturing fluid chemicals have been identified in produced water. These include some known tracer compounds, but others are known to exist whose identities have not yet been determined. Work has been done to identify environmentally benign tracers for assessing impacts, but these tracers have not been fully developed. Despite the presence in produced water of known hydraulic fracturing chemicals, the majority of organic and inorganic constituents of produced water come from the formation and cannot be minimized through actions of the operator. Throughout the formation-contact time, reactions occur between the constituents of the fracturing fluid and the formation.

Produced water spills have occurred across the country. From evaluation of data from across the United States and a focused study of North Dakota, the median produced water spill ranges from 336 to 1,000 gal (1,300 to 3,800 L). Although half of the spills are smaller than the median spill size, small numbers of much higher volume spills occur. In 2015, there were 12 spills in North Dakota greater than 21,000 gal (80,000 L), and one of 2,900,000 gal (11,000,000 L). From 2010 to 2015, there were approximately 5 to 7 produced water spills per hundred operating production wells. The major causes identified for these spills are container and equipment failures, human error, well communication, blowouts, pipeline leaks, and unpermitted discharges. Section 7.4.2 described impacts that were both of short and long term duration.

Highway transportation of produced water has resulted in crashes, but the impacts from these are unknown. Analysis of Texas crashes shows that as the oil and gas development activities increase, so do crashes, especially in rural areas. The EPA estimated the chance of a crash releasing produced water to range from 1:110 to 1:13,000.

7.6.2 Factors Affecting the Frequency or Severity of Impacts

The potential of spills of produced water to affect drinking water resources depends upon the release volume, duration, and composition, as well as watershed and water body characteristics. Larger spills of greater duration are more likely to reach a nearby drinking water resource than are smaller spills. Small releases, however, can impact resources where there are direct conduits from a source to receptor, such as fractures in rock. The composition of the spilled fluid also impacts the severity of a spill, as certain constituents are more likely to affect the quality of a drinking water resource.

Potential impacts to water resources from hydraulic fracturing related spills are expected to be affected by watershed and water body characteristics. For example, overland flow is affected by surface topography and surface cover. Infiltration of spilled produced water reduces the amount of water threatening surface water bodies. However, infiltration through soil can lead to groundwater impacts. Releases from pits can directly impact drinking water resources.

7.6.3 Uncertainties

The volume and some compositional aspects of produced water are known from published sources. The amount of hydraulic fracturing fluid returned to the surface is not well defined, because of the imprecise distinction between flowback and produced water. With regard to composition, TENORM and organics have the most limited data. Most of the available data on TENORM has come from the Marcellus Shale, where concentrations are typically high in comparison to the limited data available from other formations. Many organic constituents of produced water have been identified, and many of them are naturally occurring petroleum hydrocarbons. As methods improve and more data are collected, an increasing number of hydraulic fracturing fluid chemicals are being identified in produced water. Little is known concerning subsurface transformations and is reflected in only a few transformation products have been positively identified. Halogenation of organics has been noted, though.

Nationwide data on spills of produced water are limited in two primary ways: the completeness of reported data cannot be determined, and individual states' reporting requirements differ (U.S. EPA, 2015m). Therefore, the total number of spills occurring in the United States, their release volumes, and associated concentrations can only be estimated because of these underlying data limitations.

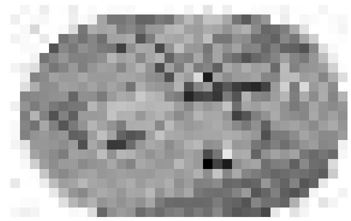
Spills vary in volume, duration, and composition, and most spill response focusses on immediate clean up, so several aspects of spills are not precisely characterized. The volume released is often a rough estimate, in part, because the spilled liquid spreads across the scene and is inherently difficult to measure. Simple measurements are often used to characterize the spill, rather than determining chemical concentrations (e.g., measuring electrical conductivity). As a consequence the suite of chemicals, and their concentrations, potentially impacting drinking water resources are usually unknown. Thus, the severity of impacts to drinking water resources is not usually well quantified.

Spills can originate from blowouts, well communication, aboveground or underground pipeline breaks, leaking pits, failed containers, human error (including unpermitted discharges, failure to detect spills, and failure to report spills) or unknown causes. The difference between these causes affects the location and size of the spill or release. For example, a container that fails may release a small amount of produced water, and be located on the well pad. A pipeline break may occur at a distance away from the well pad and release a larger amount of water from a bigger source (i.e., a pit). In addition, the factors governing transport of spilled fluid to a potential receptor vary by site: the presence and quality of secondary or emergency containment and spill response; the rate of overland flow and infiltration; the distance to a surface water body or drinking water well; and transport and fate processes. Impacts to drinking water resources from spills of produced water depend on environmental transport parameters, which can, in principle, be determined but are unlikely to be known or adequately specified in advance of a spill.

Because some constituents of produced water are constituents of natural waters (e.g., bromide in coastal surface waters) or can be released into the environment by other pollution events (e.g., benzene from gasoline releases, bromide from coal mine drainage), baseline sampling prior to impacts is one way to increase the certainty of an impact determination. Further sampling and investigation can be used to develop the linkage between a release and a documented drinking water impact. Appropriate sampling and analysis protocols, using quality assurance procedures, are essential for developing data that can withstand scrutiny. The EPA's northeastern Pennsylvania case study illustrates that the analytes that can be used to distinguish among types of water vary depending on the specifics of the situation. No single constituent or parameter could be used alone to assess impacts, and multiple lines of evidence were needed to assess the suspected impacts.

7.6.4 Conclusions

Produced water has the potential to affect the quality of drinking water resources if it enters into a surface water or groundwater body used as a drinking water resource. This can occur through spills at well pads or during transport of produced water. Specific impacts depend upon the spill itself, the environmental conditions surrounding the spill, water body and watershed characteristics, and the composition of the spilled fluid. The impacts from the majority of spills and releases is generally localized in extent as only the largest spills and releases impact large areas.



Chapter 8. Wastewater Disposal and Reuse

Abstract

This chapter addresses the practices and related impacts on drinking water resources that take place during the final stage of the hydraulic fracturing water cycle. This stage encompasses the management of wastewater, including disposal, reuse in hydraulic fracturing operations, or other uses. For this assessment, wastewater is defined as produced water from hydraulically fractured oil and gas wells that is managed by any of a number of strategies. The constituents of concern in hydraulic fracturing wastewaters that are most frequently noted include high total dissolved solids (TDS), chloride, bromide, and radionuclides (radium in particular). Other alkaline earth metals (e.g., barium), organics, and suspended solids, may be of concern as well.

Most hydraulic fracturing wastewater is managed by injection into Class II disposal wells. There are also "aboveground" management practices, which include reuse in subsequent hydraulic fracturing operations; treatment at a centralized waste treatment facility followed by reuse or discharge to surface water or a publicly owned treatment works; evaporation; irrigation; and direct discharge (under limited conditions). These practices can affect both surface water and groundwater.

Impacts on surface water arise from discharges of inadequately treated wastewater. In particular, bromide and iodide found in highly saline wastewaters can contribute to disinfection byproduct formation in downstream drinking water systems. If not removed during treatment, radium, metals, and organic compounds can also be discharged. Factors affecting the frequency and severity of impacts on surface waters include the wastewater's composition, its volume, and the processes used to treat it (common wastewater treatment processes do not significantly reduce the high TDS content in hydraulic fracturing wastewaters). In addition, site-specific factors such as local hydrology, size of the receiving water body, and other activities taking place in a watershed can affect the severity of the impact.

Pits and impoundments used for storage or disposal can impact surface water or groundwater through spills, leaks, and infiltration through soils. The frequency and severity of such impacts depend on pit construction and maintenance as well as proximity to drinking water resources. Unlined pits or those with compromised liners can cause long-lasting impacts on groundwater. Depth to the water table, soil properties, and the contaminants in the wastewater also affect the likelihood of impacts.

Characterizing the impacts from wastewater management associated with hydraulic fracturing is challenging given gaps in the data. Specifically, there are limited data on the wastewater volumes managed, on the influent and effluent concentrations and volumes from facilities that treat wastewater from hydraulic fracturing operations, and on wastewater residual characteristics and management of those residuals. Further, there is inadequate monitoring of drinking water resources for specific contaminants associated with hydraulic fracturing wastewater. However, the data that are available have shown that management of hydraulic fracturing wastewater through aboveground practices has affected the quality of water resources.

This page is intentionally left blank.

8. Wastewater Disposal and Reuse

8.1 Introduction

The final stage of the hydraulic fracturing water cycle encompasses disposal and reuse of hydraulic fracturing wastewater. For the purposes of this assessment, "hydraulic fracturing wastewater" is defined as produced water from hydraulically fractured oil and gas wells that is being managed using practices that include, but are not limited to, reuse in subsequent hydraulic fracturing operations, treatment and discharge, and injection into disposal wells.[1,2,3] Although the term "wastewater" is generally used in this chapter, when more specific information about a wastewater is known (e.g., a source indicates the wastewater is flowback), that information is also noted.

Wells producing from oil and gas reservoirs generate produced water during the course of their productive lifespan. This produced water includes the often large volumes of flowback generated immediately after fracturing in deep wells with long horizontal sections. Flowback estimates vary by formation and are noted in Section 7.2.1 to range from about 300,000 to 10 million gal (1.14 to 37.8 million L) per well (Mantell, 2013; U.S. GAO, 2012). This large volume of initial flowback necessitates having a wastewater management strategy in place before hydraulic fracturing is initiated. Also, the longer-term generation of produced water requires ongoing wastewater management.

The majority of wastewater generated from all oil and gas operations in the United States is managed via Class II injection wells (Veil, 2015). Injection may be for either disposal or enhanced recovery. As hydraulic fracturing activity expands or diminishes, choices regarding disposal practices can change in a given region due to factors such as the quality and volume of the fluids; regulations; available infrastructure; and the feasibility and cost of treatment, reuse, and disposal options.

Several articles have noted potential effects of hydraulic fracturing wastewater on water resources (Vengosh et al., 2014; Olmstead et al., 2013; Rahm et al., 2013; States et al., 2013; Vidic et al., 2013; Rozell and Reaven, 2012; Entrekin et al., 2011). One study used probability modeling that indicated water pollution risk associated with gas extraction in the Marcellus Shale is highest for the wastewater disposal aspects of the operation (Rozell and Reaven, 2012). These concerns arise from

[1] The term "wastewater" is being used in this study as a general description of certain waters and is not intended to constitute a term of art for legal or regulatory purposes. This general description does not, and is not intended to, provide that the production, recovery, or recycling of oil, including the production, recovery, or recycling of flowback or produced water, constitutes "wastewater treatment" for the purposes of the Oil Pollution Prevention regulation (with the exception of dry gas operations), which includes the Spill Prevention, Control, and Countermeasure rule and the Facility Response Plan rule, 40 CFR 112 et seq.

[2] Disposal wells are Underground Injection Control (UIC) Class II wells, including those used for disposal (Class IID), enhanced oil recovery (Class IIR), and hydrocarbon storage (Class IIH).

[3] The term "reuse" is sometimes used to imply no treatment or basic treatment (e.g., media filtration) for the removal of constituents other than total dissolved solids (TDS), while "recycling" is sometimes used to convey more extensive treatment (e.g., reverse osmosis (RO)) to remove TDS (Slutz et al., 2012). In this document, the term "reuse" will be used to indicate use of wastewater for subsequent hydraulic fracturing, regardless of the level of treatment.

the elevated concentrations of chloride, bromide, radionuclides, and other constituents of concern found in many hydraulic fracturing wastewaters.

This chapter provides follow-on to Chapter 7, which discusses the per-well volumes of produced water (Section 7.2) and composition (Section 7.3), as well as the processes involved in its generation and impacts from a number of types of spills and releases. In this chapter, discussions are provided on management practices for hydraulic fracturing wastewater, available wastewater production information, and estimated aggregate volumes of wastewater generated for several states with active hydraulic fracturing (Section 8.2). As a complement to information on the composition of wastewaters in Chapter 7, Section 8.3 presents brief information on wastewater constituents and their relevance to wastewater management. Management methods used in recent years and their potential impacts on drinking water resources are described (Section 8.4). Based on background information provided in the earlier sections of the chapter, Section 8.5 discusses documented and potential impacts on drinking water resources from particular constituents, and a final synthesis discussion is provided (Section 8.6).[1]

8.2 Volumes of Hydraulic Fracturing Wastewater

This section provides a general overview of aggregate wastewater quantities generated in the course of hydraulic fracturing and subsequent oil and gas production, including estimates at regional and state levels. It also discusses methodologies used to produce these estimates and the associated challenges. (Chapter 7 provides a more in-depth discussion of the processes affecting produced water volumes and presents some typical per-well values and temporal patterns.) Wells also generate drilling fluid waste. Compared to produced water, however, drilling fluid wastewater can constitute a relatively small portion of the total wastewater produced (e.g., <10% in Pennsylvania during 2004-2013) (U.S. EPA, 2016d) and is not discussed further in this assessment.

Wastewater volume can be relevant to treatment costs, reuse options, and disposal capacities. IHS Global Insight suggests that as a general rule of thumb, the amount of flowback produced in the days or weeks after hydraulic fracturing is roughly comparable to the amount of produced water generated long-term over a span of years, which can vary considerably among wells (IHS, 2013). Thus, on a local level, operators can anticipate a relatively large volume of wastewater in the weeks following fracturing, with slower subsequent production of wastewater.

Wastewater volumes will most likely vary in the future as the amount and locations of hydraulic fracturing activities change and as existing wells age and move into the later phases of their production cycles. Substantial increases in wastewater production have occurred during times of increasing hydraulic fracturing activity. For instance, the average annual volume of wastewater

[1] This chapter makes use of background information collected by the EPA's Office of Water (OW) as part of the development of its recent pretreatment standards for wastewater from unconventional oil and gas formations (U.S. EPA, 2016d). The pretreatment standards apply to wastewater from crude oil and natural gas produced by a well drilled into shale and tight formations. Coalbed methane is beyond the scope of those standards. In this chapter, we consider wastewater generated by the hydraulic fracturing of those unconventional oil and gas formations included in the background research done by OW. But we also consider wastewater generated by hydraulic fracturing in coalbed methane and conventional formations.

generated by all gas production (both shale gas and conventional) in Pennsylvania quadrupled from the 2001-2006 period to the 2008-2011 period (Wilson and Vanbriesen, 2012).

However, although the total volume of wastewater might be expected to generally increase and decrease as oil and gas drilling and production changes, it is not necessarily a direct correlation. Data from the Pennsylvania Department of Environmental Protection (PA DEP) (PA DEP, 2016b) show trends in volumes of wastewater compared to gas produced from wells in the Marcellus Shale in Pennsylvania (Figure 8-1). Although the data show some variation, they demonstrate a general positive correlation between the volume of wastewater and the amount of produced gas until early 2015. At that time, Baker Hughes weekly rig counts also began to drop, declining from 85 in early January 2014 to 24 in early June 2016 (Baker Hughes, 2016). This suggests that a decline in overall drilling activity (generally a measure of new wells) can be associated with a decline in wastewater production, although the exact timing depends on whether there is a time delay between drilling and completion of a well and the start of production from that well.

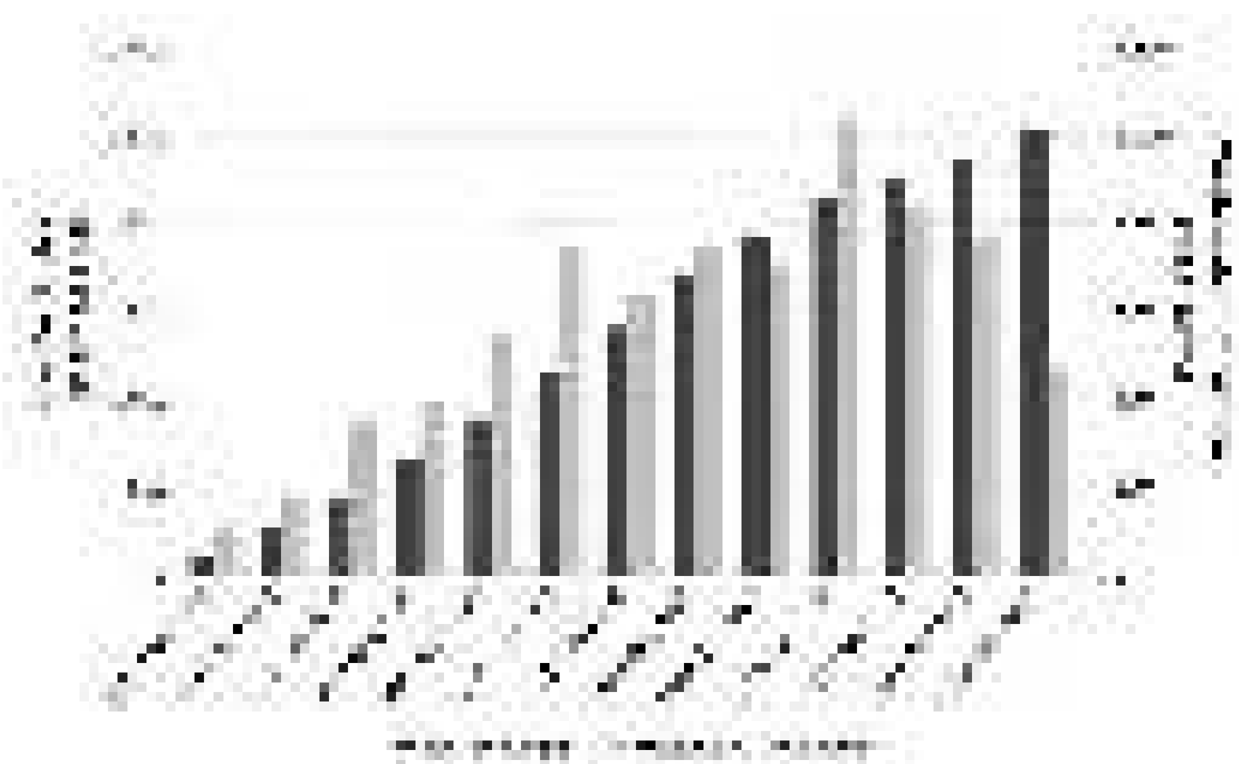


Figure 8-1. Wastewater (i.e., produced water and fracturing fluid waste) and produced gas volumes from unconventional (as defined by PA DEP) wells in Pennsylvania from January 2010 through June 2016.
Source: PA DEP (2016b).

Estimates of produced water compiled by Veil (2015) indicate that although oil and gas production in the United States increased by 29% and 22%, respectively, between 2007 and 2012, produced water volumes increased by less than 1%. There may be a number of factors contributing to this, including as noted by Veil (2015), a number of uncertainties associated with produced water estimates. First, wastewater generation varies from well to well, as do oil and gas production (see Chapter 7, Figure 7-1 for discussion of wastewater/produced water decline curves). The rates of decline in both wastewater volume and hydrocarbon production also vary among reservoirs. Additionally, some wells are drilled and completed but are not immediately put into production. Relationships between hydraulic fracturing activity, hydrocarbon production, and produced water volumes are likely reservoir- (and maybe production zone-) specific, and existing wells and production need to be considered to anticipate wastewater management needs.

8.2.1 National Level Estimate

Veil (2015) estimated that in 2012, U.S. onshore and offshore oil and gas production generated 889.59 billion gal (21.18 billion bbls) of produced water. This national-level estimate represents total oil and gas wastewater (from all oil and gas resources, and from wells hydraulically fractured and wells not hydraulically fractured). The estimate was compiled through a state-by-state analysis of survey data obtained from oil and gas agencies in the 31 states with active oil and gas production as well as the Department of Interior and U.S. EPA. However, Veil notes several issues with the data used for these estimates, including variability among states in data reporting, availability, and completeness. These issues may result in underestimation of the volumes of water produced (U.S. GAO, 2012). See Section 8.2.3 for more discussion on methods of estimating wastewater volumes.

8.2.2 Regional/State Level Estimates

A limited number of studies have described the geographic variability in oil and gas wastewater volumes. Veil (2015) reported that the top ten states nationwide for wastewater production in 2012 included Texas (35% of total), California (15% of total), Oklahoma (11% of total), and Wyoming (11% of total). A study by the Bureau of Land Management (BLM) (Guerra et al., 2011) states that in 2008, more than 80% of all oil and gas wastewater was generated in the western United States, with Texas producing the highest volume and Wyoming the second highest. The BLM report notes substantial wastewater from CBM wells, in particular those in the Powder River Basin (Wyoming). Figure 8-2 summarizes the wastewater volumes for these western states, demonstrating the wide variability from state to state (likely reflecting differences in the number of oil and gas production wells/production activity and reservoir geology). Although the authors do not identify all wastewater contributions from production involving hydraulic fracturing, the regions with established oil and gas production are likely to have methods and infrastructure available for management of hydraulic fracturing wastewater.

Figure 8-2. Wastewater quantities in the western United States (billions of gal per year).
Data from Guerra et al. (2011).

In the Marcellus region, waste data made public by the PA DEP have enabled analyses of wastewater volumes and trends since 2009. Estimates of produced water (including flowback or "fracing fluid waste" as well as "produced fluid") by Wunz (2015) and Shale Alliance for Energy Research Pennsylvania (SAFER PA, 2015) for 2014 are 1.73 and 1.64 billion gal (41.19 MMbl and 39.05 MMbl, respectively). The estimate compiled for this assessment is 0.65 billion gal (15.48 million bbls) for the first half of 2014 (Table 8-1). Variations among estimates reflect, among other factors, challenges in working with a dynamic database for which changes and corrections are ongoing.

Table 8-1 presents estimates of the volumes of hydraulic fracturing wastewater generated and the associated numbers of wells in North Dakota, Ohio, Pennsylvania, Texas (injected flowback only), and West Virginia. The data shown in this table were compiled for this assessment (except for West Virginia) and come primarily from records of produced water made publicly available on state websites.[1] These states are represented in Table 8-1 because the produced water volumes associated with hydraulic fracturing were readily identifiable. The data show that the increase in

[1] Data used for Table 8-1 were downloaded from state agency websites and compiled as needed (in either Microsoft Excel or Microsoft Access) for each state except West Virginia. Once compiled, data were filtered if needed and summed to produce estimates of wastewater production by year and a count of the numbers of wells generating the wastewater. Data were downloaded up through 2014. (Note that 2014 data for Pennsylvania and Texas are for partial years.) Differences in the years presented for the states are due to differences in data availability from the state agency databases. For West Virginia, data are from a report by Hansen et al. (2013) that compiled available flowback data from West Virginia.

the number of wells producing wastewater and the volumes of wastewater produced are generally consistent with the timing of the expansion of high-volume hydraulic fracturing and track with the increase in horizontal wells seen in Figure 3-20.

Several states with mature oil and gas industries (California, Colorado, New Mexico, Utah, and Wyoming) make produced water volumes publicly available by well as part of their oil and gas production data, but they do not directly indicate which wells have been hydraulically fractured. Some states (Colorado, Utah, Wyoming, and New Mexico) specify the producing formation or the basin along with volumes of hydrocarbons and produced water. Determining volumes of hydraulic fracturing wastewater for these states is challenging because there is a possibility of either inadvertently including wastewater from wells not hydraulically fractured or of missing volumes that should be included. This may be a particular problem where state terminology regarding what constitutes an unconventional resource or hydraulically fractured well is ambiguous or possibly different from other states. Appendix Table F-1 provides estimates of wastewater volumes in California, Colorado, New Mexico, Utah, and Wyoming in regions where hydraulic fracturing activity is taking place, along with notes on data limitations. The data in Table 8-1 and Appendix Table F-1 illustrate the challenges in both compiling a national estimate of hydraulic fracturing wastewater and comparing wastewater production among states due to dissimilar data types, presentation, and availability.

8.2.3 Estimation Methodologies and Challenges

Compiling and comparing data on wastewater production at the wide array of oil and gas locations in the United States presents challenges associated with data reporting and availability. Different approaches have been used to estimate state-specific and national wastewater volumes. Data from state agency websites and databases can be a ready source of information, whether publicly available and downloadable or provided directly by agencies upon request.

Veil (2015) notes that the reported volumes of produced water (e.g., reported by well in state production data) can be inaccurate or imprecise because produced water is not monitored continuously. Therefore, reported volumes may be estimates. Other issues such as data transcription errors or extrapolation of data can also affect reported volumes (Veil, 2015).

Using produced water volumes from state records to estimate the volume of wastewater regionally or nationally presents additional challenges due to a lack of consistency in data collection, availability, usability, completeness, and accuracy (Malone et al., 2015; Veil, 2015; U.S. GAO, 2012). Due to what are sometimes significant differences in the types of data collected and the mechanisms, formats, and definitions used, data cannot always be directly compared from state to state. This makes it difficult to aggregate volume data, and estimates may be better and more useful at a local or state level. Larger-scale estimates across regions or between states should be interpreted carefully.

Table 8-1. Estimated volumes (millions of gal) of wastewater based on state data for selected years and numbers of wells producing fluid.

State	Basin	Principal lithologies	Data type	2000	2004	2008	2010	2011	2012	2013	2014	Comments
North Dakota	Williston	Shale	Produced water	2	3	130	790	1,900	4,500	8,500	9,700	From North Dakota Oil and Gas Commission website[a]. Data provided for six members of the Bakken Shale. Produced water includes flowback (reports are submitted within 30 days of well completion.)
			Wells	*161*	*152*	*844*	*2,083*	*3,303*	*5,036*	*6,913*	*8,039*	
Ohio	Appalachian	Shale	Primarily flowback	-	-	-	-	3	29	110	-	Data from Ohio DNR Division of Oil and Gas[b]. Utica data for 2011 and 2012. Utica and Marcellus data for 2013. Brine is noted by agency to be mostly flowback.
			Wells	-	-	-	-	*9*	*86*	*400*	-	
Pennsylvania	Appalachian	Shale	Flowback plus produced water (% flowback; % produced water)	-	-	-	180 (51%; 49%)	740 (46%; 54%)	1,100 (36%; 64%)	1,300 (27%; 73%)	650 (32%; 68%)	Waste data from PA DEP[c]. Second half of 2010 and first half of 2014. Data described as unconventional as defined by PADEP. Separate codes are provided by PA DEP for flowback and produced water.
			Wells	-	-	-	*1,232*	*2,434*	*4,039*	*5,015*	*5,150*	

State	Basin	Principal lithologies	Data type	2000	2004	2008	2010	2011	2012	2013	2014	Comments
Texas	Unspecified (entire state)	Shale, Sandstone	Flowback - injected volumes	-	-	-	-	490	2,200	3,100	2,000	Waste injection data from Texas Railroad Commission[d]. Monthly totals are provided for entire state. Oct - Dec for 2011, full years for 2012 and 2013, and Jan - Oct for 2014
West Virginia	Appalachian	Shale	Flowback - Estimated total disposed	-	-	-	120	110	59	-	-	Estimates from Hansen et al. (2013).[e]

Texas state data provide an aggregate total amount of flowback injected for the past few years. (Data on brine volumes injected do not differentiate hydraulically fractured wells and, therefore, well counts are not presented here.) These values are interpreted as estimates of generated flowback as based on reported quantities of “fracture water flow back” injected into Class IID wells.

[e] West Virginia flowback estimates from Hansen et al. (2013) are based on state data. Well counts that are explicitly associated with the flowback and total disposed volumes were not available.

To compile estimates of the production and management of hydraulic fracturing wastewater, there are additional challenges. Reporting of wastewater volumes may or may not include information that helps determine whether the producing well was hydraulically fractured (e.g., an indicator of resource type or formation). It also might not be clear whether volumes listed as 'produced water' include the flowback component. Some states (e.g., Colorado and Pennsylvania) include information on disposal and management methods along with production data, and others do not.

Given the limitations of comparing state databases, some studies have generated estimates of wastewater volume using water-to-gas and water-to-oil ratios along with the reports of hydrocarbon production (Murray, 2013). The reliability of any wastewater estimates made using this method would need to be evaluated in terms of the quality, timeframe, and spatial coverage of the available data, as well as the extent of the area to which the estimates will be applied. Water-to-hydrocarbon ratios are empirical estimates. Because these ratios show a wide variation among formations, reliable data are needed to formulate a ratio in a particular region.

Another approach to estimating wastewater volumes would entail multiplying per-well estimates of produced water production rates by the numbers of wells in a given area. Challenges associated with this approach include obtaining accurate estimates of the number of new and existing wells, along with accurate estimates of per-well water production both during the flowback period and during the production phase of the well's lifecycle. In particular, it can be challenging to correctly match per-well wastewater production estimates, which will vary by formation, with counts of wells, which may or may not be clearly associated with specific formations. Temporal variability in wastewater generation would also be difficult to capture and would add to uncertainty. Such an approach, however, may be attempted for order of magnitude estimates if the necessary data are available and reliable.

8.3 Wastewater Characteristics

Along with wastewater volumes, wastewater characteristics and the characteristics of residuals produced during treatment or storage are important for understanding the potential impacts of management and disposal of hydraulic fracturing wastewater on drinking water resources. This section provides brief highlights on several important constituents known to exist in hydraulic fracturing wastewaters and residuals. Chapter 7 provides more in-depth detail on the chemistry of produced water, and Chapter 9 discusses reference values and health effects associated with hydraulic fracturing wastewater constituents.

8.3.1 Wastewater

Wastewater composition is the result of naturally-occurring constituents originating in the formation solids and fluids as well as chemicals associated with the fracturing fluid. Discussion in this chapter focuses on constituents in hydraulic fracturing wastewater for which adequate information is available to assess documented and potential impacts on drinking water resources. There may also be unknown constituents in wastewaters for which analyses have not been performed. This is due, in part, to a lack of information on fracturing fluid ingredients identified as confidential business information (CBI). In addition, there are uncertainties about how fracturing fluid ingredients are degraded or removed in the subsurface. (See Chapter 5, Section 5.8 for a discussion of processes that can cause chemicals to degrade or transform in the subsurface.)

8.3.1.1 Total Dissolved Solids and Inorganics

Hydraulic fracturing wastewaters are generally high in total dissolved solids (TDS), especially those from shales and tight formations, with TDS values ranging from less than 1,000 mg/L to hundreds of thousands of mg/L (Section 7.3.4.4). The TDS in wastewaters from shale formations is typically dominated by sodium and chloride and may also include elevated concentrations of bromide, bicarbonate, sulfate, calcium, magnesium, barium, boron, strontium, radium, organics, and heavy metals (Chapman et al., 2012; Rowan et al., 2011; Blauch et al., 2009; Orem et al., 2007; Sirivedhin and Dallbauman, 2004).

Within each formation, the minimum and maximum values presented in Section 7.3.4.4 suggest spatial variation in TDS content that may need to be accommodated when considering management strategies such as reuse or treatment. In contrast to shales and sandstones, TDS values for wastewater from CBM formations are generally lower, with reported concentrations ranging from approximately 150 mg/L to 62,000 mg/L (DOE, 2014b; Dahm et al., 2011) (Appendix Table E-3). This results in fewer treatment challenges and a wider array of management options.

Constituents commonly found in TDS from hydraulic fracturing wastewaters may have potential health impacts or create treatment burdens on downstream drinking water systems if discharged at high concentrations to drinking water resources. Bromide, for example, can contribute to the increased formation of disinfection byproducts (DBPs) during drinking water treatment (Hammer and VanBriesen, 2012); see Section 8.5.1.

8.3.1.2 Organics

Less information is generally available about organic constituents in hydraulic fracturing wastewaters than about inorganic constituents, but there are now several studies reporting analyses of organic constituents (Chapter 7). The organic content in flowback waters can vary based on the chemical additives (e.g., biocides, antiscalants, gelling agents, breakers) used in hydraulic fracturing fluids and the chemistry of the formation, but the organics generally include polymers, oil and grease, volatile organic compounds (VOCs), and semi-volatile organic compounds (SVOCs) (Akob et al., 2016; Walsh, 2013; Hayes, 2009). Examples of other constituents detected include alcohols, naphthalene, acetone, and carbon disulfide, compounds that may be remnants of hydraulic fracturing fluid chemicals (Hayes and Severin, 2012b; Hayes, 2009) (Appendix E). Wastewater associated with CBM wells may have high concentrations of aromatic and halogenated organic contaminants potentially requiring treatment depending on how the wastewater will be managed (Pashin et al., 2014; Sirivedhin and Dallbauman, 2004). Concentrations of BTEX (benzene, toluene, ethylbenzene, and xylenes) in CBM produced waters are lower than in shale produced waters (Appendix Table E-9).

New research is focusing on transformation products generated in the subsurface; experimental work by Kahrilas et al. (2015) suggests that the biocide glutaraldehyde can be present in wastewaters along with its transformation products. Low molecular weight organic acids such as acetate, formate, and pyruvate have been detected in Marcellus wastewater, indicating microbial degradation of organic compounds in the fracturing fluid or formation (Akob et al., 2015).

8.3.1.3 Radionuclides

Radionuclides are constituents of concern in some hydraulic fracturing wastewaters, with most of the available data obtained for the Marcellus Shale in Pennsylvania (Appendix Table E-8). Results from a United States Geological Survey (USGS) report (Rowan et al., 2011) indicate that the predominant radionuclides in Marcellus Shale wastewater are radium-226 and radium-228. Radionuclides in produced fluids are considered ‘technologically enhanced naturally-occurring radioactive material’ (TENORM) because they have been exposed to the accessible environment.[1]

Although data regarding radionuclides in wastewater from formations other than the Marcellus Shale are limited, there is information on the naturally occurring radioactive material (NORM) in the formations themselves.[2] In particular uranium and thorium can be found in certain organic-rich black shales. High uranium content has been measured in the Marcellus, Barnett, Woodford, and other black shales (Swanson, 1955) (Section 7.3.4.6). Radium-226 and -228 are decay products of uranium and thorium and are soluble (Sturchio et al., 2001; Langmuir and Riese, 1985). Therefore wastewater from shales with high concentrations of uranium and thorium can contain radium, especially where TDS concentrations are also high (Rowan et al., 2011; Sturchio et al., 2001; Fisher, 1998). Section 7.3.3.2 provides further information on radionuclides in produced waters and in formations.

8.3.2 Constituents in Residuals

Depending on the wastewater and the treatment processes used, treatment residuals can consist of sludges, spent media (used filter materials), or brines. Residuals may require further treatment (e.g., dewatering sludges) prior to disposal (see Section 8.4.7 for further discussion on management of residuals). Residuals can contain constituents such as total suspended solids (TSS), TDS, metals, radionuclides, and organics. These constituents will be concentrated in the residuals, with the degree of concentration depending on the type of treatment employed. Processes such as electrodialysis and mechanical vapor recompression have been found to yield residuals with TDS concentrations in excess of 150,000 mg/L after treating waters with influent TDS concentrations of approximately 50,000 – 70,000 mg/L (Hayes et al., 2014; Peraki and Ghazanfari, 2014).

Also, TENORM in wastewaters can cause residual wastes to have gamma radiation emissions (Kappel et al., 2013). A laboratory study by Zhang et al. (2014b) estimated that the barium sulfate solids precipitated during treatment to remove barium and strontium from Marcellus Shale wastewater would also contain between 2,571 and 18,087 pCi/g of radium due to coprecipitation. Another similar study using mass balances calculated that sludge from a sulfate precipitation

[1] Technologically Enhanced Naturally Occurring Radioactive Material (TENORM) is defined by the EPA as naturally occurring radioactive materials (NORM) that have been concentrated or exposed to the accessible environment as a result of human activities such as manufacturing, mineral extraction, or water processing.

[2] Naturally Occurring Radioactive Materials (NORM) are radioactive materials found in nature that have not been moved or concentrated by human activities.

process would have an average radium concentration of 213 pCi/g (Silva et al., 2012). In sludge from lime softening processes, Silva et al. (2012) estimated a radium-226 concentration of 58 pCi/g, a level that would necessitate disposal as a low-level radioactive waste.

8.4 Wastewater Management Practices and Their Potential Impacts on Drinking Water Resources

Operators have several strategies for management of hydraulic fracturing wastewaters (Figure 8-3), with the most common choice being disposal via Class IID wells (Veil, 2015; Clark et al., 2013; Hammer and VanBriesen, 2012). Other practices include reuse in subsequent hydraulic fracturing operations (with varying levels of treatment), treatment at a centralized waste treatment facility (CWT) (often followed by reuse), evaporation (in arid regions), irrigation (with no discharge to waters of the United States), and direct discharge for livestock or agricultural use (allowed west of the 98th meridian). Up until 2011, treatment of unconventional oil and gas wastewaters (as defined by PA DEP) at publicly owned treatment works (POTWs) was a common practice for wastewater management in the Marcellus region (Lutz et al., 2013); this is discussed further in Text Box 8-1.

The methods shown in Figure 8-3 represent wastewater management strategies, not all of which would be used at the same facility. Descriptions of incidents of unpermitted disposal and resulting legal actions have also been publicly reported (Chapter 7). However, such events are not generally described in the scientific literature, and the prevalence of this type of activity is unclear. Additional sources of information about potential impacts exist, but some records are sealed (e.g., litigation records) and are not publicly accessible.

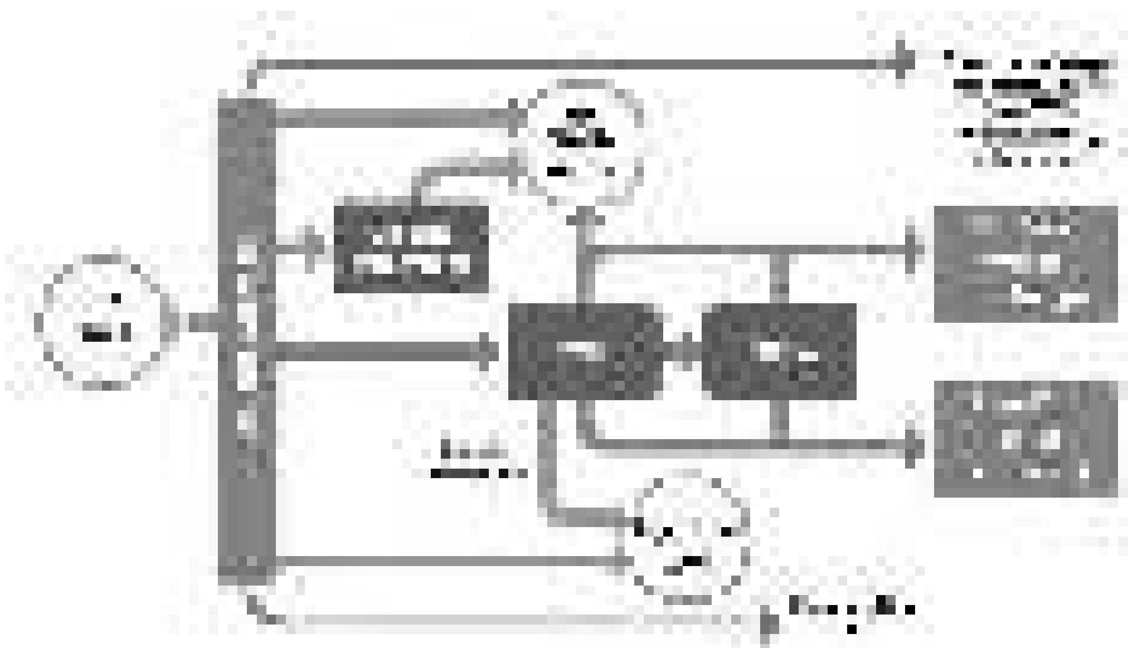

Figure 8-3. Schematic of wastewater management strategies.
Gray lines indicate management strategies that involve injection, either for reuse or disposal, and blue lines indicate management strategies that lead to other end points such as discharge, evaporation, landfills, or other uses.

Each of the wastewater management strategies can potentially lead to impacts on drinking water resources during some phase of their execution. Such impacts include, but are not limited to: accidental releases during transport (Chapter 7); discharges of treated wastewaters from CWTs or POTWs where treatment for certain constituents has been inadequate; migration of constituents to groundwater due to leakage from pits or land application of wastewaters; leakage from pits that reach surface waters (Chapter 7, Section 8.4.5); inappropriate management of liquid or solid residuals (e.g., leaching from landfills); or accumulation of constituents in sediments near outfalls of CWTs or POTWs that are treating or have treated hydraulic fracturing wastewater.[1]

A reliable census of oil and gas wastewater management practices nationwide is difficult to assemble due to a lack of consistent and comparable data among states. In addition, we do not know how often operators use more than one wastewater management strategy at a site (e.g., evaporation and injection), further complicating the tracking of wastewater management. As part of a data survey conducted by Veil (2015), some state agencies provided estimates of oil and gas wastewater volumes handled by several management practices (Table 8-2). These estimates illustrate how widespread injection for both enhanced recovery and for disposal is for managing oil and gas wastewater. The data also show regional differences in reuse and other practices. For hydraulic fracturing wastewaters, Table 8-3 illustrates nationwide variability in the primary wastewater management methods using qualitative and quantitative sources. Similar to Table 8-2, Table 8-3 shows disposal via underground injection predominates in most regions, and reuse is predominant in the Marcellus Region. (Table 8-3 does not include wastewater management in areas of CBM production.)

Management choices are affected by cost and a number of directly and indirectly related factors, including the chemical properties of the wastewater; the volume, duration, and flow rate of the wastewater generated; the feasibility of each option; the availability of necessary infrastructure; local, state, and federal regulations (Text Box 8-2); and operator discretion (U.S. GAO, 2012; NPC, 2011a). The economics (such as transport, storage, and disposal costs) and availability of treatment and disposal methods are of primary importance (U.S. GAO, 2012). For wastewater composition, there is limited information on the degradation or removal of fracturing fluid ingredients in the subsurface. Chemical disclosure requirements vary among states, and some fracturing fluid ingredients are claimed to be CBI. Therefore, the possible presence of unknown chemical constituents in wastewater contributes to uncertainty about the effectiveness and potential impacts of management strategies, particularly with regard to treatment efficacy.

[1] The term surface water as used in this assessment refers to surface waters that meet the definition of waters of the United States under the CWA (House Bill No. 1950, 2011).

Table 8-2. Estimated percentages of wastewater managed by practice and by state.
Source: Veil (2015). Estimates do not identify interstate transport (e.g., wastewater transported from PA to OH or WV for injection into disposal wells). Thus, there may have been some double counting of volumes in both the generating and receiving states.

Management practice	Percentage of produced water managed by practice and state

[a] CWT facilities identified in these formations are all operator-owned.

[b] This column indicates the type of data the EPA based the number of Xs on. In most cases, the EPA used a mixture of qualitative and quantitative data sources along with engineering judgment to determine the number of Xs.

XXX—The majority (≥50%) of wastewater is managed with this management practice; XX—A moderate portion (≥10% and <50%) of wastewater is managed with this management practice; X—This management practice has been documented in this location, but for a small (<10%) or unknown percent of wastewater. Blanks indicate the management practices have not been documented in the given location.

The availability and use of wastewater management strategies in a region can change over time as oil and gas production increases or decreases, regulations change, costs shift, and technologies evolve. Text Box 8-1 and Figure 8-4 illustrate shifting wastewater management practices in Pennsylvania as gas development in the Marcellus Shale increased and concerns over high-TDS discharges prompted a regulatory response. Reuse has increased substantially at well sites in Pennsylvania (labeled as "Reuse HF" in Figure 8-4) and wastewater management at CWTs has moved toward more facilities that provide wastewater for reuse and do not discharge (termed "zero-discharge facilities"). The estimated total reuse rate in Pennsylvania was 80% in 2012 and 90% in 2013 (PA DEP, 2015a). In contrast, wastewater disposal data in areas of Colorado where hydraulic fracturing takes place show a steady use of injection wells, an increase in surface water discharges, and a decrease in the use of on-site pits for evaporation since 2000 (Figure 8-5).

Another factor influencing reuse is the pace of hydraulic fracturing in the area. When hydraulic fracturing is active, demand for reuse is high. Some formations that are hydraulically fractured such as the Marcellus Shale and the Utica Shale are still in the early stages of development, with large potential resources not yet developed. For these plays, the need for wastewater treatment and/or reuse may remain high for decades to come, and the long-term wastewater management needs must be considered and addressed (SAFER PA, 2015).[1]

Researchers have developed optimization models to aid in the minimization of wastewater management costs as a part of comprehensive water management planning. For example, Yang et al. (2014) suggest an approach for reusing flowback in scheduled hydraulic fracturing events to minimize the operational costs of transportation, treatment, storage, and wastewater disposal. Another modeling study proposes an approach to minimize the total cost of water usage and wastewater treatment and disposal by optimizing capital costs (such as the costs of treatment units and storage pits) and operating costs for flowback management, treatment, storage, reuse, and wastewater disposal (Lira-Barragan et al., 2016).

Text Box 8-1. Temporal Trends in Wastewater Management – Experience of Pennsylvania.

Gross natural gas withdrawals from shale formations in the United States increased 518% between 2007 and 2012 (EIA, 2014b). This production increase has led to larger volumes of wastewater requiring appropriate management (Vidic et al., 2013; Gregory et al., 2011; Kargbo et al., 2010). The rapid increase in wastewater generated from hydraulically fractured oil and gas wells has led to many changes in wastewater disposal practices in the oil and gas industry. Changes have been most evident in Pennsylvania, which has experienced a more than 1,400% increase in natural gas production since 2000 (EIA, 2014b).

Lutz et al. (2013) estimated that total wastewater generation in the Marcellus region increased 570% between 2004 and 2013. The authors concluded that this increase has created stress on the existing wastewater disposal infrastructure. In 2010, concerns arose over elevated TDS in the Monongahela River

(*Text Box 8-1 is continued on the following page.)*

[1] As noted in Chapter 3, oil and gas prices influence new drilling activity. However, the links between oil and gas prices and the generation of wastewater (as a byproduct of production) appear to be less direct.

Text Box 8-1 (continued). Temporal Trends in Wastewater Management – Experience of Pennsylvania

basin, and studies linked high TDS (and, in particular, high bromide levels) to elevated DBP levels in drinking water systems (PA DEP, 2011a). In response, PA DEP amended Chapter 95 Wastewater Treatment Requirements under the Clean Streams Law for new discharges of TDS in wastewaters. This regulation is also informally known as the 2010 TDS regulation. The regulation disallowed any new direct discharges to streams as well as direct disposal at POTWs of hydraulic fracturing wastewater and set limits on treated discharges from new CWTs of 500 mg/L TDS, 250 mg/L chloride, 10 mg/L barium, and 10 mg/L strontium. Existing discharges were exempt.

In April 2011, PA DEP announced a request that by May 19, 2011, gas drilling operators voluntarily stop transporting wastewater from shale gas extraction (i.e., unconventional resources as defined by PA DEP) to the eight CWTs and seven POTWs that were exempt from the 2010 TDS regulation.[1] Follow-up letters from PA DEP to the owners of the wells specified that the role of bromides from Marcellus Shale wastewaters in the formation of total trihalomethanes (TTHM) was of concern due to the their potential public health impacts (PA DEP, 2011a).

In response to the request, the oil and gas industry in Pennsylvania accelerated the switch of wastewater deliveries from POTWs to CWTs for better removal of metals and suspended solids (Schmidt, 2013). Effluent sampling at two POTWs that had accepted Marcellus Shale wastewater showed that concentrations of bromide, chloride, barium, strontium, and sulfate dropped after the April 2011 request (Ferrar et al., 2013); data based on two sampling events, one before and one after May 2011).

Between early and late 2011, although reported wastewater production more than doubled, Marcellus Shale drilling companies in Pennsylvania reduced their use of CWTs that were exempt from the 2010 TDS regulation by 98%, and direct disposal of Marcellus Shale wastewater at POTWs was "virtually eliminated" (Hammer and VanBriesen, 2012).

Along with the decreased discharges from POTWs, there has been increased reuse of wastewater in the Marcellus Shale region. From 2008-2011, reuse of Marcellus wastewater for hydraulic fracturing increased, POTW treatment volumes decreased, tracking of wastewater improved, and wastewater transportation distances decreased (Rahm et al., 2013). Maloney and Yoxtheimer (2012) analyzed data from 2011 and found that reuse of flowback increased to 90% by volume. Eight percent of flowback was sent to CWTs. Brine water, which was defined as formation water, was reused (58%), disposed via injection well (27%), or sent to CWTs (14%). Of all the fluid wastes in the analysis, brine water was most likely to be transported to other states (28%). Maloney and Yoxtheimer (2012) also concluded that wastewater disposal to municipal sewage treatment plants declined nearly 100% from 47,221 bbls in the first half of 2011 to 408 bbls in the second half.

[1] An unconventional formation was defined in 2011 by the state of Pennsylvania as "A geological shale formation existing below the base of the Elk Sandstone or its geologic equivalent stratigraphic interval where natural gas generally cannot be produced at economic flow rates or in economic volumes except by vertical or horizontal wellbores stimulated by hydraulic fracture treatments or by using multilateral wellbores or other techniques to expose more of the formation to the wellbore." The EPA defines unconventional oil and gas as crude oil and natural gas produced by a well drilled into a shale and/or tight formation (including, but not limited to, shale gas, shale oil, tight gas, and tight oil). For the purpose of the rule, the definition of UOG does not include CBM (U.S. EPA, 2016d).

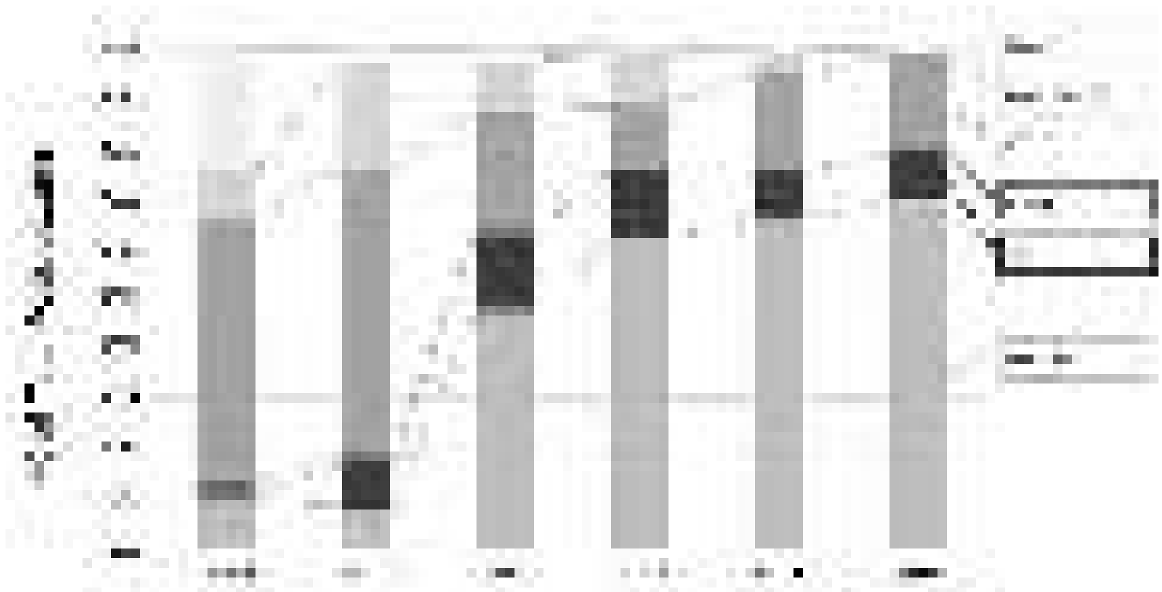

Figure 8-4. Percentages of total unconventional wastewater (as defined by PA DEP) managed via various practices for the second half of 2009 through the first half of 2014.
The volume sent to POTWs in 2013 was 0%. Note also that a majority of wastewater sent to CWTs is subsequently reused, so that when combined with "Reuse HF," the total reuse rate was approximately 90% in 2013. "Reuse HF" indicates on-site reuse. Source: Waste data from PA DEP (2015a).

Text Box 8-2. Regulations Affecting Wastewater Management.

Regulations affect wastewater management options and vary geographically as well as over time. At the Federal level, the EPA has promulgated national technology-based regulations, known as effluent limitations guidelines and standards (ELGs), for the oil and gas extraction industry, which can be found in 40 U.S. Code of Federal Regulations (CFR) Part 435. These ELGs do not apply to CBM discharges which are subject to technology based limits developed by permit writers on a case-by-case "best professional judgment" basis. The Onshore subcategory of the oil and gas, ELGs 40 CFR 125.3, Subpart C, prohibits the discharge of wastewater pollutants to waters of the United States from onshore oil and gas extraction facilities, with one exception in the arid west as discussed below. This "zero-discharge standard" means that, unless the exception applies, oil and gas wastewater pollutants cannot be discharged directly to waters of the United States. Operators have met this requirement through underground injection, reuse, or transfer of wastewater to POTWs and/or CWTs. The EPA finalized a rule in June 2016 that would prohibit operators from sending wastewater from unconventional oil and gas extraction to POTWs. Operators can continue to send wastewater to CWTs, which are subject to regulation under a separate set of ELGs in 40 CFR Part 437.

In addition, Subpart E of the oil and gas ELGs establishes an exception to the zero discharge standard west of the 98th meridian (the arid western portion of the continental United States), allowing discharges of produced water from onshore oil and gas extraction facilities to waters of the United States if the produced water has a use in agriculture or wildlife propagation when discharged into navigable waters. The term "use in agricultural or wildlife propagation" means that: (1) the produced water is of good enough quality to be used for wildlife or livestock watering or other agricultural uses; and (2) the produced water is actually put to

(*Text Box 8-2 is continued on the following page.)*

Text Box 8-2 (continued). Regulations Affecting Wastewater Management.

such use during periods of discharge (40 CFR 135.51(c)). Produced water discharged under this exception must not exceed an oil and grease concentration of 35 milligrams per liter (mg/L). Subpart E does not allow for discharge from sources other than produced water (i.e., drilling muds, drill cuttings, produced sands) to waters of the United States.

In addition to the technology-based limitations discussed above, the Clean Water Act (CWA) and the EPA's implementing regulations also require that permits include more stringent limits as necessary to meet applicable water quality standards. CWA Section 301(b)(1)(C); 40 CFR 122.44(d)(1).

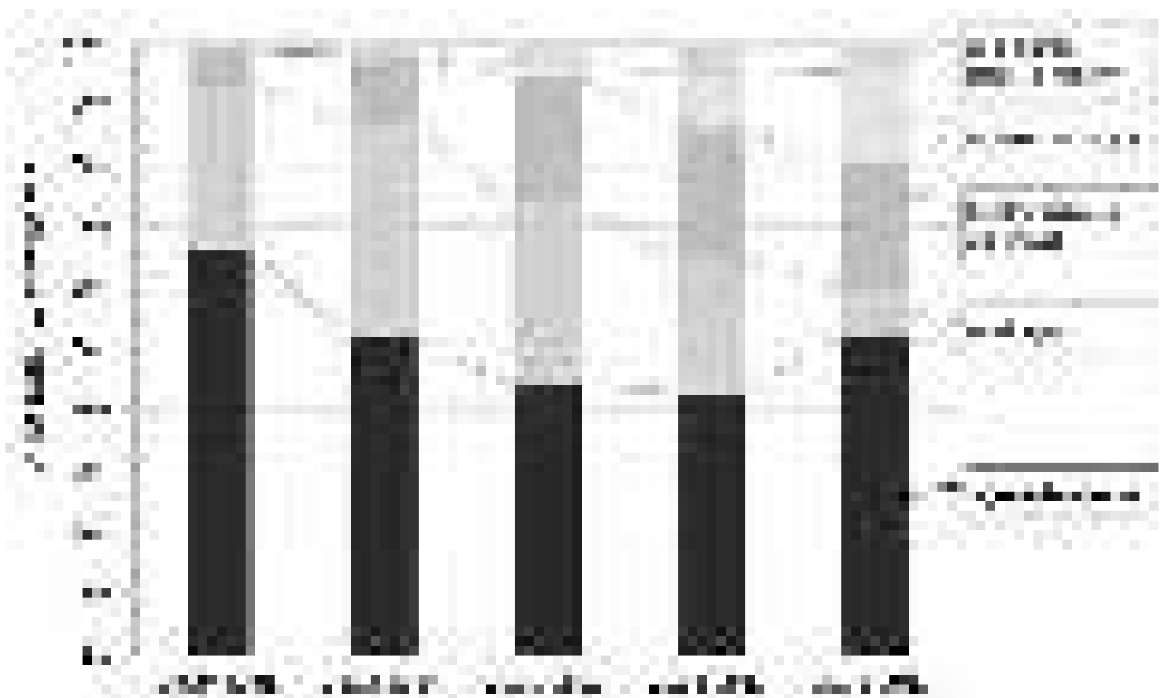

Figure 8-5. Management of wastewater in Colorado in regions where hydraulic fracturing is being performed.

See footnote for details on disposal codes.[1] Production data from Colorado Oil and Gas Conservation Commission (COGCC, 2015).

The following sections provide an overview of hydraulic fracturing wastewater management methods, with some discussion of the geographic and temporal variations in practices and their impacts on drinking water resources. In addition to currently used treatment and disposal methods, this section also briefly describes past treatment of hydraulic fracturing wastewater at

[1] Codes for wastewater disposal from COGCC are described by Veil (2015) as follows:

- Commercial disposal facility: water sent to commercial pits.
- On-site pit: most water evaporates, or excess water is hauled to disposal wells.
- Central disposal pit: Central facilities owned by a single producer to handle water from multiple wells (some recycled, much is injected).
- Injected on lease: Injected into wells, roughly half for enhanced recovery.
- Surface discharge: water is either fresh or treated to acceptable standards and discharged to surface water.

POTWs. More in-depth descriptions of treatment technologies applicable to hydraulic fracturing wastewater are available in Appendix F.

8.4.1 Underground Injection

Oil- and gas-related wastewater may be disposed of via Class II injection wells (disposal wells are referred to as Class IID whereas enhanced recovery wells are referred to as Class IIR) regulated by the UIC Program under the SDWA.[1] Nationwide, injection wells receive a large percentage of wastewater from the oil and gas industry, including wastewater associated with hydraulic fracturing. Veil (2015) estimates that in 2012, U.S. oil and gas production from onshore wells generated over 863 billion gal (20.56 billion bbls or 3.27 trillion L) of produced water, and of that volume, information on management was available for 97%. The study estimated that about 93% was injected into Class II wells, with about 47% injected into Class IID wells and 46% injected into Class IIR wells.[2]

The above national estimates are for the oil and gas industry as a whole. A good national estimate of the amount of hydraulic fracturing wastewater injected into Class II wells is difficult to develop due to lack of available information and data on injection of hydraulic fracturing wastewater. Management of hydraulic fracturing wastewater is not well tracked or made publicly available in many states (Pennsylvania being a notable exception). The local availability of Class IID wells along with generally low reuse rates, however, are consistent with Class IID wells being a primary means of wastewater management in many areas with hydraulic fracturing activity.

According to recently released data from 2012 and 2013, there are about 26,400 active Class IID wells in the United States, with more than 65% of these located in Texas, Oklahoma, and Kansas (Table 8-4). In Pennsylvania, on the other hand, there are currently nine operating disposal wells, and only three of these are commercially operated wells (at one facility) (SAFER PA, 2015). The location and number of Class IID wells is in part determined by geology (including depth and permeability of geologic formations appropriate for injection), permitting, and historical demand for disposal of oil and gas wastewater. The large Class IID well capacity in Texas, for example, is consistent with the availability of formations with suitable geology and the demand for wastewater disposal associated with a mature and active oil and gas industry. In contrast, injection plays a relatively small role in Marcellus Shale wastewater management in Pennsylvania—about 10% in 2013 and the first half of 2014 (PA DEP, 2015a).

[1] States may be given federal approval to run a UIC program under SDWA. UIC Class II wells include those used for disposal (Class IID), enhanced oil recovery (Class IIR), and hydrocarbon storage (Class IIH).

[2] Because some states surveyed by Veil (2015) do not distinguish between volumes injected for disposal versus enhanced recovery, assumptions and analyses were used in the study to estimate the two types of injection in some states.

Total		**26,400**	**41,300**	**1,050**

Abbreviations: gpd—gal per day; MGD—million gal per day.

[a] Number of active disposal wells is based primarily on data from 2012 to 2013.

[b] Typical injection volumes per well are based on historical annual volumes for injection for disposal divided by the number of active disposal wells during the same year (primarily 2012 to 2013 data).

[c] Disposal rates and volumes are unknown.

[d] These wells are not currently permitted to accept extraction wastewater from production in unconventional reservoirs.

[e] Only 24 of the 640 active disposal wells in Arkansas are in the northern half of the state, close to the Fayetteville Shale.

The decision to inject hydraulic fracturing wastewater into Class IID wells depends in part on cost, including transportation costs. Therefore, the distance between the production well and a disposal well is an important consideration. For oil and gas producers, underground injection is a low cost management strategy unless significant trucking is needed to transport the wastewater to a disposal well (U.S. GAO, 2012).

Evaluation of documented or potential impacts on drinking water resources associated with disposal at Class IID injection wells is outside of the scope of this assessment. However, disposal wells play a significant role in the overall management of hydraulic fracturing water nationwide, and their availability and capacity are integral factors in determining which wastewater management strategies are used by operators in a given region. Should the feasibility of managing wastewater via underground injection become limited or less economically advantageous, operators will need to adjust their wastewater management programs. They may evaluate and implement other local practices such as sending wastewater to a CWT for treatment and discharge or reuse.

Recent events and studies, for example, have documented a link between wastewater injection and seismic activity in some locations in several states, including Oklahoma, Colorado, New Mexico, Arkansas, and Ohio (Weingarten et al., 2015; Wong et al., 2015). The Oklahoma Geological Survey (Andrews and Holland, 2015) "considers it very likely that the majority of recent earthquakes, particularly those in central and north-central Oklahoma, are triggered by the injection of produced water in disposal wells." Walsh and Zoback (2015) correlated wastewater injection from production wells (including hydraulically fractured wells) into Oklahoma's Arbuckle formation to the steep increase in seismic events observed in that state. Farther west, in the Raton Basin of southern Colorado and northern New Mexico, Rubinstein et al. (2014) presented several lines of evidence linking injection well disposal of CBM produced water to seismic events. Horton (2012) attributed a swarm of earthquakes in Northern Arkansas to hydraulic fracturing wastewater injection, and in a study evaluating multiple states in the mid-continent region, Weingarten et al. (2015) demonstrated a relationship between Class II wells (including both Class IID and Class IIR wells) and seismicity.

The local availability of Class IID wells and the capacity to accept large volumes of wastewater could be affected by these recent findings concerning seismic activity associated with injection (U.S. EPA, 2014c). Between 2011 and 2016, some state UIC programs modified their Class II wastewater injection regulations and permitting requirements. At least eight states (Arkansas, Colorado, Illinois, Kansas, Ohio, Oklahoma, Texas, and West Virginia) consider an assessment of seismicity in their Class II programs and have regulatory provisions for banning or shutting injection wells and/or modifying injection volumes and pressures if evidence indicates that a well is near a fault and/or is contributing to seismic activity.

As an example, Oklahoma has recently taken steps to reduce the risk of induced seismicity by implementing a regional strategy intended to reduce wastewater injection in certain regions (OCC OGCD, 2016). These actions affect over 10,000 square miles and 600 wastewater injection wells in western and central Oklahoma. The measures are intended to reduce wastewater injection in the area by 40% below 2014 totals, which will affect wastewater management and disposal practices across this large area.[1]

In terms of potential impacts on drinking water resources, Class IID facilities are subject to the same general considerations regarding wastewater storage and handling as other wastewater management sites and facilities (e.g., CWTs). Changes in surface water or groundwater quality due to general wastewater handling at these facilities may be another factor affecting wastewater management practices in some locations or regions. For example, Kell (2011) identified eight groundwater contamination incidents in Texas between 1993 and 2008 due to water releases from storage facilities associated with Class II well sites. A recent study by the United States Geological Survey documented impacts on surface water from hydraulic fracturing wastewater at a Class II disposal well site in central West Virginia (Akob et al., 2016). Water samples collected downstream from the facility were indicative of wastewater from hydraulic fracturing operations handled at the site. The authors documented elevated specific conductance and elevated TDS, sodium, chloride, barium, bromide, strontium, and lithium concentrations, and different strontium isotope ratios compared to those found in upstream, background waters. The study concluded that activities at the wastewater facility have affected water quality in a nearby stream. The pathways for the movement of wastewater into the local stream include several possibilities (e.g., leaks from storage ponds and tanks, transportation activities, previous site history).

[1] For additional information on strategies and initiatives regarding wastewater injection and inducted seismicity, see the following: KDHE (2014), States First Initiative (2014), and U.S. EPA (2014c).

8.4.2 Publicly Owned Treatment Works

POTWs are designed to treat local municipal wastewater and indirect discharges from industrial users. POTWs are also used to treat wastewater and other wastes from oil and gas operations in some eastern states. Although this is not a common method of treatment for oil and gas wastewaters in the United States, the scarcity of injection wells for waste disposal in Pennsylvania drove the need for disposal alternatives (Wilson and Vanbriesen, 2012). When development of the Marcellus Shale began, POTWs were used to treat wastewater originating from these oil and gas wells (Kappel et al., 2013; Soeder and Kappel, 2009). However, elevated concentrations of constituents in wastewater from the Marcellus region (halides, heavy metals, organic compounds, radionuclides, and salts) can pass through the treatment processes commonly used in POTWs and be discharged to receiving waters (Cusick, 2013; Kappel, 2013; Lutz et al., 2013; Schmidt, 2013). In addition, sudden, extreme salt fluctuations can disturb POTW biological treatment processes (Linarić et al., 2013; Lefebvre and Moletta, 2006).

The annual reported volume of oil and gas wastewater treated at POTWs in the Marcellus Shale region peaked in 2008 and has since declined significantly (Figure 8-6). As discussed in Text Box 8-1, this was in response to an April 2011 request from PA DEP asking operators to cease sending Marcellus Shale wastewater to 15 POTWs and CWTs that were exempt from the 2010 TDS regulation (Rahm et al., 2013). Although operators complied with the request in May 2011, non-Marcellus oil and gas produced water continued to be processed at these facilities (Ferrar et al., 2013; Lutz et al., 2013; Wilson and Vanbriesen, 2012).[1] In August 2016, the EPA finalized pretreatment standards prohibiting discharges of unconventional wastewater pollutants to POTWs (U.S. EPA, 2016d).

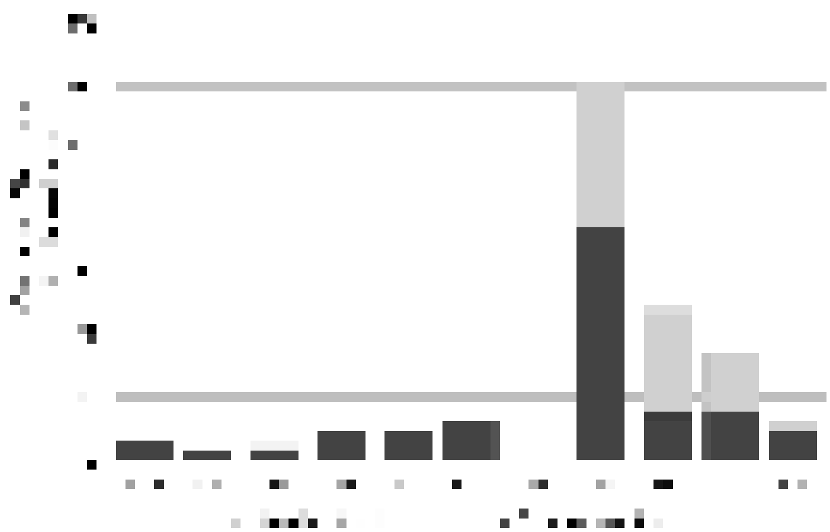

Figure 8-6. Oil and gas wastewater volumes discharged to POTWs from 2001-2011 in the Marcellus Shale. ("Conventional" is indicated by the authors as non-Marcellus wells and described as vertically drilled to shallower depths in more porous formations.)
Due to an unrecoverable data loss at the PA DEP, records for 2007 were not available. Source: Lutz et al. (2013).

[1] POTWs in Pennsylvania have likely been accepting waste considered conventional by Pennsylvania but unconventional by others based on the EPA's broader definition (Text Box 8-1).

8.4.3 Centralized Waste Treatment Facilities

A CWT facility is generally defined as one that accepts industrial materials (hazardous or non-hazardous, solid, or liquid) generated at another facility (off-site) for treatment or recovery (EPA, 2000). (Wastewater may also be treated at on-site mobile or semi-mobile facilities; see Appendix F for additional information.) The decision to treat hydraulic fracturing wastewater at a CWT and the level of treatment used depends upon several factors, such as a lack of proximity to Class II disposal wells; whether the wastewater might be reused for additional hydraulic fracturing jobs; the water quality needed if it will be reused; whether the treated wastewater can be discharged under the Subpart E agricultural and wildlife use exception in the arid west; and the water quality needed if it will be discharged to the waters of the United States. As a group, CWTs that accept oil and gas wastewater offer a wide variety of treatment capabilities and configurations (Text Box 8-3 and Appendix F).

Text Box 8-3. Wastewater Treatment Processes.

The constituents prevalent in hydraulic fracturing wastewater include TDS, TSS, radionuclides, organic compounds, and metals (Section 8.3 and Chapter 7). If the ultimate disposal or use of the wastewater necessitates treatment, a variety of technologies can be employed to remove or reduce these constituent concentrations.

The most basic treatment needed for oil and gas wastewaters, including those from hydraulic fracturing operations, is separation to remove TSS and oil and grease. This is accomplished through separation technologies including settling, skimming, hydrocyclones, dissolved air or induced gas flotation, media filtration, or biological aerated filters (Igunnu and Chen, 2014; Duraisamy et al., 2013; Barrett, 2010; Shammas, 2010).

Other treatment processes that may be used include media filtration after chemical precipitation for hardness and metals (Boschee, 2014); adsorption technologies for organics, heavy metals, and some anions (Igunnu and Chen, 2014); a variety of membrane processes (microfiltration, ultrafiltration, nanofiltration, reverse osmosis (RO)); and distillation technologies for metals and organics (Drewes et al., 2009).

Advanced processes, such as RO, or distillation methods, such as mechanical vapor recompression (MVR), are needed if the system requires significant reduction in TDS (Drewes et al., 2009; LEau LLC, 2008; Hamieh and Beckman, 2006). However, RO is typically only capable of treating TDS concentrations less than 35,000 mg/L (Shaffer et al., 2013), whereas distillation can effectively treat higher TDS waters (Hayes et al., 2014; Drewes et al., 2009). Extremely high TDS waters may require a series of advanced treatment processes, which can be very costly.

An emerging technology in hydraulic fracturing wastewater treatment is electrocoagulation, which has been used in mobile treatment systems to remove organics, TSS, and metals (Halliburton, 2014; Igunnu and Chen, 2014).

Appendix F provides more in-depth descriptions of technologies used to treat for hydraulic fracturing wastewaters and the constituents they remove. Also, Appendix Table F-4 provides an overview of influent and effluent results and removal percentages for constituents of concern at oil and gas treatment facilities reported in the literature (both conventional and unconventional) and the specific technology(ies) used to remove them. Section 8.4.7 discusses solid and liquid residuals, including treatment-related wastes.

The treated effluent from a CWT can be reused in hydraulic fracturing operations (also called zero-discharge), discharged directly to a receiving water under a National Pollutant Discharge Elimination System (NPDES) permit, discharged indirectly to a POTW, or a combination of these. Some CWTs may be configured so that they can either (1) partially treat the waste stream to suit the needs of operators who reuse it or (2) use more advanced treatment (i.e., TDS removal) if the treated wastewater will be discharged. Generally, the former option is less costly for the CWT, and some facilities that have permits to discharge do not do so continuously, opting to direct as much of the wastewater as possible for reuse. There are also CWTs permitted to discharge that do not have TDS removal capabilities. However, these facilities must still meet TDS discharge limits specified by their state. Appendix F contains additional information on treatment configurations, including examples of processes at several facilities treating oil and gas wastewater.

Facilities discharging treated wastewater to waters of the United States or POTWs are regulated under the Clean Water Act (CWA). For zero-discharge facilities, some states, including Pennsylvania and Texas, have adopted regulations to control permitting of these facilities or to encourage treatment and reuse. The PA DEP issues permits that allow zero-discharge CWTs to treat and release water back to oil and gas industries for reuse (see the Eureka Resources Facility in Williamsport, PA listed in Appendix Table F-6 as an example of a zero-discharge facility).[1]

In developing this assessment, we looked at NPDES permit information for several CWTs in the eastern United States treating wastewater from the Marcellus region and one near the Fayetteville Shale in Arkansas. The facilities include those with and without TDS removal capabilities, and some are undergoing upgrades to implement TDS removal. Some of the permits reviewed for this assessment are current, and others are expired and may be in the process of renewal. The permits require monitoring (with or without limits) for a range of constituents that may include chloride, TDS, TSS, total strontium, total barium, oil and grease, heavy metals, 5-day biological oxygen demand (BOD5), and a range of organic compounds (e.g., phenol, cresol, BTEX, phthalates), with the specific constituents varying by permit. Sample types for the facilities are generally 24-hour composites. The newer permits set limits for several important constituents such as chloride, TDS, TSS, total barium, total strontium, oil and grease, and a number of heavy metals. Bromide is generally either not included or is required to be reported but with no limit specified. However, limits on TDS will reduce bromide concentrations. Some permits require monitoring for total radium, uranium, and gross alpha, but no limits are specified. Note that these facilities do not necessarily discharge consistently because treated wastewater can be sent for reuse.

Although there are CWTs serving hydraulic fracturing operations throughout the country, the majority serve Marcellus Shale operations in Pennsylvania (Boschee, 2014). Of the 74 CWT facilities identified by the EPA (U.S. EPA, 2016d) as having accepted or having the ability to accept hydraulic fracturing wastewater (not counting facilities treating CBM wastewater), 40 are located in Pennsylvania (Table 8-5). Most are zero-discharge facilities, and many do not have treatment processes for TDS removal. Although several Pennsylvania facilities are permitted to discharge, Wunz (2015) found few that currently discharge (two CWTs in Pennsylvania, one in West Virginia,

[1] The facility is also permitted for indirect discharge to the Williamsport Sewer Authority.

Total		**44**	**13**	**9**	**0**	**1**	**7**	**74**

[a] Information is current as of 2014; it is possible that since 2014, some listed CWT facilities have closed and/or new CWT facilities not listed have begun operation. The number of facilities includes those that have not yet opened but are under construction, pending permit approval, or are in the planning stages. Facilities that are not accepting hydraulic fracturing wastewater but plan to accept it in the future are noted parenthetically and not included in the sum of total known facilities. Facilities handling CBM wastewater are not represented here.

and one in Ohio). According to EPA research (U.S. EPA, 2016d), the number of CWT facilities serving operators in the Marcellus and Utica Shales has increased since the mid-2000s, growing from roughly five in 2004 to over 40 in 2013. A similar trend has been noted for the Fayetteville Shale region in Arkansas, where there are fewer Class IID injection wells compared to the rest of the state (U.S. EPA, 2016d).

In other regions, a small number of newer facilities have emerged in the last several years, most often with TDS removal capabilities. In Texas, for example, two zero-discharge facilities with TDS removal capabilities are available to treat wastewater from the Eagle Ford Shale (beginning in 2011 and 2013), and one zero-discharge facility with TDS removal is located in the Barnett Shale region (operational since 2008). In Wyoming, there are four facilities in the region of the Mesaverde/Lance formations that started operating between 2006 and 2012. Two are zero-discharge facilities, and two have multiple discharge options; all are capable of TDS removal (U.S. EPA, 2016d).

Few states maintain a comprehensive list of CWT facilities, and the count provided by the EPA (U.S. EPA, 2016d) includes facilities that do not currently but plan to accept wastewater from unconventional formations. Therefore, the data in Table 8-5 do not precisely reflect the number of facilities currently handling hydraulic fracturing wastewaters. Other sources indicate either use of, or interest in, development of treatment facilities in other regions such as the Barnett Shale region (Hayes and Severin, 2012b), the Fayetteville (Veil, 2011), and other areas in Texas and Wyoming (Boschee, 2014, 2012). In addition, news releases and company announcements indicate that other wastewater treatment facilities are being planned (Greenhunter, 2014; Geiver, 2013; Purestream, 2013; Alanco, 2012; Sionix, 2011).

Use of specific types of CWTs has and will continue to shift due to drivers such as availability and cost of other disposal options (e.g., disposal wells), operator demand for reuse and the associated quality needed, developments in treatment, treatment costs, and regulatory changes. Practices in Pennsylvania over the last several years provide such an example. Between 2010 and 2013, the percentage of Marcellus wastewater treated at CWTs dropped from 52% to 20% (Figure 8-4), and the percentage of wastewater reused on-site rose to 65%, reflecting a shift in practice among operators. Among the percentage of the wastewater sent to CWTs, the portion sent to zero-discharge facilities for subsequent reuse rose from 10% to 65%. This is consistent with an increased emphasis on reuse in Pennsylvania. (See Section 8.4.4 for a discussion on reuse as a waste management practice.)

8.4.3.1 Relationship to Potable Surface Waters

Figure 8-7 shows the relationship between Pennsylvania potable water supplies and the CWTs that lie in their upstream watersheds. These surface waters, including streams, rivers, and waterbodies (e.g., lakes and reservoirs) have been evaluated by the PA DEP for attainment of a designated use of potable water supply as per the CWA Section 305(b) reporting and Section 303(d) listing. Ninety-four percent of the waterbodies and 98% of the streams and rivers were attaining their designated use in 2016. These stream segments may or may not currently have intakes for drinking water treatment plants. The map also shows the locations and types of CWTs that either currently accept unconventional oil and gas wastewater (as defined by PA DEP) or have accepted such wastewater

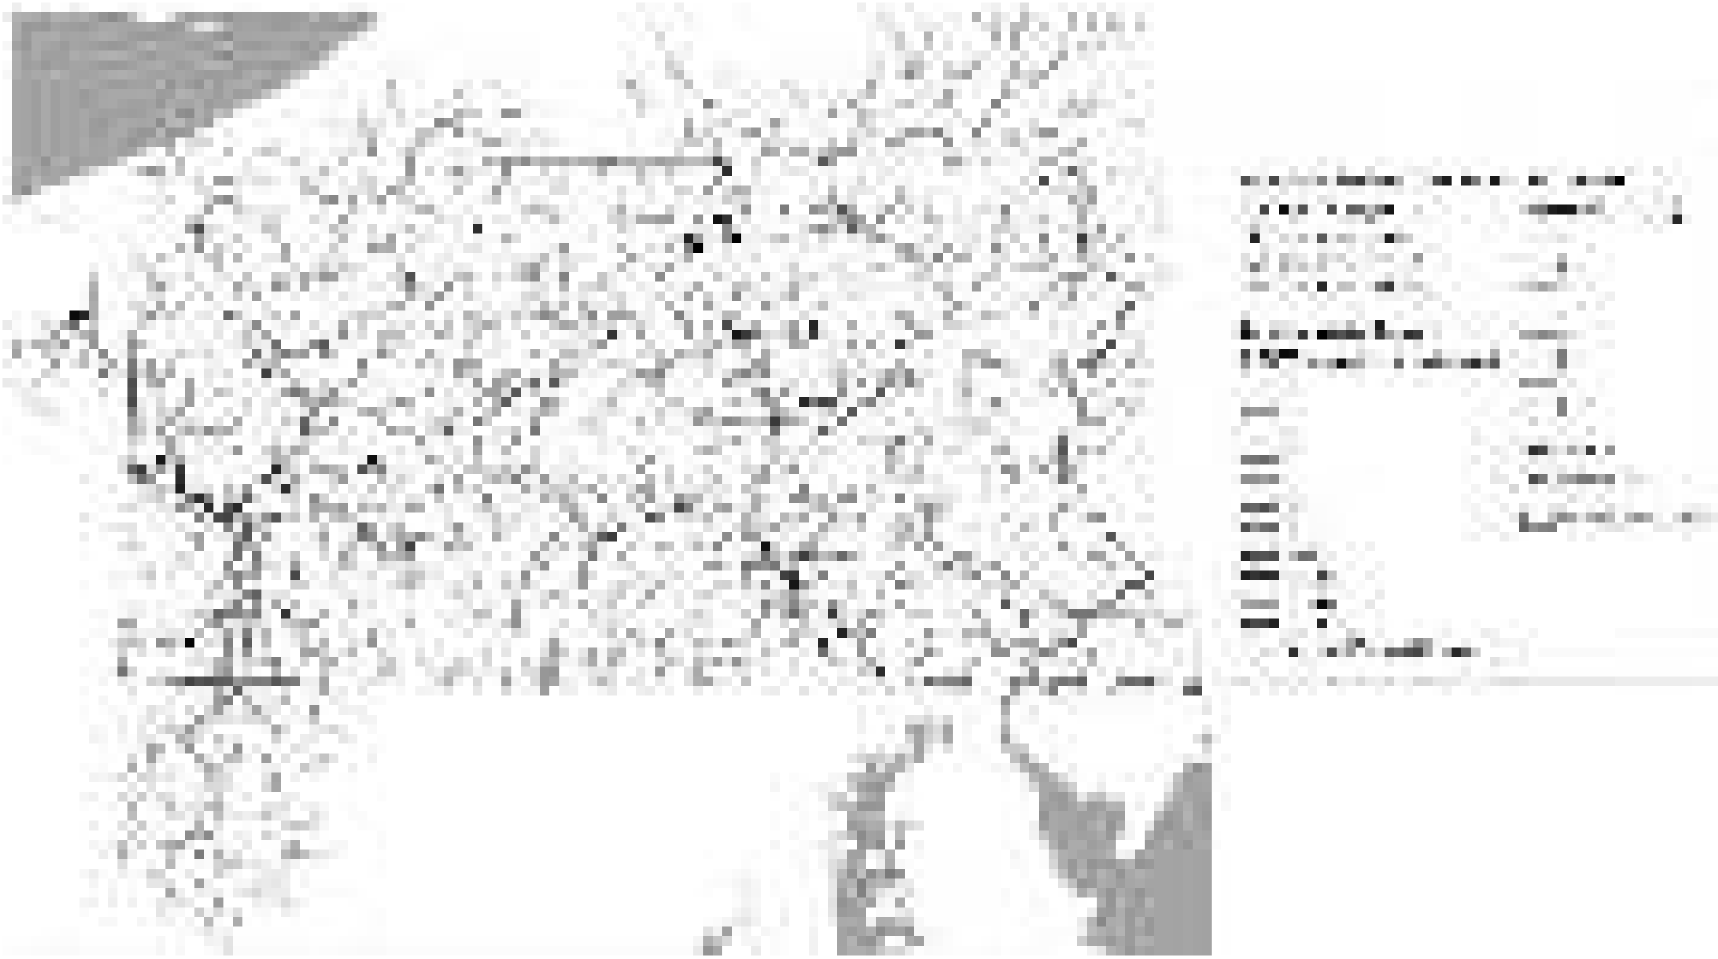

Figure 8-7. Map showing Pennsylvania surface water designated as potable water supplies and upstream CWTs.
Surface waters are colored orange to red to indicate the number of CWTs located in the upstream watershed. Blue surface waters have no upstream CWTs, and light gray lines show those not designated as potable water supplies. Symbols show the locations of CWTs that currently accept or have accepted unconventional oil and gas wastewater. Data sources: U.S. EPA (2016d), U.S. EPA (2016f), and PA DEP (2016b).

within approximately the last five years.[1] CWTs represented include both dischargers (direct and indirect) as well as zero-discharge facilities. For some facilities, we were not able to determine if the facility was zero-discharge or if it has a NPDES permit. The surface waters have been color-coded to indicate the number of CWTs that are located upstream. Darker red indicates more CWTs located in the upstream watershed, while blue indicates no upstream CWTs. Softer grey lines show portions of the stream network not designated for potable water supply. The thickness of the line indicates the size of the stream or river, categorized by the "stream order" designation.

The map provides a general illustration of how CWTs are situated within catchments in Pennsylvania, showing their spatial and general hydrologic relationships to streams that can serve as potable water supplies. The map shows that a given stream or waterbody may have a number of CWTs upstream, potentially contributing to combined impacts on surface water if there are spills or inadequately treated discharges. Note that the upstream catchment areas are large for the major rivers. Therefore, some rivers, such as the Ohio or Susquehanna, have as many as 15 or 16 upstream CWTs, although most are located far away. The map does not represent the effects of dilution on either discharges or spills; such an evaluation would necessitate currently unavailable data required to do a complete analysis of water quality. Note that many of the CWTs are zero-discharge facilities, and those that are permitted to discharge may do so intermittently. However, the storage and handling of wastewater at CWTs could impact nearby surface water through leaks and spills.

To more completely place these facilities in a watershed context, other types of discharges that could be occurring upstream should be taken into consideration. Impacts from hydraulic fracturing wastewater may be more problematic if there are additional pollutant sources within the watershed, increasing the cumulative effects of discharges and spills. For example, an EPA source apportionment study (U.S. EPA, 2015o) evaluated the relative contributions of bromide, chloride, nitrate, and sulfate from CWTs primarily treating hydraulic fracturing wastewater to the Allegheny River Basin and to two downstream public water system intakes. The study considered that the Allegheny River and its tributaries also receive runoff and discharges from an array of sources that include acid mine drainage and mining operations, coal-fired electric power stations, industrial wastewater treatment plants, and POTWs. It was concluded that CWTs treating oil and gas wastewater and coal-fired power plants with flue gas desulfurization were the primary contributors of bromide and chloride at the intakes (see Section 8.5.1 for further discussion), while nitrate and sulfate contributions were from POTWs and Acid Mine Drainage (U.S. EPA, 2015o).

8.4.3.2 Potential Impacts from CWTs

The potential impacts of managing hydraulic fracturing wastewater at CWTs depend on whether the CWT adequately treats for constituents of concern prior to discharge to surface water or a POTW, and whether treatment residuals are managed appropriately. Historically, CWTs have not

---

[1] The list of CWTs used to develop this map is based on best available data, including information in the technical development document supporting the new EPA unconventional oil and gas effluent limitation guidelines (U.S. EPA, 2016d) as well as data from PA DEP waste records. This information was supplemented with other publicly available descriptions of the facilities. The information may, however, not be complete, and the symbols may not definitively reflect the discharge status of a facility.

included processes to treat for constituents that are difficult to remove, such as the high concentrations of TDS found in wastewater from unconventional reservoirs. As a result, impacts on drinking water resources have included increased suspended solids and chloride concentrations downstream of discharging facilities that were accepting hydraulic fracturing wastewater (Olmstead et al., 2013) and elevated bromide concentrations and radium concentrations in CWT effluent (Warner et al., 2013a); see Sections 8.5.1 and 8.5.2. In addition, spills and leaks can occur in pits or impoundments associated with the storage of treated wastewater at CWTs (impacts related to spills and leaks from pits and impoundments are discussed in Section 8.4.5). Wastewater being transported by truck or pipeline to and from a CWT can also present a vulnerability for spills or leaks (Easton, 2014) (Chapter 7).

While selection of appropriate treatment processes is critical for CWTs that discharge to surface waters, there are also two important issues related to completeness of treatment that can have an impact. First, there may be unknown constituents in the wastewater. The effectiveness of treatment cannot be evaluated for constituents for which the wastewater has not been tested. This makes it challenging to know the degree to which effluent from a CWT is protective of public health. Second, even an efficient treatment process may not be able to reduce the concentrations of some constituents to levels that allow for discharge to a drinking water resource if influent concentrations are so high that they exceed the capabilities of the treatment technology(ies) to meet those discharge limits. For example, a facility described by Kennedy/Jenks Consultants (2002) removed a high percentage of boron (88%), but the effluent concentration of 1.9 mg/L (average influent concentration of 16.5 mg/L) was not low enough to meet California's action level of 1 mg/L. Thus, the influent concentration must be considered together with removal efficiency to determine whether the effluent quality will meet the requirements dictated by end use or by regulations.

Relatively few studies describe the ability of individual treatment processes to remove constituents from hydraulic fracturing wastewater. For this assessment, simple estimated effluent concentrations were calculated for several combinations of unit treatment processes, wastewater constituents, and influent concentrations (details are given in Appendix Table F-3). The purpose of the analysis was to illustrate the relative capabilities of a number of treatment processes and not to represent a complete treatment system. As an example, the estimates suggest that if wastewater contains radium with a concentration in the thousands of pCi/L, a 95% removal rate with chemical precipitation may result in an effluent that exceeds 100 pCi/L. Treatment of the same wastewater via distillation or reverse osmosis could result in effluent concentrations in the tens of pCi/L. This analysis suggests that attention should be paid to the capabilities of a planned treatment system for the full range of anticipated wastewater compositions.

To gain a better understanding of impacts, the USGS has conducted sampling for a wide array of water quality parameters in surface water and groundwater in the Monongahela River Basin in West Virginia to establish baseline water-quality conditions (Chambers et al., 2014). Future water quality sampling can be compared to this baseline to assess impacts from hydraulic fracturing activities. To address past impacts, Pennsylvania, having experienced water quality impacts on receiving streams due to discharges of high-TDS effluent modified their regulations to address these issues by setting water quality standards for CWT dischargers (Mauter and Palmer, 2014; Shaffer et al., 2013). (See Text Box 8-1.)

8.4.4 Wastewater Reuse for Hydraulic Fracturing

The reuse of hydraulic fracturing wastewater for subsequent hydraulic fracturing operations has increased in some regions of the country in recent years (Boschee, 2014, 2012; Gregory et al., 2011; Rassenfoss, 2011).[1] This practice is driven by factors that include cost (including treatment costs), the lack of availability of other management options (e.g., Class II disposal wells), and changes to state regulations (Boschee, 2014; Shaffer et al., 2013). Wastewater quality is a consideration; some constituents pose challenges for reuse and may necessitate treatment. For example, high concentrations of barium and sulfate can lead to scaling, and the presence of some constituents in wastewater can hinder crosslinking (Akob et al., 2016; Boschee, 2014). Hydraulic fracturing fluid formulations that can use high TDS waters (e.g., as high as 150,000 mg/L to over 300,000 mg/L) facilitate reuse with minimal treatment (Boschee, 2014; Mauter and Palmer, 2014). See Chapter 5 for more information regarding the chemical composition of hydraulic fracturing fluids and Appendix F for more discussion of considerations for reuse.

Reuse can be accomplished by blending either untreated or minimally treated hydraulic fracturing wastewater with fresh water to lower the TDS content (Boschee, 2014). Wastewater may be reused at a site with multiple wells, eliminating the need for transport to a CWT (Lester et al., 2015; Easton, 2014). Alternatively, wastewater can be treated at a CWT and then taken by operators for mixing with other water sources for reuse (Easton, 2014). Flowback may be preferable to later-stage produced water for reuse because of its lower TDS concentration. Also, it is typically generated in larger quantities from a single location as opposed to water produced later on, which is generated in smaller volumes over time from many different locations (Barbot et al., 2013; Maloney and Yoxtheimer, 2012). Reuse can reduce the costs associated with water acquisition and produced water management. Such economic and logistical benefits can be expected to inform ongoing wastewater management decisions.

Costs can be the most significant driver for reuse. For example, the costs of transporting wastewater from the generating well to the treatment facility and then to the new well can be weighed against the costs for transport to alternative locations (e.g., a disposal well). Trucking large quantities of water can be relatively expensive—from \$0.01 to \$0.19 per gallon (\$0.50 to \$8.00 per bbl)—rendering on-site treatment technologies and reuse economically competitive in some settings (Dahm and Chapman, 2014; Guerra et al., 2011). Reuse rates may also be driven by wastewater production rates compared to the demand for reuse, with both production and demand increasing in a region if more wells go into production or decreasing as plays mature (Lutz et al., 2013; Hayes and Severin, 2012b; Slutz et al., 2012). Other logistics to consider include proximity of the water sources for aggregation and sequencing of completion schedules (Mauter and Palmer,

[1] Reused hydraulic fracturing wastewater is discussed in Chapter 4 of this report (Water Acquisition) as well as in this chapter, though in a different context. The wastewater reuse rate described in this chapter is the amount or percentage of generated hydraulic fracturing wastewater that is managed through use in subsequent hydraulic fracturing operations. In contrast, Chapter 4 discusses reused wastewater as a source water and as one part of the base fluid for new fracturing fluid.

2014). A small survey by Mauter and Palmer (2014) indicates that the scheduling of well completions is complex, requiring optimization of labor, contractual issues, equipment usage, and water storage capacity among other factors. Boschee (2014) notes that in the Permian Basin, older conventional wells are linked by pipelines to a central disposal facility, facilitating movement of treated water to areas where it is needed for reuse. Companies drilling fewer wells or located in more remote areas may find reuse difficult because of challenges in consolidating wastewater from their wells or accessing wastewater from centralized facilities.

Regulations may also encourage reuse. For example, in 2013, the Texas Railroad Commission adopted rules eliminating the need for a permit when operators reuse on their own lease or transfer the fluids to another operator for reuse (Rushton and Castaneda, 2014). Any information on wastewater management practices in Texas that becomes available for the years after 2013 will allow evaluation of whether reuse has in fact increased.

A summary of reuse practices throughout the United States is hampered by the limited amount of data available for many regions of the country. However, current data indicate that extensive reuse takes place in the Marcellus region. Several studies using data from PA DEP data show that total reuse rates of oil and gas wastewater in Pennsylvania have risen over the last several years to between 85 and 90% (Table 8-6). This includes wastewater sent to CWTs to treat for reuse as well as reuse at the well sites without transfer to a CWT (labeled as "Reuse HF" in Figure 8-4). In particular, reuse of Marcellus wastewater at well sites in Pennsylvania has risen from about 8% in the second half of 2010 to nearly 70% in the first half of 2014 (PA DEP, 2015a). Schmid and Yoxtheimer (2015) report more recent data stating that in 2014, approximately 85% of Marcellus hydraulic fracturing wastewater was reused. Of that amount, 78% occurred on-site, and 22% was via CWTs.

Table 8-6. Estimated percentages of reuse of hydraulic fracturing wastewater.

[a] Studies focusing on the Marcellus Shale use waste data reports from PA DEP.

Reuse in the Marcellus region is higher in the northeastern part of Pennsylvania than in the southwestern portion where easier access to Class IID wells in Ohio makes disposal by injection more feasible (Rahm et al., 2013). Outside of the Marcellus region, reuse rates are lower. Ma et al. (2014) note that only a small amount of reuse is occurring in the Barnett Shale. Reuse has not yet been pursued aggressively in New Mexico or in the Bakken (North Dakota) (Horner et al., 2014; LeBas et al., 2013). Other sources, however, indicate growing interest in reuse, as evidenced in specialized conferences (e.g., "Produced Water Reuse Initiative 2014" on produced water reuse in Rocky Mountain oil and shale gas plays), and available state-developed information on reuse (e.g., fact sheet by the Colorado Oil and Gas Conservation Commission) (Colorado Division of Water Resources et al., 2014).

If hydraulic fracturing activity slows in an area that is currently reusing wastewater, demand for the wastewater may decrease and wastewater management practices may shift. Analysis by Wunz (2015) and data in Figure 8-1 suggest a decline in wastewater production in Pennsylvania. Wunz (2015) also notes that in the future, there could be a trend of more wastewater coming from late-stage produced water and less from flowback as more wells are in the production phase and fewer wells are being fractured. If the demand drops relative to production due to fewer wells being drilled and fractured, then the "excess" produced water will need to be managed by other means. Alternatives to reuse may include increased transport to disposal wells (e.g., those in Ohio), development of more disposal wells in Pennsylvania, or advanced treatment and discharge to surface water via CWTs that have TDS removal capabilities (SAFER PA, 2015; Wunz, 2015; Silva et al., 2014a).

8.4.4.1 Potential Impacts from Reuse

For companies employing reuse as a wastewater management strategy, surface spills and leaks can occur during wastewater transport to and from a treatment facility or from storage tanks/pits located at the treatment facility or at the well site. Releases may be due to failed infrastructure such as tank or pipe ruptures, from natural disasters such as floods or earthquakes, or incidents such as overfills, improper operations, or vandalism (CCST, 2015a; NYSDEC, 2011). If the spill or leak is not contained or otherwise mitigated, these releases could reach groundwater or surface water (CCST, 2015a; NYSDEC, 2011). See Chapter 7 for more discussion on types of spills associated with hydraulic fracturing activities, including storage and transport. See Section 8.4.5 for discussion of storage pits and associated impacts on drinking water resources.

With reuse there is the potential for accumulation of dissolved solids such as salts and TENORM in the wastewater over successive reuse cycles (see Section 7.3.4.6 and Section 8.5.2 for more information about TENORM). Because wastewater is often reused with minimal treatment, constituents resulting from time spent in the subsurface remain in the wastewater and can increase during additional hydraulic fracturing. This potentially concentrated wastewater can pose a bigger issue if a breach occurs in an on-site pit or tank storing this wastewater while awaiting reuse (Section 8.4.5; Chapter 7).

The issue of concentrating contaminants during reuse has not yet been quantitatively evaluated in the literature. Also, it is not known how much this problem would be mitigated due to the dilution of wastewater when reused as new fracturing fluid. Estimates of the percentages of reused wastewater in new fracturing fluids in Pennsylvania range from about 2% in 2009 to as much as 22% in 2013 (SRBC, 2016; Schmid and Yoxtheimer, 2015) (Chapter 4). However, data from Pennsylvania's TENORM study (PA DEP, 2015b) showed radium in some hydraulic fracturing fluids, presumably from a reused wastewater component. As reused wastewater continues to accumulate contaminants, the water will eventually need to be managed, either through treatment or injection.

8.4.5 Storage and Disposal Pits and Impoundments

The use of pits and impoundments as part of a wastewater management strategy is a historic as well as current practice in the oil and gas industry. These structures are either used for temporary storage (on-site at oil and gas production wells or off-site at CWTs or disposal wells) or they are intended for permanent disposal (evaporation or percolation). There are a variety of terms to describe these structures depending upon their use (Richardson et al., 2013); "pits," "impoundments," and "reserve pits" are some of the more common terms associated with wastewater management. The terms "impoundment" or "pond" are often used to refer to large area holding structures and are also used by some states for specific applications such as holding "freshwater" for fracturing fluid formulation (Quaranta et al., 2012). Definitions and terminology are not standardized and vary from state to state (Richardson et al., 2013). For the purposes of this section, the nomenclature will defer to the term used by the original author/regulating authority.

States govern the use and permitting of pits under their jurisdiction. Regulations vary from state to state regarding the circumstances in which pits can be used (e.g., chemical composition of the fluid), how they should be constructed, and whether they must be lined (e.g., proximity to drinking water resources and/or chemical composition of the fluid) (Richardson et al., 2013). Most states restrict the use of wastewater pits in environmentally sensitive areas. To avoid contamination events, some states are moving toward requiring closed loop systems (i.e., tanks) or injection wells rather than using pits for hydraulic fracturing wastewater storage. For example, Pennsylvania has modified their regulations (published October 8, 2016) to ban the use of pits for temporary storage of unconventional (as defined by PA DEP) wastewaters; many operators have already moved to closed-loop systems (PA DEP, 2016a). This development is particularly notable because of

Pennsylvania's heavy reliance on reuse for wastewater management, necessitating both on-site and off-site storage.

8.4.5.1 Locations and Numbers of Pits

The locations and number of existing pits (both for storage and for disposal) are not well documented in all states, and in the data found, pits associated with hydraulic fracturing operations were not specifically identified. With respect to larger pits for storage or disposal of wastewater, some states (e.g., Utah and Oklahoma) provide locational data on their websites. In 2016, the state of California began posting the number of active and inactive oil field produced water "ponds" (defined as unlined surface impoundments), both permitted and unpermitted, on their website. The July 2016 posting showed that 64% (682) of the 1,065 unlined ponds identified in the Central Valley and Central Coast of California were active. Of the active ponds, 21% (144) were not permitted (CA Water Board, 2016). Active ponds are primarily found in the southern San Joaquin Valley (CCST, 2015a). The EPA Region 8 conducted a survey of pits associated with oil and gas operations in Colorado, Montana, North Dakota, South Dakota, Utah, and Wyoming from 1996 through 2002. Results indicated there were approximately 28,000 pits at that time (U.S. EPA, 2003b).

In the absence of an inventory of pits in Pennsylvania, the organization SkyTruth led an effort using volunteers to produce a map of pits believed to be associated with drilling and hydraulic fracturing the Marcellus Shale (Manthos, 2014). The identification of pits was based on USDA aerial imagery taken in 2005, 2008, 2010, and 2013. SkyTruth acknowledges the uncertainties associated with identifying pits based on aerial images and volunteer labor. They have described their methodology as including multiple reviewers and QA/QC procedures. The study cannot differentiate ponds for drilling fluids and fracturing fluids from those for wastewater. Their preliminary findings indicate that the estimated number of ponds rose from 11 in 2005 to 529 in 2013, with the structures themselves increasing in size from a median size of 3,713 ft^2 (345 m^2) in 2005 to 66,844 ft^2 (6,210 m^2 in 2013. SkyTruth also notes that impoundments are not permanent and that of 581 ponds delineated in 2010, only 116 of them were found in the images from 2013.

Evaporation ponds, referred to as Commercial Oil Field Waste Disposal Facilities (COWDFs), are a waste management strategy most commonly used in the western states such as Utah, Wyoming, and Colorado (USFWS, 2014). According to a 2016 list of approved COWDFs posted by the Utah Division of Oil, Gas, and Mining (Utah Division of Oil, 2016), 20 facilities in Utah are approved to accept produced water. All are in the eastern part of the state where the Uinta and Paradox basins are found (unconventional shale formations). The Wyoming Department of Environmental Quality website, accessed in 2016, lists 35 active COWDFs (WDEQ, 2016b). The increase in hydraulic fracturing activity in Wyoming has resulted in significant increase in wastewater disposed of in COWDFs (USFWS, 2014). Data from the Colorado Oil & Gas Conservation Commission includes eight active evaporation pits, five of which are unlined (COGCC, 2016). Ninety-five other active pits are listed in Colorado, with descriptors such as "production," "multi-well pit," "skim," or "produced water." Seventy-one of these are unlined, and 22 have synthetic liners. Eleven pits are located in

Garfield County, where there is hydraulic fracturing activity. The Colorado data do not distinguish pits at centralized commercial facilities from on-site pits.

8.4.5.2 Unlined Storage Pits and Percolation Pits

Whether an unlined pit is designed and intended to percolate wastewater into the ground for disposal or if it is built for storage, it provides a pathway for wastewater to infiltrate into the subsurface and potentially reach groundwater. Such pits have been used historically for conventional oil and gas wastewater. More recently, they have received wastewater in areas where hydraulic fracturing takes place. States such as Montana and Wyoming allow unlined pits to be used for storage if the quality of the waste fluid meets specified limits and the pit is not in close proximity to environmentally sensitive areas such as drinking water resources, wetlands, and floodplains (Kuwayama et al., 2015b; Richardson et al., 2013).

In the past, several states have allowed unlined pits designed to dispose of wastewater via percolation into the subsurface. For example, until July 2015, percolation pits were permitted for wastewaters from hydraulically fractured wells in the Central Valley Region in California (Grinberg, 2016). The California Department of Conservation's Division of Oil, Gas, and Geothermal Resources (DOGGR) listed "evaporation-percolation" as the management method for almost 60% (190 million gal) of the wastewater generated via well stimulation in Kern County between 2011 and 2014 (CCST, 2015a). However, according to DOGGR's 2015 report addressing well stimulation activities in Kern County from January 1, 2014 through September 30, 2015, evaporation/percolation was not employed as a disposal option during that period (98% of the produced water was disposed of via operator-owned Class II injection wells, 1.75% was disposed of via commercial Class II injection wells, and 0.16% was reused).

While the practice of disposal via percolation pits has been discontinued in most states, as of July 2016, Wyoming's regulations still allow the use of percolation for disposing produced water specific to CBM operations in the Powder River Basin. To be permitted, the operator must demonstrate that the disposed fluid will comply with water quality standards of the Department of Environmental Quality (WYOGCC, 2015).

8.4.5.3 Evaporation Ponds

Evaporation is a simple water management strategy involving transporting wastewater to a pond or pit with a large surface area and allowing passive evaporation of the water from the surface (NETL, 2014; Clark and Veil, 2009). As discussed above, this disposal option, often referred to as a COWDF, is practical for drier climates of the western United States. Evaporation ponds have been used for oil and gas wastewater disposal in Montana, Colorado, Utah, New Mexico, and Wyoming (Veil et al., 2004). However, New Mexico no longer allows the use of pits for disposal (NM EMNRD OCD, 2013), and in Montana, evaporation ponds are no longer allowed because they do not put extracted water to a beneficial use (NRC, 2010). Figure 8-8 shows an example of a lined evaporation pit in Montana (DOE, 2006).

Figure 8-8. Lined evaporation pit in the Battle Creek Field (Montana).
Source: DOE (2006). Reproduced with permission from ALL Consulting.

As the water component of the wastewater is subject to evaporation, the fluid remaining in the pond becomes concentrated, and a sludge layer is formed. Remaining residual brines in the pond can be collected and disposed of via an underground injection well, and the solids can be taken to a landfill (see Section 8.4.7 for more details). In cold, dry climates, a freeze-thaw evaporation method has also been used to purify water from oil and gas wastewater (Boysen et al., 1999).

Nowak and Bradish (2010) describe the design, construction, and operation of two large commercial evaporation facilities in Southern Cross, Wyoming and Danish Flats, Utah. Each facility includes 14,000 gal (53,000 L) three-stage concrete receiving tanks, a sludge pond, and a series of five-acre (20,234 m^2) evaporation ponds connected by gravity or force-main underground piping. The Wyoming facility, which opened in 2008, consists of two ponds with a total capacity of approximately 84 million gal (2 million bbls or 318 million L). The Utah facility, open since 2009, consists of 13 ponds with a total capacity of approximately 218.4 million gal (5.2 million bbls or 826.6 million L). Each facility receives 0.42 to 1.47 million gal (10,000 to 35,000 bbls; 1.59 million to 5.56 million L) of wastewater per day from oil and gas production companies in the area.

Evaporation ponds or pits are subject to state regulatory agency approval and must meet state standards for water quality and quantity (Boysen et al., 2002).

8.4.5.4 Impacts and Potential Impacts from Pits and Impoundments

Pits containing hydraulic fracturing wastewater have the potential to impact drinking water resources if spills and overflows cause runoff to surface water or if wastewater percolates through the soil and reaches groundwater. In addition to contaminants in the wastewater itself, wastewater that reaches groundwater may mobilize constituents in pit bottoms or soils, and it may also reach hydrologically connected surface water. These impacts are amplified with increasing pit/impoundment size (Quaranta et al., 2012). Percolation may be accidental (through tears or improper installation of liner) or by design in unlined pits (Sumi, 2004).

Compromised pit liners can result in leaks, and extreme weather events, such as floods, can cause pits to overflow. An analysis of three state databases (New Mexico, Oklahoma, and Colorado) where pits and tanks have been used for storage of hydraulic fracturing wastewater found that for pits, the most common causes of spills were from overflows and liner malfunctions (Kuwayama et al., 2015b). For instance, of the 106 pit-related spills reported in New Mexico between 2000 and 2014, 33% were due to overflows and 26% were caused by liner malfunctions. Of the 62 tank spills reported, 44% were due to leaks, and 27% were related to overfilling (Kuwayama et al., 2015b). The types of constituents in pits that may be of concern from such events include VOCs, metals, TDS, oil, and TENORM (Kuwayama et al., 2015b).

Operational factors also influence potential impacts from pits and impoundments. These can include water level management (influent, seepage, spillage), the length of time water is stored in the pit/impoundment, the composition of the water, the local climate (rainfall and/or evaporation), and the transmission method (piped or delivered in an open channel) (NRC, 2010).

Construction and Capacity Issues

Construction requirements typically include specifications for features that can reduce the potential for impacts on groundwater or surface water. These can include liner specifications, depth to groundwater, secondary containment, setback requirements, freeboard, leak detection, and water quality monitoring (Kuwayama et al., 2015b).[1,2] For example, in a 2012 review of 19 states with shale gas development or potential for shale gas development, many states had setback requirements for pits in sensitive areas including surface water, wetlands, and floodplains. As of December 2015, however, 12 of the 19 states surveyed did not include setback requirements in their regulations. Many states did address the vertical separation of pits from the water table (e.g., 20 in (0.5 m) to seasonal high water table in PA; 10 ft (3 m) in WY; 50 ft (15 m) in NM) (Kuwayama et al., 2015b).

Despite construction standards, impacts on groundwater or surface water due to overflows, liner breaches, and other construction issues have been documented. In 2007 in Knox County, Kentucky, retention pits holding hydraulic fracturing flowback fluids overflowed into Acorn Fork Creek during the development of four natural gas wells (CCST, 2015a; Papoulias and Velasco, 2013). The incident caused the pH of the creek to drop from 7.5 to 5.6 and the conductivity to increase from 200 to 35,000 μS/cm. In addition, organics and metals including iron and aluminum formed precipitates in the stream. Fish and aquatic invertebrates were killed or distressed in the area of the stream affected by the release (Papoulias and Velasco, 2013).

---

[1] Setback is the distance between the pit and a stream, lake, building, or other feature or structure that needs protection.

[2] Freeboard is the vertical distance between the level of the water in an impoundment and the overflow elevation (an outfall or the lowest part of the berm).

Similarly, in 2009, Marcellus wastewater stored in an impoundment from a hydraulic fracturing operation in Washington County, Pennsylvania overflowed the bank of the impoundment and reached surface water (a tributary of Dunkle Run) (CCST, 2015a). NRC (2010) reported continuous overfilling of an impoundment in the Powder River Basin (Wyoming) with CBM produced water, resulting in significant erosion of a seasonal water channel. The CBM operator was required through litigation to manage flows to the impoundment to prevent overflows. The literature did not report specific impacts on groundwater or surface water from the Pennsylvania or Wyoming incidents.

In Pennsylvania in 2010, pit liner failure was reported to have impacted groundwater through leakage of Marcellus wastewater from six impoundments (Colaneri, 2014). Ziemkiewicz et al. (2014) note that a study of 15 pits and impoundments in West Virginia found that slope stability and liner deficiencies were common problems. Construction quality control and quality assurance were often inadequate; the authors found a lack of field compaction testing, use of improper soil types, excessive slope lengths, buried debris, and insufficient erosion control, although no breaches were reported. A statistical analysis of oil and gas violations in Pennsylvania found that structurally unsound impoundments or inadequate freeboard were the second most frequent type of violation, with 439 instances in the period from 2008 to 2010 (Olawoyin et al., 2013).

Unlined Pits

Impacts on groundwater from historic and current uses of unlined pits in the oil and gas industry have been documented. In a review of records spanning 25 years (1983 – 2007), 63 incidents of private water supply contamination from the infiltration of saline fluids from unlined or inadequately constructed reserve pits were identified in Ohio (Kell, 2011). The same study (Kell, 2011) identified 57 legacy (pre-1984) incidents in Texas involving groundwater contamination from unlined produced water disposal pits. Such pits were phased out in Texas by 1984, prompting a move towards disposal of oil and gas wastewater in disposal wells.

Kern County, California has experienced impacts on groundwater associated with unlined percolation pits. A 2014 study notes that there are hundreds of pits across Kern County and elsewhere in the state, stretching state resources for regulatory oversight (Grinberg, 2014). Past sampling of water in percolation pits has shown exceedances of California's Tulare Lake Basin Plan (Basin Plan), which specifies maximum levels permitted for discharges of oil field well wastewater to unlined ponds overlying groundwater (Grinberg, 2014).[1] For example, the McKittrick 1 and 1-3 pits are large percolation pits in Kern County near oil fields where most of the hydraulic fracturing in California takes place (Grinberg, 2014). The pits are situated close to a number of important resources. They are located within a few miles of the Kern River Flood Channel, the California State Water Project, farmland, and are in an area of high quality groundwater (Grinberg, 2014). Sampling of fluids in the pits dating back to 1997 showed consistent exceedances of Tulare Basin Plan standards for TDS, chlorides, and boron. Sampling also revealed the presence of BTEX, gasoline range organics (GRO), and diesel range organics (DRO) (MTA, 2014). Sampling of three monitoring

[1] The Basin Plan sets limits for salinity (1,000 μmhos/cm measured as electrical conductivity), chloride (175 mg/L), and boron (1 mg/L) (California Regional Water Quality Control Board Central Valley Region, 2015).

wells indicated that in 2004, a plume had migrated at least 4,000 ft (1,000 m) from the pits and was still detected in test wells in 2013. As of July 1, 2015, California's Code of Regulations includes a provision that no longer allows the use of pits, including percolation pits, for fluids produced from stimulated wells (Grinberg, 2016).

Unlined pits that were used from the 1960s until the mid-1990s for disposal of drilling muds and flowback and produced waters associated with hydraulic fracturing operations have been linked to groundwater contamination in Pavillion, Wyoming (Digiulio and Jackson, 2016; AME, 2015). A report by the Wyoming Oil and Gas Conservation Commission (WYOGCC) (WYOGCC, 2014a) summarizes site investigations and reclamation activities conducted by WOGCC, the Wyoming Department of Environmental Quality (WDEQ), and Encana Oil and Gas for pits in the Pavillion Well Field. The report includes information on samples collected between 2006 and 2013 from shallow groundwater in the vicinity of the pits. Some sites had detections for one or more of the following contaminants: GRO, DRO, BTEX, and/or naphthalene. Of the shallow groundwater sites with detections, some were associated with pits located within one-quarter mile of a domestic well. One of these sites exceeded clean-up levels established by the WDEQ Voluntary Remediation Program for DRO (13,000 µg/L) and benzene (110 µg/L).[1] The report noted that there was insufficient evidence to determine whether or not drinking water supply wells in the vicinity of the pits were contaminated by disposal of hydraulic fracturing wastewater in those pits (WYOGCC, 2014a).

Other examples in the literature include the detection of VOCs in groundwater downgradient of an unlined pit containing oil and gas wastewater near the Duncan Oil Field in New Mexico (Sumi, 2004) (Section 8.5). Groundwater impacts downgradient of an unlined pit in Oklahoma included high salinity (3500-25,600 mg/L) and the presence of VOCs (Kharaka et al., 2002). Neither New Mexico nor Oklahoma currently allows unlined pits for disposal or storage (OCC OGCD, 2015; NM EMNRD OCD, 2013).

Mobilization and Transport of Constituents

Groundwater impacts may result not just from constituents in the wastewater but also from mobilization of existing constituents in the soil or sediment. A CBM produced water impoundment in the Powder River Basin of Wyoming was studied for its impact on groundwater (Healy et al., 2011; Healy et al., 2008). Infiltration of water from the impoundment was found to create a perched water mound in the unsaturated zone above bedrock in a location with historically little recharge. Elevated concentrations of TDS, chloride, nitrate, and selenium were found at the site, with one lysimeter sample exceeding 100,000 mg/L of TDS (Healy et al., 2008). Most of the solutes found in the groundwater mound did not originate with the CBM produced water, but rather were the consequence of dissolution of previously existing salts and minerals (Healy et al., 2011).

Generally, the deeper that wastewater can move into an aquifer, as impacted by the volume and timing of the release, the longer the duration of contamination (Whittemore, 2007). Kharaka et al. (2007) reported on studies at a site in Oklahoma with one abandoned and two active unlined pits.

[1] WDEQ cleanup levels are derived from a combination of promulgated levels (MCL, state-assigned water quality standards) and risk-based cleanup level concentrations (WDEQ, 2016a).

Produced water from these pits penetrated 10 to 23 ft (3 to 7 m) thick shale and siltstone units, creating three plumes of high-salinity water (5,000 to 30,000 mg/L TDS). The impact of these plumes on the receiving water body (Skiatook Lake) was judged to be minimal, although the estimate was based on a number of notably uncertain transport quantities (Otton et al., 2007).

Vadose (unsaturated) zone transport was illustrated at a site in Oklahoma where two abandoned pits were major sources for releases of produced water and oil. Saline water from the pits flowed through thin soils and readily percolated into underlying permeable bedrock. Deeper, less-permeable bedrock was contaminated by salt water later in the history of the site, presumably due to fractures. The mechanisms proposed were vertical movement through permeable sand bodies, lateral movement along shale fractures, and possibly increased clay permeability due to the presence of highly saline water (Otton et al., 2007).

Summary

Collectively, the above examples show that regardless of the purpose of pits (storage or disposal), they present a potential pathway for wastewater constituents to impact groundwater or surface water. Good construction standards and practices, including liners, adequate freeboard, and setbacks, are important for minimizing potential impacts on both surface water and groundwater. Proper monitoring and maintenance (e.g., avoiding overfilling, maintaining the integrity of liners and berms) are also important for protecting surface water and groundwater. Unlined pits, in particular, can lead to groundwater contamination. This can be long-lasting, as evidenced by legacy impacts from older pits. Most states have phased out unlined disposal pits and unlined storage pits, but if such pits are still in use, they can provide ongoing potential sources of groundwater contamination (CCST, 2015a; Grinberg, 2014).

8.4.6 Other Management Practices and Issues

Additional strategies for wastewater management in some states include directly discharging to surface waters and land application. In particular, wastewater from CBM fracturing and production generally has lower TDS concentrations than wastewater from other types of unconventional formations and more readily lends itself to other uses.

8.4.6.1 Land Application and Road Spreading

Road spreading has been used as a disposal option for high-TDS wastewaters (brines) from conventional oil and gas production. Road spreading can be done for dust control and de-icing. Although recent data are not available, an American Petroleum Institute (API) survey estimated that approximately 75.6 million gal (1.8 million bbls or 286.2 million L) of wastewater was used for road spreading in 1995 (API, 2000). The API estimate does not specifically identify hydraulic fracturing wastewater. There is no current nationwide estimate of the extent of road spreading using hydraulic fracturing wastewater.

Road spreading with hydraulic fracturing wastewater is regulated primarily at the state level (Hammer and VanBriesen, 2012) and is prohibited in some states. For example, with annual approval of a plan to minimize the potential for pollution, PA DEP allows spreading of brines from conventional (as defined by PA DEP) wells for dust control and road stabilization. Hydraulic fracturing flowback, however, cannot be used for dust control and road stabilization (PA DEP, 2011b). In West Virginia, use of gas well brines for roadway de-icing is allowed per a 2011 memorandum of agreement between the West Virginia Division of Highways and the West Virginia Department of Environmental Protection, but the use of "hydraulic fracturing return fluids" is not permitted (Tiemann et al., 2014; West Virginia DEP, 2011).

Concerns about road application center on contaminants such as barium, strontium, and radium. A report from PA DEP analyzed several commercial rock salt samples and compared results with contaminants found in Marcellus Shale flowback samples. The results noted elevated barium, strontium, and radionuclide levels in Marcellus Shale brines compared with commercial rock salt (Titler and Curry, 2011). Another study found increases in metals (radium, strontium, calcium, and sodium) in soils ranging from 1.2 to 6.2 times the original concentrations (for radium and sodium, respectively), attributed to road spreading of wastewater from conventional oil and gas wells for de-icing (Skalak et al., 2014).

Potential impacts on drinking water resources from road spreading have been noted by Tiemann et al. (2014) and Hammer and VanBriesen (2012). These include potential effects of runoff on surface water and migration of brines to groundwater. Snowmelt can carry salts and other chemicals from the application site, and transport can increase if application rates are high or rain occurs soon after application (Hammer and VanBriesen, 2012). Research on the impacts of conventional road salt application has documented long-term salinization of both surface water and groundwater in the northern United States (Kelly, 2008; Kaushal et al., 2005). When conventional oil field brine was used in a controlled road spreading experiment, elevated chloride concentrations were detected in shallow groundwater (Bair and Digel, 1990). The amount of salt attributable to road application of hydraulic fracturing wastewaters has not been quantified.

To evaluate land application of solid wastes from oil and gas production, a laboratory study mimicking land spreading of conventional oilfield scales and sludges indicated that 20% of the radium in barite sulfate scales was released by microbial processes during incubation with soil (Matthews et al., 2006; Swann et al., 2004). Although the radium was then complexed with the soil, it would be more mobile and more bioavailable than when it was associated with the barite. Overall, potential effects on drinking water resources from land spreading are not well understood, including the amounts of hydraulic fracturing wastes that are managed by land spreading.

8.4.6.2 Management of Coalbed Methane Wastewater

Many, but not all, CBM wells are hydraulically fractured to enhance recovery, using fluids that range from water alone to more complex gel formulations with proppant (e.g., Engle et al., 2011; McCartney, 2011; NRC, 2010; Halliburton, 2008; U.S. EPA, 2004a). The literature indicates that hydraulic fracturing of CBM formations is being conducted in the San Juan, Raton, Piceance, and Uinta Basins, among others. Literature such as NRC (2010) notes that hydraulic fracturing may not be common in the Powder River Basin. Additionally, when CBM well stimulation does take place, it can be accomplished using very simple hydraulic fracturing fluid formulations (Chapter 3).

Wastewater from CBM wells can be managed like other hydraulic fracturing wastewater discussed above. However, the wastewater from CBM wells can also be of higher average quality (typically lower TDS content) than wastewater from other hydraulically fractured wells. The lower TDS content makes it more suitable for certain management practices and uses. A number of management strategies have been proposed or implemented, with varying degrees of treatment required depending on the quality of the wastewater and the intended use (Hulme, 2005; DOE, 2003, 2002). Although specific volumes managed through the practices discussed below are not well documented, qualitative information and considerations for feasibility are available and presented. The discussion below covers both dilute and higher-TDS wastewater from CBM formations.

The quality of CBM wastewater plays a large role in how the wastewater is managed. The TDS content can range from an average of nearly 1,000 mg/L in the Powder River Basin to an average of about 14,000 mg/L (and as high as approximately 62,000 mg/L) in the Black Warrior Basin (Appendix Table E-3). Data sources from about 2002 through 2008 indicate that operators in some basins such as the San Juan, Uinta, and Piceance, and Raton (in New Mexico), where TDS is typically higher compared to other basins (e.g., Powder River), manage most wastewater by injection into disposal wells (NRC, 2010; U.S. EPA, 2010a).

Discharge to rivers and streams, a management option governed by the CWA, may be permitted in cases where wastewater is of high quality.[1] To be discharged, the wastewater must meet technology-based effluent limitations established by the permitting authority on a case-by-case “best professional judgment” basis as well as any more stringent limitations necessary to meet applicable water quality standards. For example, as a means of protecting high-quality waters of the state, the Montana Supreme Court ruled in 2010 that treatment is required for all CBM produced water prior to discharge to surface water (NRC, 2010).

A 2008 EPA survey of CBM operators found that of the projects represented in the results, direct discharge to surface water was by far most prevalent in the Powder River Basin but was also reported as a management practice in the Green River, Raton, Black Warrior, Cahaba, Illinois, and Appalachian basins (U.S. EPA, 2013e, 2010a).[2] Discharges to surface water can provide habitat maintenance, restoration of wildlife-waterfowl fishery habitat, and flow augmentation to benefit downstream water users. However, hydrologic changes from such discharges could also have unanticipated effects on ecosystems previously adapted to intermittent streamflow.

Some CBM wastewater can be put to agricultural use, including livestock and wildlife watering, and crop irrigation. Livestock watering with CBM wastewater can be done using on-channel or off-channel impoundments, and irrigation is an area of active research (e.g., Engle et al., 2011; NRC, 2010). However, wastewater from some higher-salinity CBM basins (e.g., San Juan, Uinta, and Piceance) would need blending or treatment before such uses. Irrigation with treated CBM

[1] Although discharge to rivers and streams is generally prohibited under the EPA’s oil and gas ELGs, the ELGs do not apply to CBM.
[2] These reports did not describe certain non-discharging wastewaters management strategies in basins with few operators in order to preserve CBI. The reports also do not provide information on hydraulic fracturing activities in the basins. Not also that results are presented by numbers of projects, which may vary in the number of wells they contain.

wastewater would be most suitable on coarse-textured soils for cultivation of salt-tolerant crops (DOE, 2003). NRC (2010) remarks that "use of CBM produced water for irrigation appears practical and sustainable," provided that appropriate measures are taken such as selective application, dilution or blending, appropriate timing, and rehabilitation of soils.

Although CBM wastewater is generally lower in TDS than wastewater associated with shale gas development, it can still have higher TDS concentrations than stream water. This poses concerns regarding the sodium adsorption ratio (SAR) for agricultural soils. A USGS study performed trend analysis of water quality at sampling sites in the Tongue and Powder River watersheds (Powder River Basin) (Sando et al., 2014). One of the study objectives was to determine possible effects of CBM produced water particularly in areas where the water was discharged to impoundments or upper reaches of in-stream channels for infiltration. Trend analysis showed potential effects of CBM production on downstream water quality (increases in sodium, alkalinity, and SAR) in the main-stem Powder River but found mixed results at the Tongue River sites (some appeared to be impacted by CBM activities while others did not) (Sando et al., 2014).

Sando et al. (2014) found that CBM pumping rates (i.e., discharge of produced water) were high relative to streamflow in the Powder River Basin. For the three main-stem Powder River sites, the CBM pumping rates were 26-34% of the 2001-2010 median streamflows. For one site in the Little Powder River watershed, the CBM pumping rate was 360% of 2001-2010 median streamflow. This underscores that in arid climates in the western United States, permitted discharges from CBM activities (whether hydraulically fractured or not) at a particular site may be large relative to the size of the receiving water and may sometimes dominate flows.

As noted above, a degree of treatment is needed (or required) for some uses. Plumlee et al. (2014) examined the feasibility, treatment requirements, and potential costs of several hypothetical uses for CBM wastewater. In several cases, costs for these uses were projected to be comparable to or less than estimated disposal costs. In one case study, use of CBM wastewater for streamflow augmentation or crop irrigation could potentially cost between \$0.26 and \$0.27 per bbl. For comparison, reported disposal costs in 2000-2001 ranged from \$0.01 per bbl for a pipeline collection system with impoundment to \$2.00 per bbl for hauling to disposal or treatment. The 2010 NRC report (NRC, 2010) noted that 15 to 18% of CBM produced water in the Powder River Basin was being treated to reduce SAR in order to satisfy NPDES permits for discharge.[1] If wastewater is treated to address SAR, reported costs are approximately \$0.12 to \$0.60/bbl (NRC, 2010).

The applicability of particular uses may be limited by ecological and regulatory considerations as well as the irregular nature of CBM wastewater production (voluminous at first, and then declining and halting after a period of years). Legal issues, including overlapping jurisdictions at the state level and senior water rights claims in over-appropriated basins (in western states) can also determine the use of CBM wastewater (Wolfe and Graham, 2002).

[1] SAR is the relative proportion of sodium to other cations in water. It is also an indication of risk to soil from alkalinity. The higher the SAR, the less suitable the water is for irrigation, and long-term use can damage soil structure.

8.4.6.3 Other Documented Uses of Hydraulic Fracturing Wastewater

Uses of wastewater from shales or other hydraulically fractured formations face many of the same possibilities and limitations as those associated with wastewater from CBM operations. The biggest difference is in the quality of the water. Wastewaters vary widely in water quality, with TDS values from shale and tight sand formations ranging from less than 1,000 mg/L TDS to hundreds of thousands of mg/L TDS (DOE, 2006) (Chapter 7). Wastewaters on the lower end of the TDS spectrum could be reused in many of the same ways as CBM wastewater, depending on the concentrations of potentially harmful constituents and applicable federal, state, and local regulations. High TDS wastewaters have more limited uses, and pre-treatment may be necessary (Shaffer et al., 2013; Guerra et al., 2011; DOE, 2006). Agricultural and wildlife uses are subject to the produced water daily effluent discharge limit of 35 mg/l for oil and grease.[1]

Potential uses for wastewater in the western United States include livestock watering, irrigation, streamflow supplementation, fire protection, road spreading, and industrial uses, with each having their own water quality requirements and applicability (Guerra et al., 2011). Guerra et al. (2011) summarized the least conservative TDS standards for five possible uses in the western United States that include 500 mg/L for drinking water (the drinking water secondary maximum contaminant level (SMCL)), 625 mg/L for groundwater recharge, 1,000 mg/L for surface water discharge, 1,920 mg/L for irrigation, and 10,000 mg/L for livestock watering. The authors estimated that wastewater from 88% of unconventional wells in the western United States could be used for livestock watering without TDS removal based on a maximum TDS concentration of 10,000 mg/L. However, wastewater from only 10% of unconventional wells could be used for surface discharge without treatment for TDS based on the least conservative standard among the western states of 1,000 mg/L TDS (Guerra et al., 2011). Guerra et al. (2011) indicate that in several basins in the western United States (e.g., Wind River, Green River, and Powder River), wastewater from 50% or more of oil and gas wells is suitable for agricultural use. In other basins (e.g., San Juan, Piceance, and Permian) over 50% of oil and gas wastewater is unsuitable for use without treatment. A 2006 Department of Energy (DOE) study pointed out that the quality necessary for use in agriculture depends on the plant or animal species involved and that in the Bighorn Basin in Wyoming, low-salinity wastewater is used for agriculture and livestock watering after minimal treatment to remove oil and grease (DOE, 2006).

Although TDS is a common criterion for water quality, there are also recommended limits or considerations for some metals, alkalinity, and nitrate in water for use in livestock watering, and for metals, SAR, electrical conductivity (ECw), and pH for water for irrigation (Guerra et al., 2011). Also, using TDS/salinity as the primary criterion may not be appropriate if wells contributing to the produced water have undergone hydraulic fracturing or if maintenance chemicals are being used on the well.

The water quality standards and monitoring requirements for direct discharge for use in irrigation or livestock watering include few specifications. In California, the California Council on Science and Technology (CCST, 2015a) notes that the testing and treatment required by the regional water

[1] 40 CFR 435.52(b).

quality control boards prior to use of produced water for irrigation do not include assessment for chemicals associated with hydraulic fracturing and that there are no policies prohibiting the use of hydraulic fracturing wastewaters for irrigation.

In the Wind River Basin in Wyoming, three NPDES permits were appealed by environmental groups due to concerns that the permits failed to address maintenance and hydraulic fracturing chemicals (Natural Resources Defense Council, 2015; PEER, 2015). The environmental groups argued that the EPA's regulations do not allow for the discharge of produced water containing chemicals from well treatment, and that, moreover, the EPA lacked sufficient information regarding the well treatment chemicals to determine whether the discharge would be "good enough quality" for wildlife and agricultural use, as required under the ELG regulations. As an example, the environmental groups pointed to MSDS information provided upon request for six maintenance products, which included toxic chemicals such as ethylene glycol, benzyl chloride, isopropanol, naphthalene, benzene, and xylene, among others. This raised concerns that produced water permitted for direct discharge may contain toxic chemicals or their degradation products. Ultimately, pursuant to a settlement agreement with the environmental groups and permittees, the EPA issued modified permits that included additional conditions for handling of and reporting about well stimulation and well maintenance chemicals.

8.4.7 Management of Solid and Liquid Residuals

Solid and liquid residuals associated with hydraulic fracturing wastewater are formed from treatment processes at CWTs, buildup of sludges in tanks and pits, and scale formation on pipes and equipment. These residuals must be managed and disposed of properly to avoid impacts on ground and surface water resources. (Note that drill cuttings and drilling muds are outside the scope of this chapter.)

8.4.7.1 Solid Residuals

The solid residuals produced at a CWT depend on the constituents in the untreated water and the treatment processes used and are likely to contain TSS, TDS, metals, radionuclides, and organics. Solid residuals can consist of sludges (from precipitation, filtration, settling units, and biological processes), spent media (filter media, adsorption media, or ion exchange media), and other material such as spent filter socks used to remove gross particulates. In addition, solids that accumulate in storage tanks and pits and scale that deposits on equipment are part of the residual load from a site. These residuals can constitute a considerable fraction of solid waste in an oil or gas production area.

Handling and disposal of residual sludges from treatment processes can present some of the biggest challenges associated with these technologies (Igunnu and Chen, 2014). Additional treatment may be applied to solid residuals including thickening, stabilization (e.g., anaerobic digestion), and dewatering processes prior to disposal. The solid residuals are then typically sent to a landfill, land spread on-site, or incinerated (Morillon et al., 2002). Land spreading is a waste management method in which wastes are spread over the soil surface and tilled into the soil to allow the hydrocarbons in the wastes to biodegrade (Smith et al., 1998); note that inorganic constituents (e.g., salts, metals, metalloids, and radionuclides) will not degrade. In addition, pits or impoundments that have reached the end of their useful life have accumulated residuals. Practices used to decommission these pits include draining and leveling the pit in place or land farming the residual materials into the ground (Rich and Crosby, 2013), although more information is needed on the potential for these practices to affect water resources.

A particular concern for the management of residual wastes is TENORM that originates from the geologic formation and was present in the produced water (SAFER PA, 2015). Studies have found TENORM in solid residuals at oil and gas operations including the filter cake (PA DEP, 2015b), filter socks (Harto et al., 2014), and pit sludges (Rich and Crosby, 2013). Researchers have assessed Marcellus produced water samples, finding that many with low barium and high radium-226 levels would generate sludges that exceed the maximum acceptable radium-226 activity for nonhazardous landfill disposal in Pennsylvania (Silva et al., 2014b; Silva et al., 2014a). In scales that build up on hydraulic fracturing and treatment equipment and sludges that accumulate in tanks and pits, radium can coprecipitate with barium, strontium, or calcium sulfates (Smith et al., 1999). (See Section 8.5.2 for additional discussion of TENORM associated with residuals.)

The accumulation of TENORM in the solids generated can limit or preclude landfills as a disposal option. Walter et al. (2012) point out that wastes containing TENORM can be problematic due to the possibility of radon emissions from the landfill. Regulatory limits on permissible radionuclide levels accepted at non-hazardous landfills vary by state (Silva et al., 2014a).[1] Some states have volumetric limitations on TENORM in their landfill permits (e.g., Colorado). Also, some states write criteria, such as gamma exposure rates (radiation) and radioactivity concentration limits, into permits for many landfills that are permitted to accept TENORM. Silva et al. (2014a) note that there are 50 nonhazardous (RCRA-D) disposal facilities in Pennsylvania, but no TENORM disposal facilities. Texas and other states have disposal facilities for TENORM.

8.4.7.2 Liquid Residuals

Liquid residuals include concentrated brines (from membrane or evaporation processes) and regeneration or cleaning chemicals (from ion exchange, adsorption, and membrane processes) (Fakhru'l-Razi et al., 2009). Practices for managing liquid residual streams from treatment processes are generally the same as for untreated hydraulic fracturing wastewaters, although the treated volumes are smaller, resulting in lower costs (Hammer and VanBriesen, 2012). Concentrations of contaminants in liquid residuals, however, will be higher. The most common disposal method is injection into disposal wells.

If the liquid is not injected into a disposal well, treatment to remove salts would be required for surface water discharge to meet NPDES permit requirements and protect the water quality for downstream users such as drinking water utilities (Section 8.5). Because some constituents of concentrated liquid residual waste streams can pass through or impact municipal wastewater treatment processes (Linarić et al., 2013; Hammer and VanBriesen, 2012), these residuals would

[1] Examples of permissible radionuclide levels at non-hazardous landfills: Pennsylvania requires alarms to be set at all municipal landfills, with a trigger set at 10 μR/hr above background radiation. Texas sets a radioactivity limit, requiring that any waste disposed by burial contains less than 30 pCi/g radium or 150 pCi/g of other radionuclides.

not be appropriate for discharge to a POTW. Elevated salt concentrations, in particular, can have detrimental effects on microbiological treatment at municipal wastewater systems, such as activated sludge treatment (Linarić et al., 2013).

Liquid residuals can also be mixed with a solidifying agent such as Portland cement and then disposed of in landfills, or they can undergo advanced treatment processes to generate products such as road salt or industrial chemicals (SAFER PA, 2015).

8.4.7.3 Potential Impacts from Solid and Liquid Residuals

Residual wastes have the potential to impact the quality of drinking water resources if contaminants leach to groundwater or reach surface water. In a recent study by PA DEP, radium was detected in leachate from 34 of 51 landfills that accept waste from the oil and gas industry (Marcellus in particular). Radium-226 concentrations ranged from 54 to 416 pCi/L, and radium-228 ranged from 2.5 to 1,100 pCi/L (PA DEP, 2015b). (See also Section 8.5.2 and see Chapter 9 for health effects associated with radium). Countess et al. (2014) studied the potential for a wide array of elements to leach from sludges generated at a CWT handling hydraulic fracturing wastewater in Pennsylvania. Tests used strong acid solutions (to simulate the worst case scenario) and weak acid digestions (to simulate environmental conditions). The data illustrate the possibility of leaching of these constituents from landfills. The extent of leaching varied by constituent and by fluid type, but the authors concluded that boron, bromide, calcium, magnesium, manganese, silicon, sodium, and strontium had high potential to migrate from the residual solids, with bromide and sodium having the highest leaching potential (Countess et al., 2014). (See also Section 5.8 in Chapter 5 for discussion of the processes governing the movement of constituents in the subsurface.)

In another study assessing the leaching behavior of residuals from hydraulic fracturing operations, Sharma et al. (2015) found that alkali metals, alkaline earth metals, and bromide had the highest leaching potential of the constituents tested. The authors also found that disposing of hydraulic fracturing residuals along with other solids (e.g., at a municipal landfill) produces a greater leaching potential than if the residuals are disposed of by burying or land disposal designed for solely the hydraulic fracturing residuals. This is due to the more acidic leachate formed at the co-disposal locations (Sharma et al., 2015).

Sang et al. (2014) studied the potential for hydraulic fracturing fluid to mobilize colloidal particles in the soil. The study used microspheres and sand particles as surrogates for contaminant particles. The authors note that the chemistry of hydraulic fracturing fluid favors transport of colloids and mineral particles through rock cracks, and they found that infiltration of flowback fluid can transport existing pollutants such as heavy metals, radionuclides, and pathogens, in unsaturated soils (Sang et al., 2014). Heavy metals can also move through soil. Although not specific to hydraulic fracturing wastes, Camobreco et al. (1996) report high levels of heavy metal transport in soil columns, with 12% recovery for lead, 15% for copper, 23% for zinc, and 30% for cadmium (Camobreco et al., 1996).

Residuals, whether liquid or solid, are the most concentrated wastes and waste streams associated with hydraulic fracturing operations. Contaminants in the produced water will accumulate in the sludges in storage tanks/pits, in scale on the equipment, and in treatment facilities. Proper management and disposal of these highly concentrated wastes is critical to minimize the potential for impacts on water resources.

8.5 Potential Impacts of Hydraulic Fracturing Wastewater Constituents on Drinking Water Resources

The previous section discussed the potential impacts of specific wastewater management strategies on drinking water resources. The severity of impacts, however, depends largely on the constituents in the wastewater, the concentrations of those constituents, and their health and ecological effects. This section will discuss the potential impacts of several specific types of hydraulic fracturing wastewater constituents on drinking water resources.

The impacts or potential impacts discussed in the literature are heavily focused on discharges from CWTs, including treated wastewater that is discharged indirectly through POTWs. Available evidence suggests that the effects of hydraulic fracturing on surface water quality are related to discharges of partially treated wastewater (Kuwayama et al., 2015a). Other avenues of contamination for both surface water and groundwater include leaks from pits and impoundments, landfill leachate, and leaching from contaminated sediments and other improperly managed solid wastes.

As noted, an important consideration regarding the potential impacts of hydraulic fracturing wastewater on receiving water is whether there are constituents of concern known to have health effects or that can give rise to compounds with health effects. See Chapter 9 for discussion of the health effects of wastewater constituents. For some classes of constituents, such as DBP precursors, considerable research exists regarding concentrations in the waste stream and impacts on downstream drinking water treatment plants or the finished drinking water after treatment. For other constituents, information is limited, especially within the context of hydraulic fracturing activities. There may also be unknown constituents because some ingredients in the original hydraulic fracturing fluids are claimed to be CBI. The following subsections identify several classes of constituents known to occur in hydraulic fracturing wastewater, discuss whether potential impacts are likely, and detail information gaps.

8.5.1 Bromide, Iodide, and Chloride

Halides, including bromide, chloride, and iodide, are commonly found in high-TDS hydraulic fracturing wastewater. As noted in Section 8.3.1.1, chloride is a regulated contaminant with a secondary MCL of 250 mg/L. Bromide and iodide are not regulated, but are of concern due to their role in the formation of DBPs (Parker et al., 2014; Krasner, 2009). (See Appendix F for information on DBP formation.) High-TDS wastewaters from the Marcellus Shale have been the focus of concern due to the state's history of treating these wastewaters at POTWs (without pretreatment) and at CWTs without TDS removal capabilities (Text Box 8-1). Discontinuing the practice of sending shale gas wastewater to POTWs without pretreatment (States et al., 2013), and compliance with the new EPA pretreatment standards for discharges of unconventional oil and gas wastewaters helps mitigate this problem. This section describes the role of some constituents in high-TDS fluids in the formation of DBPs and provides more details on the effects on surface waters as observed in Pennsylvania. The lessons learned and steps taken in the Marcellus region can provide valuable knowledge for operators and state agencies in other parts of the country that treat and discharge high-bromide and high-iodide wastewaters.

8.5.1.1 Influence of Bromide and Iodide on Formation of Disinfection Byproducts

Disinfection byproducts (DBPs) are formed when organic material comes in contact with disinfectants (e.g., chlorine, chloramine, chlorine dioxide, or ozone). Of particular concern are DBPs formed in the presence of halides (e.g., bromide or iodide). The type of DBP formed depends on the organic precursors in the source water and the disinfectant used. Regulated DBPs include total trihalomethanes (TTHM), five haloacetic acids (HAA5), bromate, and chlorite. There are, however, many additional DBPs that are not regulated and may in fact be of greater concern than the regulated species. Brominated forms of DBPs, for example, are considered to be more toxic and carcinogenic than chlorinated species (McGuire et al., 2014; Parker et al., 2014; States et al., 2013; Krasner, 2009; Richardson et al., 2007). Another halide, iodide is also found in some hydraulic fracturing wastewater (Chapter 7), and although its effects have not been as well documented as those associated with bromide, iodide raises some of the same concerns regarding formation of toxic DBPs as bromide (Xu et al., 2008).

Studies have found that elevated bromide levels in water correlate with increased DBP formation in the drinking water that is delivered to customers (also called "finished drinking water") (Obolensky and Singer, 2008; Matamoros et al., 2007; Hua et al., 2006; Yang and Shang, 2004). Harkness et al. (2015) studied the chemical composition of flowback, produced waters, treated wastewaters, instream flows downstream from discharges, and accidental spill sites. The study found high concentrations of bromide and iodide in the flowback and produced waters, concluding that the elevated levels of these constituents could promote the formation of toxic brominated and iodinated DBPs in downstream drinking water systems (Harkness et al., 2015).

In terms of the resulting DBP formation, laboratory experiments using hydraulic fracturing wastewater from the Marcellus and Fayetteville shales and river water from the Allegheny and Ohio rivers suggest that a relatively small portion of hydraulic fracturing wastewater can notably affect DBP formation (Parker et al., 2014). In particular, trihalomethanes (THM; a category of DBPs) were shown to shift towards greater brominated and iodinated species with a little as 0.01% hydraulic fracturing wastewater in disinfected samples. Modeling work by Landis et al. (2016) evaluated the impact of CWT discharges on DBP formation at a drinking water system and suggested that although only a 3% increase in overall TTHM formation was predicted, the model predicted a decrease in chlorinated THM and a substantial shift toward a higher percentage of the more-toxic brominated THMs (Landis et al., 2016).

States et al. (2013) found a strong correlation between bromide concentrations in source water from the Allegheny River in Pennsylvania and the percentage of brominated THMs in finished water at a drinking water facility using Allegheny source water. Bromide concentrations in the river water measured during the study ranged from less than 25 μg/L to 299 μg/L. The authors noted that source water containing 50 μg/L of bromide resulted in treated drinking water with approximately

62% of total THMs consisting of brominated species. When the source water contained 150 µg/L bromide, the brominated THM percentage was 83% (States et al., 2013).

Pope et al. (2007) reported that increased bromide levels are the second best indicator of DBP formation, with pH being the first. Furthermore, bromine (which may be formed from bromide in the water during disinfection) reacts as much as ten times faster and more efficiently with DBP precursors than chlorine (Westerhoff et al., 2004). These studies show that increased bromide concentration in a drinking water resource shifts the DBP formation towards more-toxic brominated forms.

If disinfection is accomplished using ozonation instead of or in addition to chloramination or chlorination, bromide and iodide in the source water can form two additional constituents: bromate and iodate. Iodate, although formed during disinfection by ozonation, is not considered a DBP and is non-toxic (Allard et al., 2013). Bromate, however, is a DBP of concern and has an MCL of 0.010 mg/L (U.S. EPA, 1998).

Another category of DBP that is not regulated is the nitrogenous DBPs, including nitrosamines. Data are lacking on the formation of nitrogenous DBPs specifically linked to hydraulic fracturing wastewater, but their formation is possible. During chloramination, bromide can enhance the formation of the nitrosamine N-nitrosodimethylamine (NDMA) in waters containing the precursor dimethylamine (DMA) (Le Roux et al., 2012; Luh and Mariñas, 2012). As with some other non-regulated DBPs, nitrogenous DBPs may be more toxic than the regulated ones (Harkness et al., 2015; McGuire et al., 2014; Parker et al., 2014).

As discussed in Section 8.4 and Text Box 8-3, removal of dissolved solids, including chloride and bromide, requires advanced treatment processes such as reverse osmosis (RO), distillation, evaporation, or crystallization. Unless the treatment plant receiving the high-TDS wastewater employs processes specifically designed to remove these constituents, effluent discharge may contain high levels of bromide and chloride. Drinking water systems with intakes downstream of these discharges may receive water with correspondingly higher levels of bromide and chloride and may have difficulty complying with SDWA regulations related to DBPs.

8.5.1.2 Effects on Receiving Waters

Studies show that discharges from oil and gas wastewater treatment facilities can elevate TDS, bromide, and chloride levels in receiving waters, and potential impacts may be detectable far downstream (> 1km) of an outfall (States et al., 2013; Warner et al., 2013a; Wilson and Van Briesen, 2013). The work by Landis et al. (2016) in the Allegheny River mentioned above is consistent with these findings. The authors studied the impacts of a CWT accepting oil and gas wastewater on water quality at a downstream drinking water intake. They found that compared to data from upstream (background) locations, bromide concentrations at the intake were increased by 53% at low streamflow and 22% during high streamflow.[1]

[1] Background samples are those taken from locations upstream of, and therefore unaffected by, permitted facilities.

Elevated TDS, chloride, and bromide can serve as indicators of potential influence from hydraulic fracturing wastewater in surface water and can also raise concerns about DBP formation in downstream drinking water systems. Elevation of bromide has been shown to place a burden on downstream drinking water systems. The Pittsburgh Water and Sewer authority (PWSA) drinking water system concluded that elevated bromide in their source water led to elevated TTHMs in their finished drinking water, with a substantial increase in the percentage of brominated TTHMs (States et al., 2013). The utility modified their treatment process and proposed improvements to their storage facilities to address the elevated TTHM levels in the distribution system (Chester Engineers, 2012).

Conversely, changes in regional wastewater handling that reduce bromide discharges can be reflected in receiving waters. A three-year study at water intakes downstream of wastewater discharges on the Monongahela River in western Pennsylvania evaluated water chemistry in the context of flow measurements. The authors concluded that an overall decrease in bromide concentrations at drinking water intakes from 2010 to 2012 was likely associated with shale gas operators voluntarily ceasing the practice of sending high-bromide wastewaters to treatment facilities that discharge to surface waters without adequate TDS removal (Wilson and Van Briesen, 2013).

Elevated TDS and halides need to be interpreted in the context of other inputs into a watershed. An EPA source apportionment study of the Allegheny River in Pennsylvania (U.S. EPA, 2015o) found that CWTs accounted for almost 90% of the bromide at one drinking water treatment plant intake and 37% of the bromide at another intake. Other sources include coal-fired power plants and acid mine drainage. Furthermore, although effluent is diluted when discharged to a water body, this may not always be sufficient to avoid water quality problems if there are existing pollutant loads in the waterbody from other contributors (e.g., such as acid mine drainage or power plant effluent) (Ferrar et al., 2013). Warner et al. (2013a) evaluated effluent from the Josephine Brine Treatment Facility, which treated both conventional and unconventional (as defined by PA DEP) oil and gas wastewater at the time of the study. The authors concluded that even a 500 to 3,000-fold dilution of the wastewater would not reduce bromide levels to background. Modeling by Weaver et al. (2016) suggests that bromide levels in receiving streams can be improved by reducing concentrations in the effluent, discharging during periods of high streamflow, and discharging intermittently (pulsing). (See Appendix F for additional description of modeling studies.)

In addition to concerns about formation of DBPs within downstream drinking water systems, treatment at the upstream CWTs and POTWs themselves can also produce DBPs if the facilities disinfect prior to discharge. The DBPs may then be released into receiving waters and increase concerns about the total loads of brominated and iodinated DBPs at downstream drinking water systems (Hladik et al., 2014). A study by Hladik et al. (2014) documented brominated and iodinated DBPs at the outfalls of CWTs and POTWs treating both conventional and unconventional wastewater and noted that this DBP signature was different than for those plants that did not accept oil and gas wastewater.

8.5.1.3 Other Constituents That Can Affect Downstream DBP Formation

In addition to halogens, organic matter and ammonium can also be present in hydraulic fracturing wastewater (Chapter 7; Appendix E) and can have an influence on the formation of DBPs at downstream drinking water systems (Harkness et al., 2015). Experimental work by Parker et al. (2014) found that a mixture of river water with 1-2% flowback by volume could contribute to DBP formation due to the higher dissolved organic carbon content of the flowback. Harkness et al. (2015) studied the chemical composition of water associated with oil and gas production and found high concentrations of ammonium in the flowback and produced waters. Elevated levels of ammonium can convert chlorine to chloramines at downstream drinking water treatment plants. This could have an impact on the plant's disinfection practices because chloramines are a weaker disinfectant than chlorine (Harkness et al., 2015; Parker et al., 2014).

8.5.1.4 Mitigating Impacts from TDS and Halides on Drinking Water Utilities

High bromide concentrations and low flow conditions in waterways have been shown to increase DBP formation in downstream drinking water systems (States et al., 2013). Most drinking water treatment plants are not designed to address high concentrations of TDS (including bromide and iodide), limiting their options for restricting the formation of brominated and iodinated DBPs when these halides are present.

To mitigate these impacts, one strategy that was implemented in Pennsylvania was to disallow influent of high-TDS wastewaters to POTWs and CWTs that discharged to streams and were not designed to treat for TDS. Wilson and Van Briesen (2013) showed that this strategy was effective for reducing bromide concentrations at drinking water utilities downstream from POTWs and CWTs that had formerly accepted hydraulic fracturing wastewaters (States et al., 2013; Warner et al., 2013a; Wilson and Van Briesen, 2013). Alternatively, advanced treatment processes such as reverse osmosis, distillation, evaporation, and crystallization, can be employed to reduce constituents that contribute to high TDS (e.g., such as chloride, bromide, and iodide), reducing impacts on surface waters and, subsequently, downstream drinking water utilities. Strategies such as discharging during higher streamflow periods and using a pulsing or intermittent discharge could also reduce the frequency and severity of potential impacts on drinking water systems from elevated TDS.

8.5.2 Radionuclides

Potential impacts on drinking water resources from TENORM associated with hydraulic fracturing wastewater can arise through a number of pathways, including: treated wastewater in which radionuclides were not adequately removed; accumulation of radionuclides in surface water sediments downstream of wastewater treatment plant discharge points; migration or mobilization from soils that have accumulated radionuclides from previous activities such as pits or land application; and inadequate management of treatment plant solids (such as filter cake), landfill leachate, or sediments in pits or tanks that have accumulated radionuclides.

An additional concern is the potential for underestimation of radium concentrations in hydraulic fracturing wastewater due to the high TDS content. When using wet chemical techniques, high TDS concentrations can result in poor recovery of some chemical constituents. For radium, recovery may be as low as <1% in a high-salt matrix (Nelson et al., 2014). This may lead to the inability to identify an impact on drinking water resources or an underestimation of the severity of an impact. Research suggests that spectroscopic methods are more appropriate for analysis of radium in high-TDS wastewaters (Nelson et al., 2014).

A recent study by the PA DEP (PA DEP, 2015b) provides information that helps fill a general data gap regarding TENORM content in oil and gas wastes that are treated and discharged to surface waters. The study, although not exclusive to Marcellus wastes, was motivated by concerns over an increase in radionuclides in oil and gas wastes observed during the expansion of Marcellus Shale production. The study began in 2013 and quantified radionuclide (radium-226, radium-228, K-40, gross alpha, and gross beta) levels at CWTs, POTWs, well sites, and landfills and discussed human health and environmental implications. Other relevant studies addressing radionuclides focus on CWTs that have handled Marcellus wastewater, evaluation of solids in storage pits, and analysis of scale on pipes and tanks.

8.5.2.1 Effluent from POTWs

In Pennsylvania between 2007 and 2010, TENORM-bearing wastewaters were sent to POTWs, which are generally not required to monitor for radioactivity (Resnikoff et al., 2010). Although management of Marcellus wastewaters via POTWs has declined, there is still potential for input of radionuclides to surface waters via discharge of CWT effluent either directly to surface water or indirectly through discharge to POTWs. The potential for TENORM to pass through treatment at POTWs is one of the concerns addressed in the EPA's recently promulgated pretreatment standards for unconventional oil and gas wastewaters that discharge to POTWs.

Six of the POTWs in the PA DEP TENORM study received effluent from a CWT along with municipal wastewater. Note that the CWTs in the study are not described as receiving exclusively Marcellus wastewater. The POTWs that receive both CWT effluent and municipal waste had radium in their effluent (overall average effluent radium-226 concentration of 103 pCi/L, with a range of <35 to 340 pCi/L). Those POTWs receiving only municipal wastewater also contained radium, with an average effluent radium-226 concentration of 145 pCi/L.[1] These concentrations are many times higher than the MCL for radium (5 pCi/L) and are also orders of magnitude higher than typical background values; radium-226 in river water generally ranges from 0.014 pCi/L to 0.54 pCi/L (IAEA, 2014).[2]

[1] These values are for unfiltered samples. In filtered samples, the POTWs that receive both CWT effluent and municipal waste had higher average radium-226 values than those for POTWs only treating municipal waste (497 pCi/L vs. 85 piCi/L). Filtered samples are passed through a filter to remove fine particles; concentrations of constituents in filtered samples are often lower than in unfiltered samples. However, liquid samples in this study were filtered after preservation with acid. Therefore, the difference between unfiltered and filtered samples may not be reliable.

[2] A confounding issue for this study is that it was not clear why the radium-226 concentrations were comparable or higher for those POTWs not receiving oil and gas CWT effluent. However, sample sizes were small and possible alternative sources for the radium were not discussed. The report also did not describe how it was verified that the POTWs did not receive contributions from oil and gas wastewater.

8.5.2.2 Effluent from CWTs

Four of the ten CWTs sampled during the PA DEP TENORM study (PA DEP, 2015b) discharged to surface water under a National Pollution Discharge Elimination System (NDPES) permit, and the other six discharged to POTWs. The average radium-226 concentration in the effluent from the CWTs (1,840 pCi/L for unfiltered samples) was an order of magnitude higher than in effluent from the POTWs. Samples of treated wastewater from zero-discharge facilities contained higher concentrations, averaging 2,610 pCi/L radium-226 and 295 pCi/L radium-228 (PA DEP, 2015b). The treated wastewater from these zero-discharge facilities will likely be reused for subsequent hydraulic fracturing jobs, postponing the need for disposal, but reuse could result in overall increases in some constituents of concern due to repeated passage through the subsurface. In addition, there is also a potential for impacts on drinking water resources from spills and leaks associated with wastewater storage and handling at these facilities.

Sampling done at the Josephine Brine Treatment Plant in western PA from 2010 – 2012 (Warner et al., 2013a) detected radium in the effluent (mean values of 4 pCi/L of radium-226 and 2 pCi/L of radium-228). Treatment at the facility removes radium by coprecipitation with barium sulfate. The authors note that if the activities of radium-226 and radium-228 in Marcellus brine influent at the CWT are similar to those reported by other researchers (Rowan et al., 2011), then the CWT achieved a 1,000-fold reduction in radium content. (This facility also accepted conventional oil and gas wastewater.) The detection of radium in the effluent from this CWT suggests that if the influent concentration is extremely high, radium will still be found in the effluent of a treatment plant even if the treatment process removes a high percentage (see Section 8.4 and Appendix F for additional discussion on constituent removal efficiencies at CWTs).

8.5.2.3 Accumulation in Sediments

In addition to concerns about TENORM in discharges to surface waters, studies have shown the potential for a legacy of radionuclide accumulation in surface water sediments. The PA DEP TENORM study (PA DEP, 2015b) found radium in sediments near the outfalls for CWTs (averages of 84.2 pCi/g and 19.8 pCi/g for radium-226 and -228, respectively) and three POTWs receiving treated oil and gas wastewater from CWTs (radium-226 and radium-228 concentrations ranging from 1.8 to 18.2 pCi/g). Typical background soil levels of radium are approximately 1 to 2 pCi/g (PA DEP, 2015b).

Warner et al. (2013a) measured radium-226 levels in stream sediment samples at the point of discharge of a CWT that had treated both conventional oil and gas wastewater and unconventional Marcellus wastewater. They found concentrations approximately 200 times greater than upstream and background sediments. This indicates the potential for accumulation of contaminants in localized areas near wastewater discharge facilities. Although the CWT studied by Warner et al. (2013a) also accepted conventional oil and gas wastewater, the authors observed that the radium-228/radium-226 ratio in the river sediments near the discharge (0.22 – 0.27) is consistent with ratios in Marcellus wastewater. The authors indicate that the radium likely accumulated in the sediments, originating from the discharge of treated unconventional Marcellus oil and gas wastewater. Accumulation of TENORM can also occur in sediments receiving discharged effluent from landfills that accept oil and gas wastes. In the PA DEP TENORM study (PA DEP, 2015b), samples of impacted soils were collected at three landfill outfalls. Radium-226 and -228 were detected in all samples (2.82 to 4.46 pCi/g and 0.979 to 2.53 pCi/g, respectively).

A study by Skalak et al. (2014), on the other hand, did not find elevated levels of alkali earth metals (including radium) in sediments just downstream of the discharge points of five POTWs that had previously treated Marcellus wastewater. These inconsistencies among studies suggest that accumulation of contaminants in sediment may depend on treatment processes and their removal rates for each constituent as well as stream chemistry and hydrologic characteristics. Contamination with radium-226 would potentially be long lived because of the long half-life of radium.[1]

The association of radium with sediments near discharge points is attributed to adsorption of radium to the sediments, a process governed by factors such as the salinity of the water and sediment characteristics. Increased salinity promotes desorption of radium from sediments, while lower salinity promotes adsorption, with radium adsorbing particularly strongly to sediments high in iron and manganese (hydr)oxides (Porcelli et al., 2014; Gonneea et al., 2008). Warner et al. (2013a) speculate that when saline CWT effluent is discharged into stream water, the lower salinity of the stream environment facilitates sorption of radium onto streambed sediments. The long-term fate of radium sorbed to sediments depends upon changes in water salinity and the sediment properties, including any reduction/oxidation chemical reactions that affect iron and manganese minerals in the sediments. Additionally, the sediment may be physically transported downstream due to high flows or if sediment is disturbed and resuspended.

8.5.2.4 Pits and Tanks

Where pits or impoundments are used, radionuclides may accumulate in the bottom sludges and can also be found in soils once the pit is closed and leveled. A study of three centralized wastewater storage impoundments in southwestern Pennsylvania (Zhang et al., 2015a) showed that radium-226 accumulated in various components of the bottom solids, including through coprecipitation with barium sulfate. Sludge from one pit showed a substantial increase in radium-226 between sampling events 2.5 years apart (from 8.8 pCi/g to 872 pCi/g). The authors attributed the steep increase to enrichment in radium during cycles of wastewater reuse. In Texas, accumulation of radionuclides (potassium, thorium, bismuth, radium, and lead) was documented for two pits that stored fluids associated with hydraulic fracturing (Rich and Crosby, 2013). One pit was decommissioned and used as farmland, and the other was active at the time of sampling. Analyses of soil and sludge samples detected a number of radionuclides, including radium-226, radium-228, thorium-228, strontium-90, and potassium-40 (radium-226 was only found at the former pit). Rich and Crosby (2013) note a total beta radiation value of 1,329 pCi/L in one sample from the active pit. They note that this value exceeded regulatory guidelines even though the values for individual

[1] The half-life of radium-226 is approximately 1,600 years, while the half-life of radium-228 is 5.76 years. The half-life is the time it takes for half of the nuclei in a sample of a radioactive element to decay. After two half-lives, one fourth of the original sample will be left, and after three half-lives there will be one eighth of the original sample remaining, and so forth.

radionuclides did not exceed regulatory guidelines, suggesting that using a single radionuclide (i.e., radium) as an indication of exposure can underestimate total radioactivity.

Although the sample sizes were small for both the Zhang et al. (2015a) and the Rich and Crosby (2013) studies, the results suggest that radionuclides associated with sediments from some pits could have potential impacts on surface water or groundwater. These studies illustrate the need for appropriate management where wastes have high TENORM content. Rich and Crosby (2013) note that pits are often found in agricultural regions. If pit solids that are incorporated into soils (e.g., during draining and leveling or during land application) contain radionuclides, they may reach surface water in runoff or leach from the solids and migrate to groundwater. In active pits, Rich and Crosby (2013) note that TENORM in the contents may be deposited onto crops and soil through aerosolization or breaching. The Pennsylvania study (Zhang et al., 2015a) suggests that landfill leachate may be affected by receiving sludges from impoundments that store produced water and will need to be managed appropriately.

With radium-226 values of 121 pCi/g and 872 pCi/g, sludges from the pits studied by Zhang et al. (2015a) exceeded the limit for disposal as a nonhazardous solid in a municipal or industrial solid waste landfill but would meet the radium-226 limits for disposal in a hazardous waste landfill. There are currently no federal requirements to test solid residuals for radionuclides before disposal. At landfills studied in the PA DEP TENORM report (PA DEP, 2015b), seven samples of treated effluent from nine facilities that accept oil and gas waste had radium-226 values ranging from 105 pCi/L to 378 pCi/L and radium-228 values ranging from <6 pCi/L to 1,100 pCi/L. Untreated effluent from the nine landfills had radium-226 contents ranging from 70 to <139 pCi/L. The study authors conclude that there is "limited potential" for environmental impacts from spills or discharges of leachate from these facilities.

Where wastewater is stored in tanks, TENORM concentrations can increase through radioactive ingrowth.[1] Radium-226 and radium-228 are generally considered the radionuclides of greatest concern in wastewaters and are the most frequently measured. But recent research indicates that in closed environments such as tanks, where the radium decay product radon cannot escape, total radioactivity may increase due to ingrowth of other decay products of radium such as Pb-210, Po-210, and Th-228 (Nelson et al., 2015). Experimental work by Nelson et al. found that concentrations of these decay products in Marcellus produced water that was stored in a sealed drum started growing immediately. Concentrations started at zero and reached 10.49 pCi/L for Po-210 and 155 pCi/L for Th-228 over the first 50 and 66 days of storage, respectively. The authors note that these decay products are not soluble, would be associated primarily with particulates, and could be bioavailable. This study demonstrates that analyzing for radium will not provide a complete indication of sample radioactivity if the water is stored in a closed environment and that subsequent management decisions would need to take into account possible increases in radioactivity due to ingrowth.

[1] The ingrowth, or growth within a sample, of radioactive daughter products from radionuclides initially present in the sample can cause greater radioactivity than that resulting from the parent radionuclides alone.

8.5.2.5 Other Solids

Other solid wastes associated with unconventional oil and gas production that may contain radionuclides include solid residuals from POTWs and CWTs and scale in oil and gas equipment. Filter cake samples from POTWs were found by PA DEP (2015b) to have highly variable radium-226 concentrations, with an average of 16 pCi/g, while typical soil concentrations in Pennsylvania have been found to be less than 2.5 pCi/g (Greeman et al., 1999). Filter cake from CWTs had an average radium-226 concentration of 111 pCi/g. The authors conclude that there could be impacts on surface waters through spills or effects on groundwater from landfill leachate containing contaminants originating in residuals sent to landfills.

Accumulation of TENORM-bearing scale in CWTs or POTWs may continue to affect the treatment plant even after discontinuing treatment of wastewaters containing high radionuclide concentrations. Radium can adsorb onto scales in pipes and tanks and can also be removed from water by coprecipitation if sulfate or carbonate is added to hydraulic fracturing wastewater to precipitate calcium, barium, or strontium (Kappel et al., 2013; USGS, 2013a). Pipe scale in oil and gas production facilities has been found to have radium concentrations as high as 154,000 pCi/g, although concentrations of less than about 13,500 pCi/g are more common (Schubert et al., 2014). A similar issue, the potential for accumulation and possible release of radionuclides and other trace inorganic constituents in water distribution systems, has gained attention, with the potential for drinking water concentrations to exceed drinking water standards (Water Research Foundation, 2010). Scale eventually removed from pipes or other oil and gas equipment can end up in landfills and then leach into groundwater or run off to surface water (USGS, 2013a). Also, laboratory research suggests that radium in land-applied barium sulfate scales from conventional oil and gas operations may become mobilized by microbial processes, rendering the radium more mobile and bioavailable (Matthews et al., 2006; Swann et al., 2004); see discussion in Section 8.4.6.1. Monitoring would be needed in order to ascertain the potential for accumulation and release of radionuclides from systems that have treated or continue to treat hydraulic fracturing wastewaters with elevated TENORM concentrations.

8.5.2.6 Road Spreading

Salt and radionuclide accumulation can occur near road spreading sites; one study in Pennsylvania describes a roughly 20% increase in average radium-226 concentrations in soils near five roads where wastewaters from conventional operations had been spread for de-icing (Skalak et al., 2014). However, the standard deviation for the samples was large (24 pCi/g), and background concentrations were approximately 1 pCi/g. Should significant accumulation of radionuclides in soils near roads occur, it would present a vehicle for potential impacts on drinking water resources. The frequency with which hydraulic fracturing wastewater contributes to this type of impact depends on state-level regulations dictating whether the wastewater can be used for road spreading.

8.5.2.7 Potential for Monitoring

Effluent from treatment plants (e.g., CWTs, POTWs) and receiving waters can be monitored for radionuclides. Research suggests that radium-226 and radium-228 are the predominant radionuclides in Marcellus Shale wastewater, and they account for most of the gross alpha and gross beta activity in the waters studied (Rowan et al., 2011). Gross alpha and gross beta measurements may, therefore, serve as an effective screening mechanism for the presence of radionuclides in hydraulic fracturing wastewater. This in turn can help in evaluating management strategies. Portable gamma spectrometers allow rapid screening of wastewater effluent. Sediments can also be measured for radionuclide concentrations at discharge points. If an accurate assessment of total radioactivity is needed rather than a screening, measuring radium content may not be adequate depending upon how wastewater has been stored. Analyses of other radionuclides such as Pb-210, Po-210, and Th-228 may be warranted, especially if the wastewater has been stored in closed loop systems.

8.5.3 Metals

Given the presence in hydraulic fracturing wastewaters of some heavy metals, as well as barium and strontium concentrations that can reach hundreds or even thousands of milligrams per liter (Table 7-5), surface waters may be impacted if discharges from CTWs or POTWs indirectly receiving oil and gas wastewater via CWTs are not managed appropriately or if spills occur.

Common treatment processes, such as chemical precipitation, are effective at removing many metals (Section 8.4). Effluent sampling results collected between October 2011 and February 2013 from seven facilities in Pennsylvania treating oil and gas wastewaters were requested by the EPA. The results revealed low to modest concentrations of copper (0 – 50 μg/L), zinc (14 – 256 μg/L), and nickel (8 – 22 μg/L) (U.S. EPA, 2015f, g). However, metals such as barium and strontium were found to range from low to elevated concentrations in the effluent for some of the facilities. The data showed effluent barium concentrations ranging from 0.35 to 25 mg/L (median of 3.5 mg/L and average of 6.7 mg/L). For results that were greater than 2 mg/L, the drinking water MCL for barium was exceeded. Strontium concentrations ranged from 0.36 to 546 mg/L (median of 297 mg/L and mean of 236 mg/L) (U.S. EPA, 2015g). (See Chapter 9 for information on health effects for barium and strontium.)

Volz et al. (2011) discussed a December 2010 effluent sampling effort at a Pennsylvania CWT that had been treating both conventional and Marcellus wastewater; they measured average barium and strontium concentrations of 27 mg/L and nearly 3,000 mg/L, respectively (eight samples from the one plant) (Volz et al., 2011). NPDES compliance data submitted for 2011 shows that effluent from the same CWT had average barium effluent levels ranging from 26 to 98 mg/L in the months prior to PA DEP's April 2011 request to cease sending hydraulic fracturing wastewater to this and other facilities exempt from the 2010 TDS regulation (U.S. EPA, 2015f, g). After May, 2011, barium effluent concentrations dropped to average values of 9 to 22 mg/L. The facility is scheduled to upgrade its TDS removal capabilities, which should help decrease concentrations of metals in the effluent.

Limited data are available on metal concentrations in wastewater and treated effluent that are directly discharged; additional information would be needed to assess whether there could be downstream effects on drinking water utilities. NPDES discharge permits, which restrict TDS discharge concentrations, would likely reduce metal effluent concentrations due to the additional treatment necessary to minimize TDS.

8.5.4 Volatile Organic Compounds

Benzene is a common constituent in hydraulic fracturing wastewater, and it is of concern due to recognized human health effects. A wide range of concentrations of BTEX compounds occurs in wastewater from the Barnett and Marcellus shales. Natural gas formations generally produce more BTEX than oil formations (Veil et al., 2004), and lower concentrations of BTEX naturally occur in wastewater from CBM production (Appendix Table E-9). The organic chemistry of Marcellus wastewater has been found by Akob et al. (2016) to be more variable than that of inorganic constituents, indicating the need to consider the concentrations of organic compounds when planning wastewater management.

Processes such as air stripping or dissolved air flotation can remove VOCs during treatment, but if treatment is not adequate prior to discharge, the VOCs may reach water resources. For example, the average benzene concentration measured in the discharge from a Pennsylvania CWT in December 2010 was 12 μg/L (Volz et al., 2011) exceeding the MCL for benzene of 5 μg/L.[1] The facility was receiving wastewater from both conventional and unconventional operations at that time. Ferrar et al. (2013) measured for BTEX in effluent from the same facility, and mean concentrations among the four compounds ranged from approximately 2 to 46 μg/L. Concentrations were lower for samples taken after May 19, 2011 (when Marcellus operators voluntarily stopped sending wastewater to POTWs and CWTs exempt from the 2010 TDS regulation), and the difference between pre and post May 2011 sampling was considered statistically significant.

Spills and leakage from pits creates another potential route of entry to drinking water resources, as described in Section 8.4.5. Akob et al. (2016) documented the microbial degradation of organic compounds in Marcellus produced water and note that more research is needed to evaluate how this could mitigate the migration of organic constituents in the event of spills or leaks.

8.5.5 Semi-Volatile Organic Compounds

Little is known about the fate of the SVOC, 2-butoxyethanol (2-BE) (an antifoaming and anti-corrosion agent used in slick-water) (Volz et al., 2011) or its potential impact on surface waters, drinking water resources, or drinking water systems. This compound is very soluble in water and is subject to biodegradation, with an estimated half-life of approximately 1-4 weeks in the environment (Wess et al., 1998). It is classified by the EPA's Integrated Risk Information System (IRIS) as not likely to be carcinogenic to humans, and the International Agency for Research on Cancer (IARC) classifies it as having insufficient evidence to determine carcinogenicity (see Chapter 9 for more information). 2-BE was detected in the discharge of a Pennsylvania CWT at

[1] Among the BTEX compounds, the MCL for benzene is the lowest at 5 μg/L; the MCL for ethylbenzene is 700 μg/L, the MCL for toluene is 1,000 μg/L, and the MCL for xylenes is 10,000 μg/L.

concentrations of 59 mg/L (Volz et al., 2011). Ferrar et al. (2013) detected 2-BE in the effluent from a CWT in western Pennsylvania at average concentrations of 34 – 45 mg/L; the latter value was measured when the CWT was receiving only conventional oil and gas wastewater. Data are lacking on 2-BE concentrations in surface waters that receive treated effluent from hydraulic fracturing wastewater treatment systems.

Polyaromatic hydrocarbons (PAHs; a group of SVOCs) have been found in hydraulic fracturing wastewater (Section 7.3.4.7, Table 7-6). PAHs detected in an unlined pit containing oil and gas wastewater near the Duncan Oil Field in New Mexico were also detected in soils 82 ft (25 m) downgradient at concentrations ranging from 2,000 to 4,900 μg/kg and 164 ft (50 m) downgradient, with concentrations ranging from 22 to 370 μg/kg (Sumi, 2004; Eiceman, 1986).

8.5.6 Oil and Grease

Oil and grease in oil and gas wastewater can come from the formation or from oil-based drilling fluids. Typically, oil and grease are separated from the wastewater before discharge either by heat treatment or by gravity separation followed by skimming. If these processes are inefficient, oil and grease can be integrated with the discharge to surface waters. For example, in some cases, oil and grease are allowed to separate in pits, and water is then withdrawn from the lower part of the pit. If the oil layer is allowed to drop to the level of the standpipe or if the water is agitated, oil and grease may be discharged along with the water. Oil and grease are also often dispersed in wastewater in the form of small droplets that are 4 to 6 microns in diameter. These droplets can be difficult to remove using typical oil/water separators (Veil et al., 2004).

A study was conducted in Wyoming by the U.S. Fish and Wildlife Service from 1996 to 1999 of sixty five oil and gas sites that discharge to ephemeral streams and subsequently to wetlands. Fifteen percent of the wetlands receiving wastewater contained oil-stained vegetation and had a visible oil sheen on the sediments. In addition, ten of twelve sites that were randomly selected for water sample collection (from oil field separator or skim pit effluent) exceeded the discharge limit of 10 mg/L for oil and grease with one site as high as 54 mg/L (Ramirez, 2002).

8.6 Synthesis

A variety of strategies may be considered for the management of hydraulic fracturing wastewater. Important factors for planning management include cost, logistics, wastewater composition, wastewater volumes, and regulations. Available information suggests that Class IID wells regulated under the UIC Program are the most frequently used wastewater management practice, but reuse, sending to a CWT, and various other methods are also employed.

8.6.1 Summary of Findings

8.6.1.1 Wastewater Volumes

The most current national estimate of the total wastewater volume generated in the oil and gas industry (both onshore and offshore) was 889.59 billion gal (21.18 billion bbls or 3.37 trillion L) in 2012, although this estimate is subject to a number of uncertainties (Veil, 2015). The total amount of wastewater generated may increase if hydrocarbon production increases in a region, although Veil (2015) suggests that this trend may not hold true at the national level. Geographically, a large portion of onshore oil and gas wastewater in the United States is reported to be generated in the western part of the country, consistent with the areas where most oil and gas wells are located and most production takes place.

Obtaining reliable national estimates of the amount of wastewater attributable to hydraulic fracturing is a challenge. State data collection efforts vary, and in many states, production data do not identify which wells have been hydraulically fractured. However, annual estimates compiled from those states where hydraulic fracturing wastewater is identified range from hundreds of millions to billions of gallons of wastewater generated each year. Data from individual states indicate that along with an increase in the numbers of hydraulically fractured wells, associated wastewater volumes have generally increased over the last several years into 2014. However, while there is a general correlation between unconventional oil and gas production and wastewater volume, the relationship is complicated by several factors such as timing of drilling and production. More complete and comparable estimates of local, state, and regional wastewater volumes would facilitate wastewater management on the part of operators as well as planning on the part of agencies that oversee wastewater management.

8.6.1.2 Wastewater Management Practices

Hydraulic fracturing wastewater is managed in a variety of ways, including disposal via Class IID wells; minimal treatment and reuse (in subsequent fracturing operations); more complete treatment followed by reuse; sending to CWTs for treatment followed by direct discharge or transfer to POTWs; evaporation; and other uses such as agriculture and wildlife use (allowed only in the arid west when the wastewater is of good enough quality for such uses). All of these strategies have the potential to affect drinking water resources. Wastewater management practices continue to shift in response to evolving understanding of environmental concerns, emplacement of new regulatory controls, changes in costs, and changes in technology and operator practices. Unauthorized discharges of hydraulic fracturing wastewater have also been documented, and such discharges can potentially impact drinking water resources.

As of 2015, available information suggests that Class IID disposal wells are a primary wastewater management practice for operators in most of the major unconventional reservoirs in the United States, with the notable exception of the Marcellus Shale region in Pennsylvania. Class IID wells tend to be economically favorable, especially if they are located within a reasonable transportation distance from well sites (U.S. GAO, 2012). In particular, large numbers of active injection wells are found in Texas (7,876), Kansas (5,516), Oklahoma (3,837), Louisiana (2,448), and Illinois (1,054) (U.S. EPA, 2016d).

Pennsylvania is somewhat unique in having only nine Class IID wells (as of February 2015), along with having experienced significant growth of shale gas production in the Marcellus and corresponding production of large volumes of wastewater. Operators producing from unconventional formations (as defined by PA DEP) have managed their wastewater through the use of POTWs (a practice that is subject to recently promulgated regulations), CWTs, extensive reuse for hydraulic fracturing operations, and hauling to disposal wells (to a lesser degree). The wastewater management history in Pennsylvania provides an example of evolving strategies to manage the treatment, discharge, storage, and reuse of hydraulic fracturing wastewaters that are high in constituents of concern (e.g., bromide, TDS, and TENORM).

Reuse of hydraulic fracturing wastewater to formulate fluid for subsequent hydraulic fracturing jobs is most prevalent in Pennsylvania (as high as 90%), with much of the reuse happening on-site (PA DEP, 2015b). Reuse is practiced in other regions as well (e.g., Haynesville Shale, the Fayetteville Shale, the Barnett Shale, and the Eagle Ford Shale), but at much lower rates (about 5 – 20%). Reliable estimates are not available for all areas of the United States because waste management practices are not consistently reported across all states. If hydraulic fracturing activity slows, demand for wastewater for reuse will also likely decrease, and other forms of wastewater management will be needed. Potential impacts associated with reuse center on concerns over the storage of untreated or minimally treated wastewater on-site or transport to CWTs.

Treatment of hydraulic fracturing wastewater may be done at CWTs or using mobile or semi-mobile systems designed for on-site use. Treatment at a CWT may be followed by direct discharge by the CWT to surface water, indirect discharge to a POTW in accordance with recently promulgated regulations, or reuse. Most CWTs treating hydraulic fracturing wastewater are located in Pennsylvania (about 40 facilities), with a limited number in other states. CWTs vary widely in treatment capabilities, ranging from producing high-quality effluent to minimal treatment for reuse.

Other wastewater management practices, such as evaporation and agricultural uses, represent a smaller fraction of wastewater management nationally. These practices can, however, be locally significant. Although specific instances of contamination were not identified for this assessment, these practices could lead to impacts on drinking water resources if facilities are not properly constructed and maintained or if water quality is not adequately characterized to ensure that management is appropriate.

8.6.1.3 Treatment and Discharge

Wastewater that is treated and subsequently discharged by CWTs can result in impacts due to inadequate treatment. A frequently cited concern is the high TDS content in wastewaters from unconventional formations, which poses challenges for treatment, discharge, and reuse. Treatment processes such as sedimentation, filtration, flotation, and chemical precipitation are capable of removing constituents such as oil and grease, major cations, metals, and TSS. They do not, however, adequately reduce TDS in high-salinity wastewaters. More advanced processes such as reverse osmosis (RO) or distillation are needed if TDS removal is required (Shaffer et al., 2013; Younos and Tulou, 2005). Most available information on treatment of hydraulic fracturing wastewater is based on practices used in Pennsylvania because that is where most data have been collected.

Hydraulic fracturing wastewater discharged from treatment facilities without advanced TDS removal processes has resulted in elevated TDS concentrations (including bromide, iodide, and chloride levels) in receiving waters. Impacts from these discharges is due largely to the role of bromide and iodide in DBP formation at downstream drinking water systems, potentially causing higher levels of harmful DBPs in finished drinking water.[1] Modeling suggests that very small percentages of hydraulic fracturing wastewater added to a river used as a source for drinking water systems could cause a notable increase in DBP formation.

Radionuclides (i.e., TENORM), which are present in some hydraulic fracturing wastewaters, can cause impacts if the wastewater is discharged without adequate treatment. TENORMs have been measured in effluent from wastewater treatment facilities receiving Marcellus wastewater (which includes effluent sent for reuse and not discharged to surface water). Radium-226, radium-228, gross alpha, and gross beta are most cited as the radioactive constituents of concern, likely due to the availability of test methods for these constituents in wastewater. Radium concentrations can range up to thousands or tens of thousands of pCi/L. Fewer data are available on concentrations of uranium and other radionuclides in hydraulic fracturing wastewaters. Also, fewer data exist on radionuclide concentrations in wastewaters from unconventional formations other than the Marcellus, limiting our ability to assess potential impacts from TENORM on a nationwide basis.

Other constituents posing health or environmental concerns that can be discharged in inadequately treated hydraulic fracturing wastewater include organic compounds, barium, strontium, and other metals. Chemicals used in the fracturing fluid or their degradation products could also be present. A variety of treatment processes can be used for removal of these contaminants, from commonly used methods such as chemical precipitation and filtration to more advanced and more costly techniques, such as reverse osmosis, distillation, and mechanical vapor recompression.

8.6.1.4 Storage and Disposal Pits and Impoundments

Regardless of the wastewater management practices used, some type of temporary storage of fluids is generally required. Storage can be in the form of tanks as well as pits and/or impoundments. Pits encompass a variety of structures, from on-site pits for storage at the well site to larger, centralized facilities (typically referred to as "impoundments" or "ponds"). Some states allow evaporation pit facilities or percolation pits as a means of wastewater disposal. The locations and number of pits are not well documented in most states, nor are pits associated with hydraulic fracturing operations necessarily identified, despite efforts by the U.S. EPA (U.S. EPA, 2003b) and environmental groups such as SkyTruth to identify pits in use. Information that is typically available on state websites includes permitted centralized commercial evaporation facilities (COWDFs) most commonly used in the western United States.

Impacts on both groundwater and surface water resources due to inadequate pit capacities, overfilling, and leaks have been documented. In extreme precipitation events, pits can be overtopped. Leaks can occur if liners are compromised or were not used. With an increased emphasis on reuse in some regions, the need for temporary storage of high-TDS wastewater increases the potential for leaks and spills from pits and during fluid handling.

[1] Some types of DBPs are regulated under SDWA's Stage 1 and Stage 2 DBP Rules, but a subset of DBPs, including a number of chlorinated, brominated, nitrogenous, and iodinated DBPs, are not regulated. Brominated and iodinated DBPs are more toxic than other species of DBPs.

Unlined pits, in particular, provide a pathway for contaminants to reach groundwater, and impacts on groundwater from historic and current uses of unlined pits in the oil and gas industry have been documented. The resulting contamination can be long-lasting. States have taken measures to phase out the use of unlined disposal and storage pits, but unlined pits that are still in use can provide an ongoing potential source of contamination for groundwater (Grinberg, 2014).

8.6.1.5 Residuals

Solid and liquid residuals associated with hydraulic fracturing wastewater (treatment residuals from CWTs, sludges from tanks and pits, and pipe scale) could have impacts on drinking water resources if not managed and disposed of properly. Liquid residuals are inappropriate for surface water discharge or discharge to a POTW due to high concentrations of salts and other contaminants; they are commonly disposed of in an injection well. Solid residuals may leach a number of constituents, such as alkali metals, alkaline earth metals, and bromide. They can also contain TENORM if radionuclides are present in the wastewater being treated. Given that residuals are commonly disposed of in landfills, TENORM can be problematic due to the possibility of radon emissions and radioactivity in the landfill leachate. Solids from pits or tanks can also contain TENORM if the wastewater contains radionuclides, and one study has shown the potential for radioactivity to increase in the closed environment of tanks.

8.6.2 Factors Affecting the Frequency or Severity of Impacts

The frequency and severity of impacts on drinking water resources from hydraulic fracturing wastewater will depend upon the wastewater composition and volumes, and the mix of wastewater management strategies used.[1] The types of potential impacts (along with frequency and severity) may shift in time as management practices change in response to evolving environmental, regulatory, economic, or logistical drivers. The frequency and severity of impacts can also depend on the size and initial quality of the drinking water resource and its proximity to wastewater management operations.

8.6.2.1 Role of Changing Wastewater Management Practices

The most common disposal option for hydraulic fracturing wastewater is injection into Class II disposal wells. If this option becomes restricted in a given location, the wastewater management options could shift, at least locally, towards other options such as sending wastewater to CWTs for treatment and either discharge or reuse. Although reuse avoids the immediate need to discharge wastewater by directing it to ongoing hydraulic fracturing activities, the practice could concentrate radionuclides or other constituents as fluid moves through cycles of reuse. Whether such concentrations would be significant depends on the ratio of recycled to "fresh" water when the wastewater gets reused. Alternatively, wastewater might need to be transported to more distant

[1] Both national and state regulations affect the wastewater management practices used. At a national level, although the EPA's oil and gas ELG regulations generally prohibit the direct discharge of oil and gas wastewater to waters of the U.S., treatment and discharge of hydraulic fracturing wastewater can occur under certain limited circumstances, such as under an exemption authorizing discharge for agricultural and wildlife use in the arid west, or by Centralized Waste Treatment facilities. For additional information on national regulations relevant to hydraulic fracturing wastewater management, see Text Box 8-2.

Class IID wells. This option, while attractive from the perspective of limited disposal impacts, could increase the frequency of impacts from spills and leaks during transportation (see Chapter 7 for discussion of roadway transport of produced water).

8.6.2.2 Treatment and Discharge

Both the frequency and severity of potential impacts on drinking water resources from treated hydraulic fracturing wastewater depend on the influent concentrations of the constituents in the wastewater and the type and adequacy of the treatment processes employed. If treatment and/or blending is inadequate, the resulting quality in a receiving water could, for example, influence formation of DBPs during subsequent drinking water treatment, impair biological treatment processes, and release TENORMs into receiving waters.

The volume of treated effluent discharged relative to the size of the receiving water body is an important local factor affecting the frequency and severity of potential impacts. Because of dilution effects, drinking water systems drawing from smaller rivers will likely face greater challenges in dealing with contaminants in their source water than systems drawing from larger rivers receiving the same volume of effluent. Seasonal changes in streamflow will also affect frequency and severity by affecting the degree of dilution. Existing loadings of pollutants from other sources in a watershed can increase the frequency and severity of potential impacts if the additional contributions from hydraulic fracturing wastewater cause concentrations to exceed thresholds.

Direct discharges of wastewaters with lower TDS concentrations to ephemeral streams are allowed in parts of the country where the wastewater is considered to be "of good enough quality" for livestock watering and wildlife use, and the discharges may constitute a large portion of streamflow. Permits authorizing such discharges may only require monitoring for a limited set of constituents. In particular, they may not necessarily require monitoring for specific constituents associated with hydraulic fracturing. The potential for water quality impacts from such discharges depends upon whether chemicals used for fracturing fluid or maintenance (or their degradation products) are present and at what concentrations. Long-term discharges to these ephemeral streams could result in ongoing impacts if there are unrecognized or unaddressed water quality issues.

Concerns about radionuclides in hydraulic fracturing wastewater have received considerable public attention, especially in the Marcellus region. The severity and frequency of impacts on receiving waters and sediments from TENORM depends upon the TENORM content in the wastewater (highest in regions with NORM-rich formations), temporal variability in the wastewater composition, and the treatment processes used. There are insufficient data to indicate whether radionuclides from these wastewaters have reached drinking water intakes. However, data do suggest that radionuclides can accumulate in sediments at or near discharge points from facilities that treat and discharge oil and gas wastewater. A recent PA DEP study (PA DEP, 2015b) reported radium in the effluent of both CWTs handling oil and gas wastewater and POTWs receiving effluent from such facilities.

Analysis of TENORM concentrations in hydraulic fracturing wastewaters prior to treatment, selection of appropriate treatment processes that adequately address the TENORM levels, and monitoring of TENORM in the treated effluent and receiving waters could help address the frequency and severity of potential impacts on drinking water resources in these areas. However, a confounding issue is underestimation of radium concentrations when using traditional wet chemical methods with high-TDS waters. This could consequently cause underestimation of frequency or severity of impacts. Newer studies have begun to use gamma spectroscopy for better recovery, which could help with more accurate assessment of frequency and severity of impacts (Nelson et al., 2014).

Accumulation of other contaminants such as organic compounds or metals in sediments at or near discharge points is also possible. If the sediments are disturbed or entrained due to dredging or flood events, contaminated sediments could be transported downstream closer to drinking water systems. The fate of such sediments and likelihood of mobilization of contaminants originating from hydraulic fracturing wastewaters have not been explored. The frequency and severity of impacts related to contaminated sediments would depend on a number of site-specific factors such as concentrations in the sediments, effluent quality, volume from the discharging facility, stream water quality, and stream hydrodynamics.

8.6.2.3 Storage and Disposal Pits and Impoundments

Tanks, pits, and impoundments, ever-present at oil and gas operations and CWTs, provide an opportunity for impacts on drinking water resources. Tanks are generally regarded as being safer than pits in terms of containment, although recent research has shown the potential for an increase in radioactivity in tank sediment if the wastewater contains TENORM. For pits and impoundments, the likelihood and severity of impacts due to spills and leaks depends in part on state construction and maintenance requirements for pits and how well these are observed. Frequency and severity of impacts will be lessened by attention to design standards, competent construction, and operational practices.

Liners, in particular, are an important measure to protect groundwater resources and are a common aspect of pit construction requirements. Liner specifications address materials, thickness, and leak detection. If a liner is compromised or nonexistent, the severity of impacts on groundwater will be affected by the volume leaked, the composition of the water in the pit, the depth to the water table, soil permeability, and the capacity of the soil to retain certain pollutants as the water percolates through. If substantial sediment has built up in the bottom of the pit, then in the event of a liner breach, contaminants may leach if the sediments permit water to pass through and into the soil. The fate and transport of wastewater contaminants in the subsurface is governed by a complex set of physical, chemical, and biological processes that dictate interactions between wastewater constituents and soil minerals, degradation or transformation of wastewater constituents, and possible mobilization of constituents in the soil under a pit (see Section 5.8 in Chapter 5 for a thorough discussion of processes affecting movement of constituents in the subsurface). Duration of use is also a consideration; the longer a pit with a faulty or nonexistent liner receives wastewater, the more severe the ultimate impact could be on underlying sediment and groundwater.

In the event of overtopping of a pit due to overfilling or extreme weather, the severity of impacts on surface water or groundwater will depend on the volume that overflows, wastewater composition, distance to surface water (if wastewater flows over land), depth to the water table, and soil properties (if the overflow infiltrates into the soil). If the overflow reaches a stream or river, the size of the spill relative to stream size and flow rate could also affect the severity of the impact. The combined factors that can contribute to overflows include capacity of the pit, the volume of fluid stored in the pit (i.e., freeboard) at the start of the precipitation event, and failure to monitor/ reduce pit fluid levels if needed.

As with concerns over discharges, the potential for impacts will be tied to other, existing stresses within a watershed. If the surface water is already receiving pollutant loadings from other sources, then an additional contribution from a pit-related leak or spill may not be as readily accommodated without causing water quality impairment.

8.6.2.4 Other Management Practices and Management of Residuals

Other management strategies such as irrigation, road spreading, and evaporation are less frequently employed for hydraulic fracturing wastewaters. The severity of impacts on surface waters from irrigation and road spreading will depend on the constituents in the wastewater (e.g., salts, radionuclides, and chemicals used in hydraulic fracturing), the distance to a receiving water, and whether stormwater management measures exist to mitigate runoff. The factors influencing whether constituents will migrate to shallow groundwater include depth to the water table, precipitation, soil permeability, and the soil's ability to retain pollutants that can adsorb to particles. If irrigation and road spreading are long-term management practices, the frequency of impacts will likely be proportional to the frequency with which the practices are employed.

Liquid and solid residuals generated from the treatment, storage, and handling of hydraulic fracturing wastewater have highly concentrated waste constituents. This could increase the potential severity of impacts due to spills that reach surface water resources or leach to groundwater. Potential impacts from management of residuals can be lessened in frequency and severity through careful handling, adequate characterization (including TENORM content), and selecting an appropriate disposal method, including use of a landfill that can accept TENORM waste if needed.

8.6.3 Uncertainties

A full understanding of hydraulic fracturing wastewater management is limited by a lack of available data in several areas. First, it is difficult to assemble a complete national- or regional-level picture of wastewater volumes and the management practices used because the tracking and availability of data vary from state to state. Although some states provide well-organized and relatively thorough data, not all states collect or make such information available. It can be difficult to identify wastewater volumes specifically associated with hydraulic fracturing (as compared to all oil and gas production activities). Such data would be needed to place hydraulic fracturing wastewater in the broader context of all oil and gas wastewaters. It is also generally difficult to determine whether hydraulic fracturing wastewater is being injected under a given disposal well permit because the permit rarely identifies which production wells are contributing to the wastewater stream. Data are also generally difficult to locate for wastewater production volumes, the chemical composition and concentrations in wastewater, and the management and disposal strategies for residuals.

Up-to-date information on the volume of hydraulic fracturing wastewater disposed of via underground injection by state is not uniformly available. Without this information, it is difficult to assess whether disposal well capacity will become an issue in areas where hydraulic fracturing activity is expected to increase or where use of disposal wells may become restricted locally or regionally.

For CWTs permitted to discharge to surface water, the ability to assess the potential effects of these discharges on drinking water resources is limited by the lack of effluent water quality data. Some monitoring data are required by the permit, but the list of monitored constituents may be limited. Selection of the appropriate water quality parameters to be monitored is critical to ensure that potentially problematic constituents are identified (e.g., chemicals associated with hydraulic fracturing fluids, maintenance chemicals, and degradation products of those chemicals). Some chemicals used in fracturing fluids are not disclosed, and analytical methods are lacking for some chemicals of concern and their degradation products.

Pollutant removal capabilities of the treatment facilities would also be valuable information to have, but this would require well-coordinated collection of both influent and effluent samples; this type of data is even less commonly available. In addition, the use of inappropriate analytical methods for the high TDS wastewater associated with hydraulic fracturing operations can complicate the use of available data. Methods used should be suitable for the highly complex matrix of contaminants encountered with oil and gas wastewater to have confidence in the results of chemical analyses.

Monitoring of surface waters downgradient of discharges, such as screening with a TDS proxy (i.e., conductivity), would also help assess the frequency of impacts on receiving waters by hydraulic fracturing activities (including spills and discharges of wastewater). Such data can also give an estimation of the severity of those impacts. Other than a few studies in the Marcellus Shale region, these types of water quality data are lacking. Existing data are also limited regarding legacy effects, such as accumulation of contaminants in sediments at discharge points, soil accumulation due to application of de-icing brines or salts from wastewater treatment, and handling of wastewater treatment residuals.

Assessing longer-term impacts on surface water quality from hydraulic fracturing activities in general is severely hampered by inadequate data. Bowen et al. (2015) state that available national-level databases are inadequate for addressing the question of whether there is evidence of national-level trends in surface water quality (as measured by specific conductivity and chloride) in areas where unconventional oil and gas production is taking place. Work by the Northeast-Midwest Institute and the USGS (Betanzo et al., 2016) was undertaken to explore the types and amounts of data needed to assess whether shale gas development activities contaminate surface water or groundwater in the Susquehanna River Basin. The focus was on longer-term cumulative impacts because detection of such impacts requires water quality monitoring. Detection of impacts (in either surface water or groundwater) requires a systematic monitoring approach that includes sampling at appropriately selected locations at an adequate frequency and duration and for a suite of water quality parameters to detect changes over time. Comparison sites without hydraulic fracturing activity are needed as well. The authors concluded that the data necessary to detect changes in surface water or groundwater due to hydraulic fracturing activities do not currently exist for the Susquehanna River Basin.

8.6.4 Conclusions

Oil and gas operations in the United States generated an estimated 2.43 billion gal of wastewater per day (about 60 million bbls/day) in 2012 (Veil, 2015). This includes wastewater associated with hydraulic fracturing activities, although what portion of this oil and gas wastewater is attributable to hydraulic fracturing operations is difficult to estimate. Available information indicates that the majority of hydraulic fracturing wastewater is injected into Class IID wells regulated under the UIC Program. In the Marcellus Shale region in Pennsylvania, this option is limited, and the majority of wastewater is reused (either with or without treatment) for new hydraulic fracturing jobs. Hydraulic fracturing wastewater may also be treated at a CWT and discharged by the CWT to surface water or to a POTW. In the western United States, wastewater is used in other ways (e.g., livestock watering) if water quality allows. Wastewater is also sent to evaporation ponds for disposal or stored on-site or in centralized pits or impoundments prior to final disposal or reuse.

Impacts on drinking water resources have resulted from discharges of inadequately treated wastewater and from leaks, spills, and percolation associated with pits. Other mechanisms for impacts include improper handling of treatment residuals or pit and tank sludges as well as leaching and runoff associated with other wastewater management practices. The impacts related to pits and residuals/sludges affect both surface water and groundwater; unlined pits or those with compromised liners present a particular concern (see Chapter 7 for additional discussion of spills). The constituents that have received the greatest attention in the literature include TDS, DBP precursors (especially bromide), and radium, although hydraulic fracturing wastewater can contain elevated concentrations of a number of organic and inorganic constituents of concern. Regardless of the management option utilized, if the wastewater is not thoroughly characterized or sampling is not conducted for analytes of concern, the severity and frequency of the impacts will be unknown or unquantified. The nature and volume of wastewater generated through hydraulic fracturing activities necessitate careful consideration of handling, treatment, and ultimate reuse or disposal to ensure that water resources are not adversely impacted. There is also a need for reliable and consistent waste generation data collection and reporting, improved efforts to characterize wastewater quality (both treated and untreated), and systematic monitoring efforts to be able to detect impacts on drinking water resources.

Chapter 9. Identification and Hazard Evaluation of Chemicals across the Hydraulic Fracturing Water Cycle

Abstract

This chapter identifies chemicals associated with hydraulic fracturing and provides an overview of the potential human health effects associated with these chemicals, as well as variables that could affect chemical occurrence in drinking water. The EPA has identified 1,606 chemicals associated with hydraulic fracturing, including 1,084 chemicals that are used in hydraulic fracturing fluid and 599 chemicals that have been detected in produced water. There is some uncertainty surrounding this chemical list, as it does not include a subset of chemicals that are classified as confidential business information, and because understanding of produced water composition is constrained by limitations of analytical chemistry as well as site-specific variations in the geochemistry of hydraulically fractured rock formations.

The EPA used selected federal, state, and international sources of toxicological data to identify toxicity values that can be used to support risk assessment for these chemicals, including chronic oral reference values (RfVs) for noncancer effects and oral slope factors (OSFs) for cancer. Chronic oral RfVs or OSFs were available for 173 (11%) of the total 1,606 chemicals. Health effects associated with chronic oral exposure to these chemicals include carcinogenicity, neurotoxicity, immune system effects, changes in body weight, changes in blood chemistry, liver and kidney toxicity, and reproductive and developmental toxicity.

For the majority of chemicals that lack chronic oral RfVs or OSFs, risk assessors will have to turn towards other sources of toxicological information that may have greater uncertainty than RfVs and OSFs, including quantitative structure-activity relationship (QSAR) models or additional data from the EPA's Aggregated Computational Toxicology Resource (ACToR) database. To understand whether specific chemicals can affect human health through their presence in drinking water, data on chemical concentrations in drinking water are needed. In the absence of these data, a preliminary analysis of relative hazard potential for drinking water resources can be conducted using the multi-criteria decision analysis (MCDA) approach outlined in this chapter. The MCDA combines data on toxicity, occurrence, and physicochemical properties for selected subsets of chemicals and was used in this chapter to highlight several chemicals that may be more likely than others to reach drinking water resources and present a health hazard.

Overall, while evidence suggests that hydraulic fracturing has the potential to impact human health, the actual human health implications are not well understood or well documented. Given that chemicals in hydraulic fracturing fluids and produced water are likely to vary on a regional basis and even between individual wells, the materials presented in this chapter are best applied for risk assessment and risk management decision-making at the local level.

This page is intentionally left blank.

9. Identification and Hazard Evaluation of Chemicals across the Hydraulic Fracturing Water Cycle

9.1 Introduction

In this chapter, we present and integrate what is known about chemicals in the hydraulic fracturing water cycle, and provide an initial assessment of the potential for these chemicals to impact human health. The discussion is focused on the availability of toxicity values and qualitative assessments that can be used to inform the risk assessment of these chemicals for oral exposure via drinking water—in particular, the available noncancer oral reference values (RfVs), cancer oral slope factors (OSFs), and qualitative cancer classifications.[1,2,3] Public health impacts will depend upon both the inherent toxicity of these chemicals and the potential for human exposure. We highlight several field studies that have detected hydraulic fracturing-related chemicals in drinking water resources, and discuss properties of chemicals related to environmental fate and transport that could affect their potential impact on drinking water resources. To the extent information was available to do so, knowledge of toxicological and chemical properties was combined to illustrate a preliminary analysis of the relative hazard that these chemicals could pose to drinking water resources. The data are presented in this chapter as follows:

Section 9.2 provides a brief background on public health concerns surrounding hydraulic fracturing and unconventional oil and gas extraction, which have been highlighted in several recent studies.

Section 9.3 discusses how information sources were used to create a list of chemicals used in or detected in various stages of the hydraulic fracturing water cycle. The consolidated chemical list includes chemicals reportedly added to hydraulic fracturing fluids in the chemical mixing stage, as well as fracturing fluid chemicals, formation chemicals, or their reaction products that may be carried in produced water.

Section 9.4 provides an overview of the methods that were used for gathering information on toxicity and physicochemical properties for all chemicals identified in Section 9.3, and outlines the number of chemicals that had available data on these properties. For toxicological data, the primary focus is on chronic oral RfVs, OSFs, and qualitative cancer classifications from selected data sources that met the EPA's criteria for inclusion in this assessment. This section also discusses other

[1] A reference value (RfV) is an estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfV is a generic term not specific to a given route of exposure (U.S. EPA, 2011f). In the context of this report, the term RfV refers to reference values for non-cancer effects occurring via the oral route of exposure and for chronic durations, except where noted.

[2] An oral slope factor (OSF) is an upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100 (U.S. EPA, 2011f).

[3] Qualitative cancer classifications are a system used for the hazard identification of probable carcinogens, in which human data, animal data, and other supporting evidence are combined to characterize the weight of evidence (WOE) regarding the potential of an agent to cause cancer in humans.

potential sources of toxicity information: the use of quantitative structure-activity relationship (QSAR) modeling to estimate chemical toxicity, as well as the availability of toxicological information on the EPA's Aggregated Computational Toxicology Resource (ACToR) database. A brief description of other potential tools and approaches that may be used by stakeholders for site-specific evaluation of chemical hazards, but are not used in this report, is provided in Appendix G.

Section 9.5 describes the potential hazards of subsets of chemicals identified as being of interest in previous chapters of this report. This includes chemicals in hydraulic fracturing fluid (Chapter 5); organic chemicals, inorganic chemicals, and pesticides detected in produced water (Chapter 7); stray gas, such as methane (Chapter 6); and disinfection byproducts (DBPs) formed from constituents of hydraulic fracturing fluid wastewaters (Chapter 8). We discuss instances in which these chemicals have been detected in drinking water resources in areas of hydraulic fracturing activity, and provide an overview of the available toxicological information for these chemicals.

Section 9.6 uses a multi-criteria decision analysis (MCDA) framework to provide a preliminary analysis of the potential hazards of chemicals used in hydraulic fracturing fluids or detected in produced water. The MCDA framework is used to integrate data on chemical toxicity, occurrence, and physicochemical properties. In this context, occurrence and physicochemical properties are used as metrics to estimate the likelihood that a chemical will reach and impact drinking water resources. Chemicals considered in these hazard evaluations include a subset of chemicals identified in the EPA FracFocus 1.0 project database, as well as a subset of organic chemicals that have been detected in produced water.

This chapter is not a human health risk assessment. As shown in Text Box 9-1, risk assessment consists of four basic steps: hazard identification, dose-response assessment, exposure assessment, and risk characterization. This chapter provides an overview of hazard identification and dose-response assessment for these chemicals, but lacks information to fully characterize exposure and risk. In Section 9.5, we highlight instances in which these chemicals have been detected in drinking water resources, but these data are only available for a small number of chemicals. The MCDA approach in Section 9.6 provides a method for integrating data on toxicity and exposure potential, but should be considered only as a preliminary analysis, and should not be used in place of local data on chemical exposure.

This chapter is focused on potential human health hazards of chemicals for the oral route of exposure (drinking water); therefore, the toxicological properties and physicochemical ranking metrics described herein do not necessarily apply to other routes of exposure that may occur with these chemicals, such as inhalation or dermal exposure. We additionally note that this analysis is focused on individual chemicals, rather than mixtures of chemicals used as additives.

In general, characterizing chemicals and their properties on a national scale is challenging and the use and occurrence of chemicals is likely to differ between geological basins and possibly on a well-to-well basis (Chapters 5 and 7). Therefore, for the protection of human health at the local level, chemical hazard evaluations are best conducted on a regional or site-specific scale. This level of analysis is outside the scope of this report; however, the methods of hazard evaluation presented here can also be applied on a regional or site-specific scale in order to identify chemicals that may present a potential human health hazard.

Text Box 9-1. Applying Toxicological Data for Human Health Risk Assessment.

Understanding potential human health impacts requires knowledge not only of the inherent toxicity of the chemicals found in contaminated environmental media, but also of the potential for exposure to these chemicals. The process of evaluating the nature and probability of such impacts is known as human health risk assessment. Overall, human health risk assessment includes four basic steps (U.S. EPA, 2016a):

1. Hazard identification: Examining whether a chemical has the potential to cause harm to humans and/or ecological systems, and if so, under what circumstances.

2. Dose-response assessment: Examining the numerical relationship between exposure and effects.

3. Exposure assessment: Examining what is known about the frequency, timing, and levels of contact with a chemical.

4. Risk characterization: Examining how well the data support conclusions about the nature and extent of risk from exposure to a chemical. Information from the hazard identification, dose-response assessment, and exposure assessment are summarized and integrated into quantitative and qualitative expressions of risk.

The RfVs and OSFs compiled by the EPA in this study pertain to the first two steps of human health risk assessment: identifying chemicals that have the potential to affect human health (hazard identification), and characterizing the exposure levels at which those effects occur (dose-response assessment). These toxicity values may be used in combination with site-specific chemical exposure information (exposure assessment) in order to evaluate potential human health risks (risk characterization). Qualitative cancer classifications characterize the weight of evidence regarding the potential for a chemical to cause cancer, and therefore provide additional information that can be used for hazard identification.

Toxicity information spans a wide range with respect to extent, quality and reliability. The RfVs, OSFs, and qualitative cancer classifications compiled in this study are those identified by the EPA as being of the highest quality and reliability, per the criteria discussed in this chapter. The QSAR-based toxicity estimates discussed in this chapter are considered to be lower on the continuum of quality and reliability, but may provide useful information pertaining to hazard identification and dose-response assessment when a chemical does not have an RfV or OSF available. The EPA's ACToR database provides an aggregation of a wide range of toxicological data that may also be useful for supporting the risk assessment of these chemicals. This chapter provides information on whether a chemical has data available from ACToR; however, it is beyond the scope of this report to evaluate the quality and reliability of data for these chemicals within ACToR, or to provide guidance on how the data within ACToR should be used to support human health risk assessment.

9.2 Overview: Hydraulic Fracturing and Potential Impacts on Human Health

As discussed in the previous chapters of this assessment, a variety of chemicals are associated with the hydraulic fracturing water cycle. Chemicals are added to hydraulic fracturing fluids at the chemical mixing stage (Chapter 5), and then injected into the well (Chapter 6). These chemical additives may return to the surface in produced water, along with chemicals from the formation (Chapter 7). The chemicals in produced water may persist in wastewater effluents, with some constituents contributing to the formation of disinfection byproducts in treated wastewater (Chapter 8). Through events such as large volume spills (Figure 9-1), mechanical integrity failures, hydraulic fracturing directly into groundwater resources, or discharge of inadequately treated hydraulic fracturing wastewater, there are specific instances in which these chemicals have been demonstrated to enter drinking water resources. Thus, there is potential for human exposure to these chemicals, and the potential for adverse human health effects resulting from exposure.

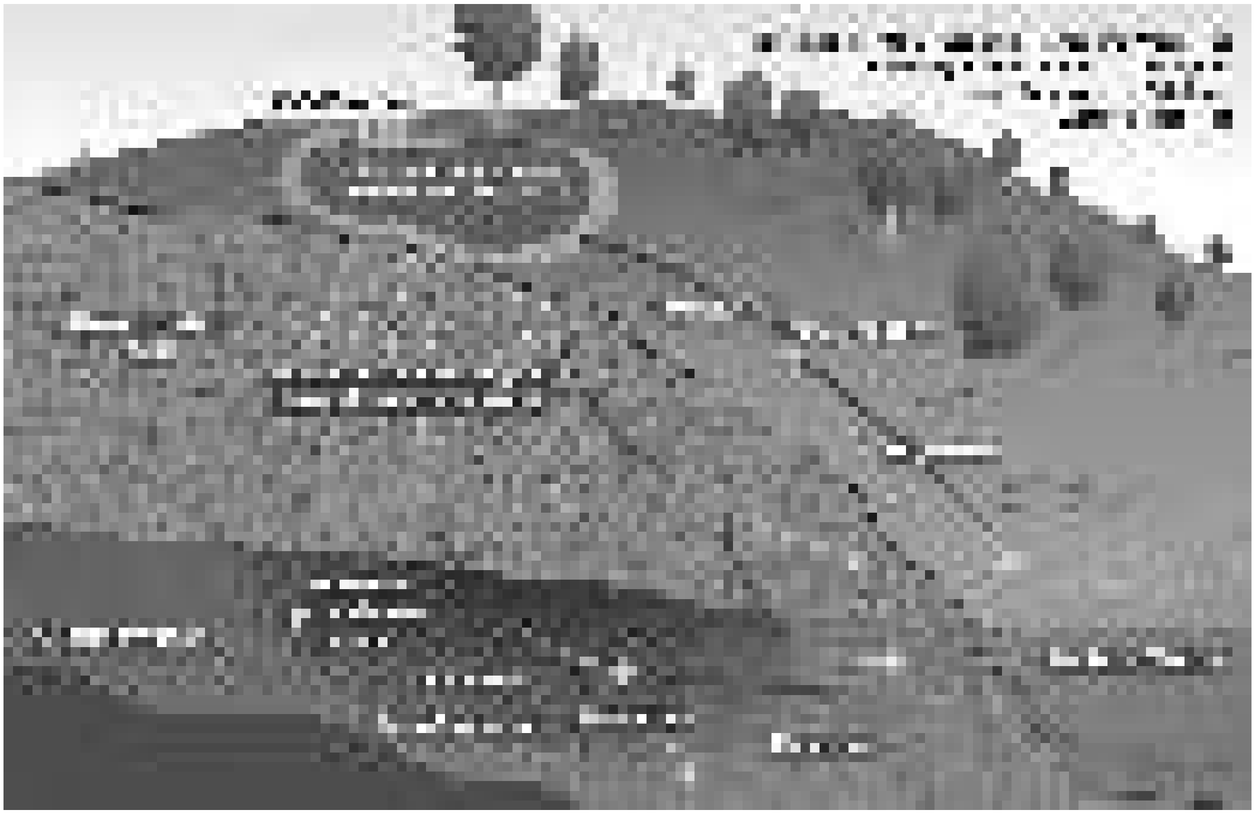

Figure 9-1. Fate and transport schematic for a hydraulic fracturing-related spill or release.

Multiple authors have noted with the recent increase in hydraulic fracturing operations there may be an increasing potential for significant public health and environmental impacts (Goldstein et al., 2014; Finkel et al., 2013; Korfmacher et al., 2013; Weinhold, 2012). These concerns have been highlighted in several recent studies. An epidemiological study in Colorado demonstrated residential proximity of pregnant mothers to natural gas wells is associated with an increased incidence of congenital heart defects, and, to a lesser extent, neural tube malformations (Mckenzie et al., 2014). A similar study in Pennsylvania found pregnant mothers living closer to unconventional natural gas wells were more likely to have infants that were small for gestational age, with lower birth weights compared to infants from mothers living farther from wells (Stacy et al., 2015). Residential proximity to natural gas wells in the Marcellus Shale is associated with an increase the number of self-reported health symptoms, particularly upper respiratory and dermal symptoms (Rabinowitz et al., 2015), chronic rhinosinusitis, migraine headache, and fatigue symptoms (Tustin et al., 2016). Laboratory studies have found that endocrine disrupting activity measured using in vitro bioassays may be elevated in surface and groundwater at known hydraulic fracturing spill sites (Kassotis et al., 2014) and in surface water downstream from a hydraulic fracturing wastewater injection facility (Kassotis et al., 2016). Although none of these studies demonstrate a direct effect of hydraulic fracturing activity on human health, and none of the epidemiological studies provided measures of individual or population level exposures or differentiated between drinking water contamination and other potential routes of exposure (e.g., air pollution), all are suggestive of a relationship between unconventional oil and gas development and adverse health outcomes.

Previous chapters of this report have identified cases in which contamination of drinking water resources could clearly be linked to hydraulic fracturing activity. For example, equipment failure and human error have led to spills of hydraulic fracturing fluids across the country and have affected the quality of drinking water resources (U.S. EPA, 2015m; Brantley et al., 2014; COGCC, 2014; Gradient, 2013). Other studies highlighted in previous chapters provide indirect evidence hydraulic fracturing activity has contaminated surface water or groundwater. For example, two recent studies in the Marcellus Shale detected known hydraulic fracturing-related chemicals in nearby groundwater wells, and used multiple lines of evidence to link the origin of these chemicals to hydraulic fracturing activity (Drollette et al., 2015; Llewellyn et al., 2015).

There have also been documented impacts on ecological receptors. In Knox County, Kentucky, retention pits holding hydraulic fracturing flowback fluids overflowed into Acorn Fork Creek during the development of four natural gas wells, causing a decrease in pH and increase in conductivity.[1] Organics and metals including iron and aluminum formed precipitates in the stream, and fish and aquatic invertebrates were killed or displaced in a 2.7 km length of the stream affected by the release (Papoulias and Velasco, 2013). A field report from the Pennsylvania Department of Environmental Protection (PADEP) described a leak in an overland pipe carrying a mixture of flowback and freshwater between two impoundments that impacted a 0.6 km length of a stream, in which 168 fish and 6 salamanders were killed (PA DEP, 2009b).

In some instances, chemical concentrations in drinking water resources impacted or potentially impacted by hydraulic fracturing activity exceeded their respective primary or secondary maximum contaminant level (MCL), or health advisory levels provided by the EPA's National Primary Drinking Water Regulations (NPDWRs) and Drinking Water Standards and Health Advisories (DWSHA) tables (U.S. EPA, 2012b), indicating that these chemicals are present at levels that may impact human health.[2] Examples will be discussed in Section 9.5. These studies generally did not indicate the contaminated water was used directly for human consumption, so it is not clear that people are being exposed to these chemicals at these levels. Nevertheless, these studies indicate that hydraulic fracturing activity may contribute to the entry of chemicals into drinking water resources at potentially harmful levels.

[1] "Flowback" refers to fluids containing predominantly hydraulic fracturing fluid that return from a well to the surface. Flowback is a type of produced water. See Chapter 7 for more details.

[2] Maximum contaminant level (MCL): The highest level of a contaminant that is allowed in drinking water. MCLs are set as close to the maximum contaminant level goal (MCLG) as feasible using the best available analytical and treatment technologies and taking cost into consideration. MCLs are enforceable standards. The MCLG is a non-enforceable health benchmark goal which is set at a level at which no known or anticipated adverse effect on the health of persons is expected to occur and which allows an adequate margin of safety (U.S. EPA, 2012b).

Risk assessment and risk management decisions will be informed by scientific information on the toxicity of chemicals in hydraulic fracturing fluid and wastewater. The U.S. House of Representatives' Committee on Energy and Commerce Minority Staff released a report in 2011 noting that more than 650 products (i.e., chemical mixtures) used in hydraulic fracturing contain 29 chemicals that are either known or possible human carcinogens or are currently regulated under the Safe Drinking Water Act (House of Representatives, 2011). More recently, several studies have performed a reconnaissance of toxicity and/or physicochemical property data for specific subsets of chemicals used in hydraulic fracturing fluids (Elliott et al., 2016; Wattenberg et al., 2015; Stringfellow et al., 2014; Colborn et al., 2011), and have provided discussion on the hazards inherent to these chemicals. In all cases, authors reported toxicity data was not available for many of the chemicals assessed in these studies, with some studies indicating significant data gaps. For instance, Wattenberg et al. (2015) evaluated 168 chemicals commonly used in hydraulic fracturing fluids in North Dakota, and reported that 59% did not have chronic toxicity data available, and 35% did not have acute toxicity data available. Elliott et al. (2016) performed a systematic evaluation of reproductive and developmental toxicity for 1021 chemicals used in hydraulic fracturing fluids or detected in wastewater, and found this toxicity information was lacking for 76% of these chemicals.

Overall, while combined evidence suggests hydraulic fracturing has the potential to impact human health via contamination of drinking water resources, the actual public health impacts are not well understood and not well documented. Available information indicates there are many chemicals within the hydraulic fracturing water cycle that are known to be hazardous to human health, as well as hundreds of chemicals for which toxicological data is limited or unavailable.

In this chapter, our primary goal is to evaluate the availability of toxicity data for a list of chemicals used in hydraulic fracturing fluids or present in produced water, focusing primarily on toxicity values from sources that meet the criteria for inclusion in this assessment, and to highlight chemicals that may pose human health hazards.

9.3 Identification of Chemicals Associated with the Hydraulic Fracturing Water Cycle

As the initial step towards evaluating the hazards of chemicals in the hydraulic fracturing water cycle, the EPA compiled a list of chemicals used in or released by hydraulic fracturing operations across the country.[1] This section describes the compilation of that list. This consolidated list includes a total of 1,606 chemicals, and can be broken down into two sublists: (1) a list of chemicals used in hydraulic fracturing fluids, and (2) a list of chemicals detected in produced water from hydraulically fractured wells (Text Box 9-2).

This list demonstrates the range and variety of chemicals that are associated with the hydraulic fracturing industry. These chemicals should not be considered unique to the hydraulic fracturing

[1] We use the word "chemical" to refer to any individual chemical or chemical substance that has been assigned a CASRN (Chemical Abstracts Service Registry Number). A CASRN is a unique identifier for a chemical substance, which can be a single chemical (e.g., hydrochloric acid, CASRN 7647-01-0) or a mixture of chemicals (e.g., hydrotreated light petroleum distillates (CASRN 64742-47-8), a complex mixtures of C9 to C16 hydrocarbons). For simplicity, we refer to both pure chemicals and chemical substances that are mixtures, which have a single CASRN, as "chemicals."

industry; many of the chemicals used in hydraulic fracturing fluids are widely used industrial chemicals, and many of the chemicals in produced water are naturally occurring. Although this list represents the best information available to the EPA at the time of the assessment, it should not be considered comprehensive. It is likely that, as industry practices change, chemicals may be used or detected that are not included on these lists. Some additional limitations to this chemical list are described in the subsections below.

Text Box 9-2. The EPA's List of Chemicals Identified in Hydraulic Fracturing Fluids and/or Produced Water.

This chemical list progressed through multiple iterations as the EPA's hydraulic fracturing study was developed, culminating in the list of 1,606 chemicals presented in this report.

The first iteration of this chemical list was published in the interim progress report (U.S. EPA, 2012h), and included 1,026 chemicals that were identified from ten sources of information. Seven of these information sources were documents from federal and state governmental units—including the EPA (U.S. EPA, 2011a, e, 2004a; Material Safety Data Sheets), the U.S. House of Representatives (House of Representatives, 2011), the New York State Department of Environmental Conservation (NYSDEC, 2011), and the Pennsylvania Department of Environmental Protection (PA DEP, 2010a)—which obtained data directly from industry. This includes a list of chemicals provided directly to the EPA by nine well operating companies, representing chemicals used in hydraulic fracturing fluids between 2005 and 2009, and a list of chemicals detected by these companies in produced water from 81 wells. The remaining three sources are as follows: a technical report prepared by the Gas Technology Institute for the Marcellus Shale Coalition, which is a drilling industry trade group (Hayes, 2009); a peer-reviewed journal article by Colborn et al. (2011); and the FracFocus Chemical Disclosure Registry, which is a national hydraulic fracturing chemical registry developed by the Ground Water Protection Council and the Interstate Oil and Gas Compact Commission (GWPC, 2012).

In the external review draft of the EPA's hydraulic fracturing study report (U.S. EPA, 2015d), this chemical list was updated to 1,173 chemicals. The updated chemical list includes the 1,026 chemicals published in the progress report, along with additional chemicals that were identified in the EPA FracFocus 1.0 report (U.S. EPA, 2015a).

For the final version of this assessment, the list has again been updated to include additional chemicals in produced water, which were identified from 18 additional literature sources. The final list includes a total of 1,606 chemicals that have been reported as used in hydraulic fracturing fluids or detected in produced water. The complete list of sources used to compile the final chemical list is provided in Appendix Table H-1. To the extent possible, after chemicals were identified from the sources in Table H-1, the EPA verified the identity of the chemicals used in hydraulic fracturing fluids and detected in produced water of hydraulically fractured wells as described in Appendix Section H.1.

9.3.1 Chemicals Used in Hydraulic Fracturing Fluids

Of the 1,606 total chemicals, the EPA identified 1,084 chemicals as being used in hydraulic fracturing fluids. This list was originally introduced in Chapter 5 of this assessment (Section 5.4), which describes some of the chemical classes and their purpose, and identifies the most frequently used chemicals. This list of 1,084 chemicals is shown in Appendix Table H-2.

Although a total of 8 sources were used to identify the list of chemicals used in hydraulic fracturing fluids, only one source—the EPA analyses based on disclosures submitted to FracFocus—had sufficient information for estimating the frequency with which these chemicals were used (Section 5.4, Text Box 5-1).[1] Of the 1,084 chemicals, 688 were identified in the EPA FracFocus 1.0 report (U.S. EPA, 2015a).[2] Frequency of use for individual chemicals ranged from low (480 chemicals on the list were reported in less than 1% of disclosures nationally) to very high (methanol was reported in 73% of disclosures nationally).

As discussed in Chapter 5, this list provides valuable information on the chemicals used in hydraulic fracturing fluids, but should not be considered complete. For example, in the analysis of the disclosures submitted to the FracFocus 1.0 registry, the EPA was only able to assign standardized chemical names to 65% of ingredient records. The remaining 35% of ingredient records did not have valid CASRNs and were excluded from the analysis because they could not be assigned a standardized chemical name (U.S. EPA, 2015a). In a more recent analysis of data reported to the FracFocus registry through April 2015, Konschnik and Dayalu (2016) found that 80% of chemicals had valid CASRN. That analysis identified an additional 263 CASRNs that are not on the EPA's list of chemicals used in hydraulic fracturing fluids (Dayalu and Konschnik, 2016).

Industry use of CBI is another factor that likely limits the completeness of this chemical list and introduces uncertainty. For example, companies submitting to FracFocus 1.0 were not required to disclose chemicals claimed as CBI. EPA determined that approximately 70% of the disclosures submitted to FracFocus 1.0 contain at least one CBI chemical, and for those disclosures, the average number of CBI chemicals per disclosure was five. Overall, 11% of ingredients were reported to FracFocus 1.0 as CBI (U.S. EPA, 2015a). Konschnik and Dayalu (2016) report a 5.6% increase in the number of CBI ingredients, as well as an increase in the number of disclosures reporting the use of at least one CBI ingredient (Section 5.4; Text Box 5-2).

Although FracFocus disclosures do not provide the name or CASRN of CBI chemicals, the chemical family is sometimes provided. The EPA determined that 79% of CBI ingredient records submitted to FracFocus 1.0 had enough information to partially define the chemical and assign it to a chemical family (U.S. EPA, 2015a). This resulted in the designation of 448 standardized chemical families to which these chemicals could be assigned. The most common standardized chemical families for CBI ingredients were oxyalkylated alcohol (4.7% of CBI ingredient records), petroleum distillates (4.0% of CBI ingredient records), and quaternary ammonium compounds (3.6% of CBI ingredient records) (U.S. EPA, 2015a) (Appendix Table B-1). These standardized chemical family designations are not discussed further in this chapter, but may be useful for site-specific risk assessment, as they

[1] The FracFocus frequency of use data presented in this chapter is based on 35,957 FracFocus disclosures that were deduplicated, within the study time period (January 1, 2011 to February 28, 2013), and with ingredients that have a valid CASRN. In the interest of including as many chemicals as possible, this analysis includes chemicals that do not have valid concentration data. The 692 chemicals includes 16 chemicals that are listed as being used as proppants.

[2] EPA analyses based on disclosures submitted to FracFocus identified 692 unique CASRN. Of these 692, we determined that 4 chemicals are listed under two different CASRN (indicated in the footnote of Appendix Table H-2). Frequency of use data is therefore available for 688 chemicals that were included on EPA's list of chemicals in hydraulic fracturing fluids.

may provide insight into potential physicochemical properties and toxicity of CBI chemicals used at a particular site.

9.3.2 Chemicals Detected in Produced Water

Of the 1,606 total chemicals, the EPA identified 599 as having been detected in produced water. Included among these chemicals are naturally occurring organic compounds, metals, radionuclides, industrial chemicals, and pesticides. These chemicals were originally introduced in Chapter 7 of this assessment, and were compiled from a total of 21 sources. Seventy-seven of the total 599 chemicals in produced water were also identified by at least one of the sources in Appendix H as being used in hydraulic fracturing fluid. However, the EPA used different sets of sources to identify chemicals used in hydraulic fracturing fluids versus those detected in produced water, and there is not a matched comparison between the chemicals used in hydraulic fracturing fluids and returned in produced water at each particular well. Therefore, it is difficult to draw direct comparisons between these two chemical lists, or to use these lists to draw conclusions on the persistence of chemicals in produced water from hydraulically fractured wells. The list of 599 chemicals identified in produced water is shown in Appendix Table H-4.

Although this list provides useful information on the chemical composition of produced water, it is not likely that the data sources were able to capture all of the chemicals present. Chemicals and their metabolites may go undetected in produced water because they were not targeted in the analytical protocols, they were below the limit of detection, or because no standard analytical method exists. Additionally, as discussed in Chapter 7, the composition and concentration of chemicals in produced water will differ depending upon factors like the geology of the formation, the chemicals used for hydraulic fracturing, and the amount of time that has elapsed since hydraulic fracturing. There is therefore expected to be a high degree of local and temporal variation in these chemicals, and there was not sufficient information to determine the frequency with which these chemicals were detected on a national basis.

Concentration data in produced water are available for 175 of these 599 chemicals (Appendix E), including inorganic contributors to salinity (Appendix Tables E-4 and E-5), metals (Appendix Tables E-6 and E-7), radioactive constituents (Appendix Table E-8), and organic constituents (Appendix Tables E-9, E-11, E-12, and E-13). The remaining chemicals were detected in produced water, but concentration was not reported. For these chemicals with concentration data, the measured concentrations spanned several orders of magnitude. For instance, for organic chemicals in produced water from the Marcellus shale formation (Appendix Table E-11), average or median measured concentrations ranged from 2.7 μg/L for N-nitrosodiphenylamine to 400 μg/L for carbon disulfide.

9.4 Toxicological and Physicochemical Properties of Hydraulic Fracturing Chemicals

As the next step towards evaluating the hazards of chemicals in the hydraulic fracturing water cycle, toxicological and physicochemical data were collected as available for each of the chemicals identified in Appendix H. This section describes the compilation of these data, and discusses the extent to which toxicological and physicochemical property data are available for this list of chemicals.

The primary focus of the toxicological analysis in this chapter is on the availability of chronic oral RfVs and OSFs from sources that met the EPA's criteria for inclusion in this study. Qualitative cancer classifications were also identified from these sources when available. This is not intended to be an exhaustive compilation of toxicity values for this chemical list. Rather, it is intended to be a reconnaissance of high-quality toxicological information that met the EPA's criteria for inclusion in this study. If a source of RfVs, OSFs, or qualitative cancer classifications was not included here, that only means that it did not meet the criteria for the purposes of the EPA's study, which are described in this chapter in Section 9.4.1.

Section 9.4.1 describes the criteria used to identify and select RfVs, OSFs, and qualitative cancer classifications, and describes the availability of these toxicological data for the chemicals on the EPA's list of hydraulic fracturing-related chemicals. The next two sections describe additional sources of toxicological information, which may be useful for hazard evaluation when chronic oral RfVs and OSFs are not available: Section 9.4.2 describes the use of a QSAR model to estimate chronic oral toxicity, and Section 9.4.3 describes the availability of additional toxicological information on the EPA's ACToR database. Section 9.4.4 describes other available software tools and approaches that may be used by stakeholders for site-specific risk assessment, but are not utilized in this report. Section 9.4.5 discusses the methods used in this report to generate physicochemical property data, and presents the availability of physicochemical property data for the chemicals on the EPA's list. A brief overview of the toxicity values discussed in the chapter is presented in Text Box 9-3.

As a resource that can be used to support risk assessment at hydraulic fracturing sites, all of the selected RfVs, OSFs, qualitative cancer classifications, QSAR-based toxicity estimates, and physicochemical property data described in this chapter will be compiled into an electronic database that will be publicly accessible via the EPA's website. Additionally, the EPA's compilation of toxicity data for this chemical list has been discussed in two recent manuscripts, both of which focused on the list of 1,173 chemicals that was presented in the external review draft of the EPA's hydraulic fracturing study report (U.S. EPA, 2015d). Yost et al. (2016b) describes the compilation of RfVs and OSFs for the list of 1,173 chemicals. Yost et al. (2016a) describes the use of a QSAR model to estimate toxicity for the list of 1,173 chemicals.

Text Box 9-3. Toxicity Values for Hydraulic Fracturing-Related Chemicals.

Here we provide a brief description of the toxicity values that are presented in this chapter, and how they should be interpreted and used to evaluate chemical hazards. Formal definitions of these terms are footnoted in the chapter and can also be found in the glossary (Appendix J).

Reference value (RfV): RfVs are health-protective values, which describe the dose of a chemical that is likely to be without an appreciable risk of adverse health effects. In general, lower RfVs indicate greater toxicity; however, comparison of RfVs among a set of chemicals requires careful consideration. RfVs are developed by considering the full database of epidemiological and experimental studies available for a particular chemical.

(Text Box 9-3 is continued on the following page.)

Text Box 9-3 (continued). Toxicity Values for Hydraulic Fracturing-Related Chemicals.

These data are used to identify the critical effect, which is the first adverse effect, or its known precursor, that occurs as the dose rate increases (U.S. EPA, 2011f). An RfV is then derived by starting with a quantitative point of departure (POD), which is the toxicological dose-response point that marks the beginning of a low-dose extrapolation for the critical effect, and applying uncertainty factors (UFs) to derive a value for the protection of human health. UFs are applied to account for 5 areas of uncertainty: (1) intraspecies variability; (2) interspecies uncertainty; (3) extrapolation from a subchronic study; (4) extrapolating from a no-observed-adverse-effect level (NOAEL); and (5) deficiencies in the database. A UF of 1, 3, or 10 can be applied for any of these areas of uncertainty depending upon the amount and/or type data available, up to a maximum total UF of 3,000 (U.S. EPA, 2002). Thus, a chemical with a low RfV may reflect high uncertainty in the value, and not necessarily the toxicity of the chemical. Chemicals with a lower total UF generally have more reliable and robust health effect information.

Oral slope factor (OSF): An OSF is a measure of the increased cancer risk from a lifetime oral exposure to an agent. Higher OSFs indicate greater carcinogenic potency. As with RfVs, OSFs are developed by considering the full database of epidemiological and experimental studies for a particular chemical, and evaluating the increase in cancer incidence as dose rate increases. OSFs should be considered in conjunction with qualitative cancer classifications, which characterize the weight of evidence regarding the agent's potential to cause cancer in humans.

No-observed-adverse-effect level (NOAEL): NOAEL is defined as the highest exposure level at which there are no biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered adverse or precursors of adverse effects (U.S. EPA, 2011f).

Lowest-observed-adverse-effect level (LOAEL): LOAEL is defined as the lowest exposure level at which there are biologically significant increases in the frequency or severity of adverse effects between the exposed population and its appropriate control group (U.S. EPA, 2011f). Lower LOAELs indicate greater toxicity.

Maximum contaminant level (MCL): MCLs are the highest level of a contaminant that is allowed in drinking water. MCLs are set as close to the maximum contaminant level goal (MCLG) as feasible using the best available analytical and treatment technologies and taking cost into consideration. MCLs are enforceable standards. The MCLG is a non-enforceable health benchmark goal which is set at a level at which no known or anticipated adverse effect on the health of persons is expected to occur and which allows an adequate margin of safety (U.S. EPA, 2012b). Whereas RfVs, LOAELs, and NOAELs are expressed in terms of dose (mg/kg-day), MCLs are expressed in terms of the concentration of an agent in water (μg/L).

9.4.1 Reference Values (RfVs), Oral Slope Factors (OSFs), and Qualitative Cancer Classifications

For the purpose of this study, the EPA's primary goal was to identify high quality toxicity values that met the criteria for inclusion in this study, and that could be used by stakeholders to support the risk assessment of hydraulic fracturing chemicals (Text Box 9-1). Briefly, the sources of RfVs, OSFs, and qualitative cancer classifications selected by the EPA for the purposes of this chapter met the following key criteria:

1. The body or organization generating or producing the peer-reviewed RfVs, peer-reviewed OSFs, or peer-reviewed qualitative assessment must be a governmental or intergovernmental body.
2. The data source must include peer-reviewed RfVs, peer-reviewed OSFs, or peer reviewed qualitative assessments.
3. The RfVs, OSFs, or qualitative assessments must be based on peer-reviewed scientific data.
4. The RfVs, OSFs, or qualitative assessments must be focused on protection of the general public.
5. The body generating the RfVs, OSFs, or qualitative assessments must be free of conflicts of interest with respect to the chemicals for which it derives reference values or qualitative assessments.

These five criteria were developed by the EPA specifically for the purpose of this assessment, and are similar to the EPA Office of Solid Waste and Emergency Response (OSWER) recommendations for selecting toxicity values in conducting site-specific risk assessments (Regional Tier 3 Toxicity Value Workgroup, 2013; U.S. EPA, 2003a, 1989).[1] The OSWER directives provide recommendations on the appropriate sources of toxicity values and toxicological information that should be considered in risk assessments, and were designed to recognize toxicity values that were developed using the best available scientific information. In addition, these directives outline references to various resources that provide guidance on the approaches and issues considered in deriving toxicity values. This type of information can be especially important in cases in which multiple sources of toxicity values need to be considered or evaluated, or in which a value needs to be developed. More detail on these criteria for selection and inclusion of data sources, as well as the full list of data sources that were considered for this study, are available in Appendix G.

Table 9-1 shows the data sources that met these five criteria for the selection of toxicological information. The federal databases of RfVs or OSFs that met these criteria are the EPA's Integrated Risk Information System (IRIS) database, the EPA's Provisional Peer-Reviewed Toxicity Value (PPRTV) database, the EPA's Human Health Benchmarks for Pesticides (HHBP) database, and the Agency for Toxic Substances and Disease Registry (ATSDR) database. IRIS and PPRTV also provide qualitative cancer classifications. One state source of RfVs and OSFs, the California Environmental Protection Agency (CalEPA) Toxicity Criteria Database, met the criteria for inclusion.[2] One intergovernmental source of RfVs, the World Health Organization (WHO) International Programme on Chemical Safety (IPCS) Concise International Chemical Assessment Documents (CICAD), met the criteria for inclusion. The International Agency for Research on Cancer (IARC) and U.S. National Toxicology Program (NTP) Report on Carcinogens (RoC) also met the criteria and were used as additional sources for qualitative cancer classifications.

[1] OSWER changed its name to the Office of Land and Emergency Management (OLEM), effective December 15, 2015.

[2] State RfVs and OSFs are also publicly available from Alabama, Texas, Hawaii, and Florida, but they did not meet the criteria for consideration as sources for RfVs and OSFs in this report. See Appendix G for details.

Table 9-1. Sources of selected RfVs, OSFs, and qualitative cancer classifications.

Type of toxicological Information	Data source	Website
RfVs, OSFs, and qualitative cancer classifications	EPA Integrated Risk Information System (IRIS) database	http://cfpub.epa.gov/ncea/iris/index.cfm?fuseaction=iris.showSubstanceList
RfVs, OSFs, and qualitative cancer classifications	EPA Provisional Peer-Reviewed Toxicity Value (PPRTV) database	http://hhpprtv.ornl.gov/index.html
RfVs, OSFs	EPA Human Health Benchmarks for Pesticides (HHBP) database	http://iaspub.epa.gov/apex/pesticides/f?p=HHBP:home
RfVs	Agency for Toxic Substances and Disease Registry (ATSDR) Minimum Risk Levels	http://www.atsdr.cdc.gov/toxprofiles/index.asp#bookmark05
RfVs, OSFs	California Environmental Protection Agency (CalEPA) Toxicity Criteria Database	http://oehha.ca.gov/tcdb/index.asp
RfVs	World Health Organization (WHO) International Programme on Chemical Safety (IPCS) Concise International Chemical Assessment Documents (CICAD)	http://www.who.int/ipcs/publications/cicad/en/
Qualitative cancer classifications	National Toxicology Program (NTP) 13th Report on Carcinogens (RoC)	https://ntp.niehs.nih.gov/pubhealth/roc/
Qualitative cancer classifications	International Agency for Research on Cancer (IARC) Monographs	http://monographs.iarc.fr/

In addition to the sources in Table 9-1, we also consulted the NPDWRs and DWSHA tables (U.S. EPA, 2014a) to determine whether the chemicals on this list are regulated as drinking water contaminants. NPDWRs provide a list of MCLs, which are legally enforceable standards on the concentration of a substance that is allowed in drinking water under the Safe Drinking Water Act. In this chapter, MCL values are referenced as a means of comparison with reported concentration data where appropriate, and are reported in Appendix G and are compiled on the EPA's electronic database for the hydraulic fracturing study.

As noted above, this chapter focuses on the presentation and use of chronic RfVs. Chronic RfVs account for the potential that chemical exposure may be continuous, in low concentration, and over a longer duration. In the absence of reliable information on the potential duration of chemical exposure, this is a conservative assumption for the protection of human health. Chronic RfVs are also lower than less-than-chronic RfVs (e.g., acute, intermediate, or subchronic toxicity values), and are therefore more health protective. For these reasons, chronic RfVs are generally preferred as the default by risk assessors when conducting site-specific risk assessments (U.S. EPA, 1989) and when developing regional screening levels (U.S. EPA, 2016b). In contrast, acute RfVs are more applicable for single exposures and/or exposures of limited frequency to high concentration and shorter durations (e.g., emergencies). However, the availability of less-than chronic RfVs are also presented for the sake of completeness.

Some chemicals had chronic oral RfVs or OSFs available from more than one of the sources in Table 9-1. For these chemicals, we selected a single value for use in this chapter by applying a modification of the EPA OSWER Directives 9285.7-53 and 9285.7-86 tiered hierarchy of toxicity values (U.S. EPA, 2003a). A single RfV and/or OSF was selected from the sources in this order: HHBP (pesticides only), IRIS, PPRTV, ATSDR, and then other available values. The RfVs considered from these sources included chronic oral reference doses (RfDs) from the IRIS, PPRTV, and HHBP programs; chronic oral minimal risk levels (MRLs) from ATSDR; oral maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intakes (TDIs) from CICAD.[1,2,3,4,5]

Of the 1,606 chemicals identified by the EPA, 173 (11%) have federal, state, or international chronic oral RfVs and/or OSFs from sources listed in Table 9-1. Chronic oral RfVs and/or OSFs from the selected sources are lacking for the remaining 1,433 (89%) chemicals that the EPA has identified as associated with hydraulic fracturing. All available chronic oral RfVs and OSFs from the sources listed in Table 9-1 are tabulated in Appendix G. Chronic oral RfVs and OSFs for chemicals used in hydraulic fracturing fluids are listed in Appendix Tables G-1a through G-1c, and chronic oral RfVs and OSFs for chemicals reported in hydraulic fracturing flowback or produced water are listed in Appendix Tables G-2a through G-2c. The EPA's IRIS database was the most abundant source of these toxicity values.

Overall, when chemicals in hydraulic fracturing fluid and chemicals in produced water are considered separately, the availability of chronic RfVs and OSFs can be summarized as follows:

- For the 1,084 chemicals used in hydraulic fracturing fluid, chronic oral RfVs or OSFs from at least one of the selected federal, state, and international sources were available for 98 chemicals (9%). From the US federal sources alone, chronic oral RfVs were available for 81 chemicals (7%), and OSFs were available for 15 chemicals (1%).

---

[1] The OSWER hierarchy indicates that sources should be used in this order: IRIS, PPRTV, and then other values. In this report, this hierarchy was followed, but HHBP values were used in lieu of an IRIS value for a few chemicals that are pesticides.

[2] An RfD is an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily oral exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. It can be derived from a NOAEL, LOAEL, or benchmark dose, with uncertainty factors generally applied to reflect limitations of the data used. Generally used in the EPA's non-cancer health assessments (U.S. EPA, 2011f). This estimate is expressed in terms of mg/kg-day.

[3] An MRL is an estimate of daily human exposure to a hazardous substance at or below which the substance is unlikely to pose a measurable risk of harmful (adverse), non-cancerous effects. MRLs are calculated for a route of exposure (inhalation or oral) over a specified time period (acute, intermediate, or chronic). MRLs should not be used as predictors of harmful (adverse) health effects (ATSDR, 2016). Chronic MRL: Duration of exposure is 365 days or longer. This estimate is expressed in terms of mg/kg-day.

[4] An MADL is the maximum allowable daily level of a reproductive toxicant at which the chemical would have no observable adverse reproductive effect, assuming exposure at 1,000 times that level (OEHHA, 2012). This estimate is expressed in terms of μg/day.

[5] A TDI is an estimate of the intake of a substance, expressed on a body mass basis, to which an individual in a (sub) population may be exposed daily over its lifetime without appreciable health risk (WHO, 2015). This estimate is expressed in terms of mg/kg-day.

- For the 599 chemicals reported in produced water, chronic oral RfVs or OSFs from at least one of the selected federal, state, and international sources were available for 120 chemicals (20%). From the US federal sources alone, chronic oral RfVs were available for 97 chemicals (16%), and OSFs were available for 30 chemicals (5%).

In addition to these chronic values, some of the chemicals also have less-than-chronic oral RfVs available from the sources listed in Table 9-1. Subchronic, acute, or intermediate oral RfVs were identified for 103 chemicals on the consolidated list, including 60 chemicals used in hydraulic fracturing fluid (Appendix Table G-1d), and 73 chemicals reported in produced water (Appendix Table G-2d). The majority of these chemicals also had chronic oral RfVs available, although there were 10 chemicals that had less-than-chronic oral RfVs but lacked a chronic oral RfV. All of these less-than-chronic RfVs were found on the PPRTV, ATSDR, or HHBP databases. As stated above, chronic values more protective of human health than less-than-chronic values, and are generally preferred for risk assessment. These less-than-chronic values are therefore not discussed further in this report, but are provided in Appendix G as supporting information.

Of the 1,606 chemicals identified by EPA, 207 (13%) had a qualitative cancer classification available from at least one of the sources listed in Table 9-1, which include IRIS, PPRTV, IARC, and RoC. These classifications are based on the weight-of-evidence (WOE) that a chemical causes cancer in humans. Of these 207 chemicals:

- 21 were reported by at least one source to be a known carcinogen in humans.
- 66 were reported by at least one source to be a probable or possible carcinogen in humans. These chemicals have been demonstrated to be carcinogenic in animal models, but have limited or insufficient data to adequately assess carcinogenicity in humans.
- 117 were reported to be not classifiable as to carcinogenicity in humans. These chemicals have been evaluated by at least one of these sources for their potential to cause cancer, but had inadequate evidence from human exposure and animal studies to assess carcinogenic potential.
- 3 were reported as not likely to be a human carcinogen.

The complete list of chemicals with qualitative cancer classifications are shown in Appendix Table G-1e (chemicals in hydraulic fracturing fluids) and Appendix Table G-2e (chemicals in produced water).

9.4.2 Estimating Toxicity Using Quantitative Structure Activity Relationship (QSAR) Modeling

Because the majority of chemicals identified in this report do not have RfVs and/or OSFs from the selected sources, it is likely that risk assessors at the local and regional level may turn to alternative sources of toxicological information. One potential resource is QSAR modeling software, which is able to provide estimates or predictions of toxicity based on chemical structure. A key advantage to QSAR models is that they are able to rapidly and inexpensively estimate toxicity values for chemicals. A disadvantage is that QSAR estimates may be of higher uncertainty and less reliable than values generated using traditional toxicological methods. However, because they increase the available pool of toxicity information, QSAR estimates may be a useful resource for risk assessors that are faced with evaluating potential exposures to data-poor chemicals.

A recent study by Yost et al. (2016a) used TOPKAT (Toxicity Prediction by Komputer Assisted Technology) QSAR software to estimate toxicity for the EPA's list of chemicals used in hydraulic fracturing fluids or detected in produced water, and evaluated how effectively these toxicity estimates could be used to rank chemicals based on toxicity. The chemical list examined in this study is the list of 1,173 chemicals published in the external review draft of the EPA's hydraulic fracturing study report (U.S. EPA, 2015d) (Text Box 9-2), so the full list of 1,606 chemicals was not assessed using the QSAR model. TOPKAT is commercially available QSAR software that is able to estimate the rat chronic oral lowest-observed-adverse-effect level (LOAEL), which is the LOAEL measured in a rat model following chronic oral exposure to a chemical.[1]

The authors of this study used TOPKAT to generate rat chronic oral LOAEL estimates for EPA's list of chemicals, and assigned qualitative confidence scores (high, medium, or low) to each estimate based on parameters reported by the model. The authors then examined a list of 48 chemicals that had both a high-confidence TOPKAT LOAEL estimate and a chronic oral reference dose (RfD) from EPA's IRIS database. The authors ranked these 48 chemicals from most toxic to least toxic based on either TOPKAT LOAEL estimate or on IRIS chronic oral RfD, and then used Spearman rank correlation to examine the similarity between these chemical rankings.

Of the 1,173 hydraulic fracturing chemicals, TOPKAT was able to generate toxicity estimates for 515 (44%) of the chemicals, including 453 chemicals that are used in hydraulic fracturing fluids, and 86 chemicals that have been detected in produced water. The authors found a strong and statistically significant correlation between chemical rankings based on high-confidence TOPKAT LOAEL estimates and on IRIS chronic oral RfDs, indicating that high-confidence TOPKAT LOAEL estimates can effectively be used to rank chemicals based on toxicity when experimentally derived toxicity values are not available. Overall, TOPKAT LOAEL estimates were available for 417 chemicals in this study that lack chronic oral RfVs or OSFs from the sources identified by EPA. Of these, 389 were found to be high-confidence estimates.

When available, the high-confidence TOPKAT LOAEL estimates from Yost et al. (2016b) are discussed in this chapter as an additional resource that can be used to rank chemicals based on toxicity. Low- or medium-confidence TOPKAT LOAEL estimates are not shown in this chapter, as the use of these values for chemical ranking has not been validated.

[1] LOAEL is defined as the lowest exposure level at which there are biologically significant increases in the frequency or severity of adverse effects between the exposed population and its appropriate control group following chronic (lifetime) exposure.

9.4.3 Chemical Data Available from EPA's Aggregated Computations Toxicology Resource (ACToR) Database

An additional tool for obtaining information focused on toxicology and risk assessment is the EPA's ACToR database.[1] ACToR is a large data warehouse developed by the EPA to consolidate large and disparate amounts of public data on chemicals, including data on chemical identity, structure, physicochemical properties, in vitro assay results, and in vitro toxicology data. The primary goals of ACToR are to make information on chemical health effects and exposure potential readily accessible, to characterize chemical toxicological data gaps, and to provide a resource for model building to address data gaps in environmental risk information (Judson et al., 2012).

ACToR contains data on over 500,000 chemicals from over 2,500 data sources, covering many domains including hazard, exposure, risk assessment, risk management, and use. Data sources and collections in ACToR include the US EPA, National Institutes of Health (NIH), the Centers for Disease Control and Prevention (CDC), US Food and Drug Administration (FDA), State Agencies, the European Chemicals Agency (ECHA), corresponding government agencies in Canada (e.g., Health Canada), Europe and Japan, the World Health Organization (WHO), and non-governmental organizations (NGOs). Data within ACToR ranges from the federal RfVs and OSFs discussed in Section 9.3.1, which have undergone extensive peer review, to other toxicity values and study and test results that have undergone little to no peer review.

ACToR organizes these data into several levels of "assays" and "assay categories," which serve to classify data sets according to the nature of the data. For instance, the "Hazard" assay category includes all data that are associated directly or indirectly with toxicology experiments. The "Risk Management" assay category includes regulatory and non-regulatory risk management benchmarks. Considering the diversity and overlapping nature of the data resources within ACToR, a single data set may fall into multiple assay categories (Judson et al., 2012).

We searched the ACToR database for information related to the list of 1,606 hydraulic fracturing-related chemicals. Specifically, we searched within the "Hazard" and "Risk Management" assay categories of ACToR. Results of the query were then filtered to include the assays that are most relevant to chemical exposure via drinking water. These assays were assigned into the following nine data classes: carcinogenicity, dose response values, drinking water criteria, genotoxicity or mutagenicity, hazard identification, LOAEL/NOAEL, RfV, OSF, and water quality criteria.[2]

Of the 1,606 chemicals, it was found that 735 (46%) have some data available within these data classes on ACToR, with the total number of data points found for individual chemicals ranging from 1 to 243. Figure 9-2 shows the percentage of the total 1,606 chemicals that had data available in each of the nine ACToR data classes, and indicates the fraction of those chemicals that also had a chronic oral RfV or OSF available from at least one of the selected sources in Table 9-1. As can be seen in Figure 9-2, 37% of the chemicals had some information on hazard identification, 25% had

[1] The ACToR database, including the full list of data collections and assays, is available at: http://actor.epa.gov.

[2] NOAEL is defined as the highest exposure level at which there are no biologically significant increases in the frequency or severity of adverse effect between the exposed population and its appropriate control; some effects may be produced at this level, but they are not considered adverse or precursors of adverse effects. Source: U.S. EPA (2011f).

information on carcinogenicity, and 24% had a LOAEL or NOAEL identified. A LOAEL and/or NOAEL identified from a well conducted dose-response study are often considered the minimum data needed for RfV derivation (U.S. EPA, 2002).

Focusing on the 1,433 chemicals that lacked a chronic RfV and/or OSF from the selected sources described in Section 9.3.1, 567 (40%) had available data within at least one of these data classes on ACToR. Thus, ACToR has a significant amount of potentially useful data on chemical hazards, including for some data-poor chemicals, and might help to fill data gaps in the ongoing effort to understand potential hazards of hydraulic fracturing chemicals.

It is outside the scope of this assessment to evaluate the quality and reliability of data within ACToR that has not already undergone peer review. Therefore, with the exception of data from the sources listed in Table 9-1, data from ACToR was not considered in the hazard evaluation presented in this chapter. However, as a potential resource for risk assessors, the tables in this chapter indicate whether a chemical had data available on ACToR.

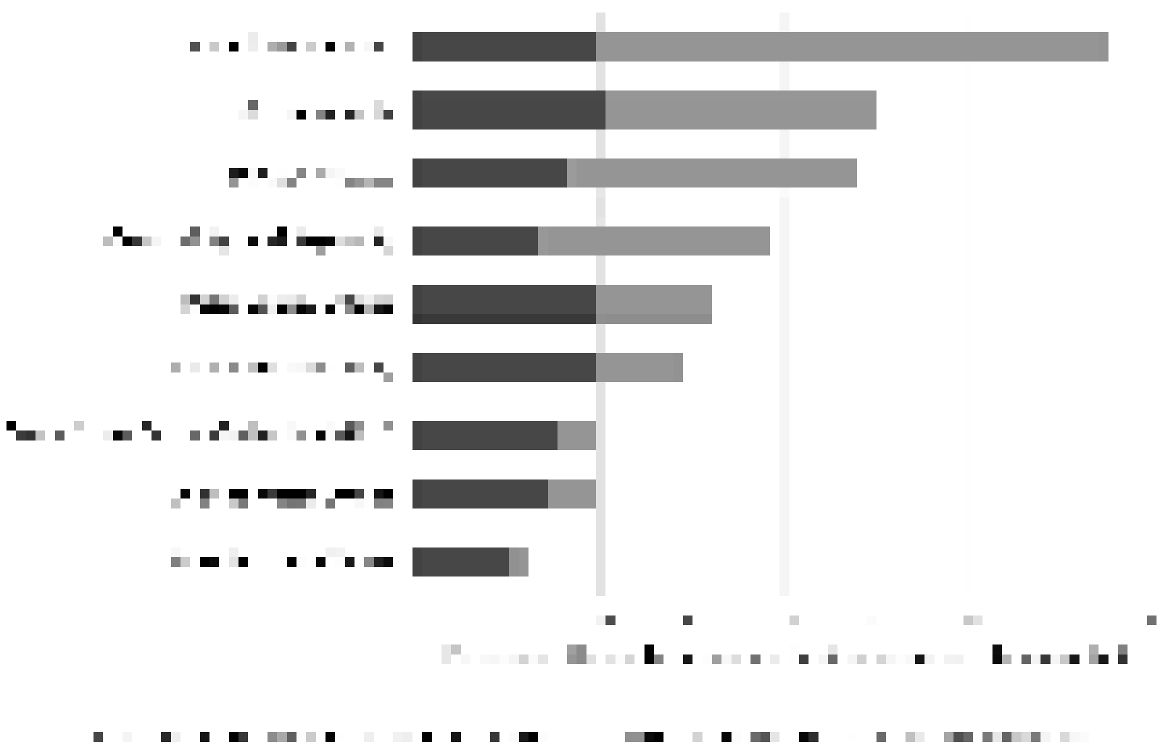

Figure 9-2. Percentage of hydraulic fracturing-related chemicals (out of 1,606 total) with at least one data point in each ACToR data class.

9.4.4 Additional Tools for Hazard Evaluation

In addition to the methods and approaches utilized in this chapter, there are other potential tools and approaches that could be used by stakeholders to prioritize and estimate toxicity of chemicals that have a limited toxicity database. We briefly describe three such approaches in Appendix G (Section G.4): the Threshold of Toxicological Concern (TTC) approach, the Organisation for

Economic Co-operation and Development (OECD) QSAR Toolbox, and the application of data from high throughput screening (HTS) assays. Toxicity predictions from these additional data sources can be either quantitative or qualitative, and may be used to fill and address gaps related to risk assessment.

Although these additional tools may be potentially useful for the evaluation of chemical hazards, they currently have limited utility in this chapter, and are not discussed further. The TTC approach requires an estimate of human intake, which is challenging for hydraulic fracturing-related chemicals, since the potential for human exposure is generally not clear. The OECD QSAR Toolbox is potentially useful for qualitative assessment, and may be useful for quantitative toxicity assessment as its human health hazard and repeated dose toxicity databases expand. HTS assays are an emerging technology, and the potential application of these data for human health risk assessment is not well understood. These tools would be more appropriately applied by stakeholders on a site-specific basis, as preliminary steps to identify potential chemicals of concern.

9.4.5 Physicochemical Properties

As presented in Chapter 5, EPI Suite™ software was used to generate data on the physicochemical properties of the hydraulic fracturing-related chemicals identified by EPA. EPI Suite provides an estimation of physicochemical properties based upon chemical structure, and will additionally provide experimentally measured values for these properties when they are available for a given chemical. For more details on this software and on the use of physicochemical properties for fate and transport estimation, see Chapter 5.

From the total list of 1,606 chemicals associated with hydraulic fracturing, EPI Suite was able to generate data on physicochemical properties for 917 (57%) of the chemicals (Appendix H). This includes 455 chemicals that are reported in hydraulic fracturing fluids, 521 chemicals that have been reported in produced water, and 59 chemicals that were both used in hydraulic fracturing fluids and reported in produced water. The remaining 689 chemicals on EPA's total list lacked the structural information necessary to generate estimates.

In addition to EPI Suite, two other software programs were consulted to generate physicochemical property data for EPA's list of hydraulic fracturing-related chemicals. QikProp (Schrodinger, 2012) and LeadScope (Leadscope Inc., 2012) are commercial products designed primarily as drug development and screening tools, which are able to estimate properties related to chemical fate and transport as well as pharmacokinetics. Properties generated by QikProp and LeadScope are generally more relevant to drug development than to environmental assessment. The properties generated by QikProp and LeadScope were not used in the analysis presented in this report, but will be compiled on the electronic database for EPA's hydraulic fracturing study.

9.4.6 Summary of Available Toxicological and Physicochemical Information for Hydraulic Fracturing Chemicals

Figure 9-3 summarizes the toxicological and physicochemical information that is available for the list of hydraulic fracturing chemicals identified by EPA in this study. This figure also summarizes the availability of data on the occurrence of these chemicals in hydraulic fracturing fluids (frequency of use) or in produced water (measured concentrations).

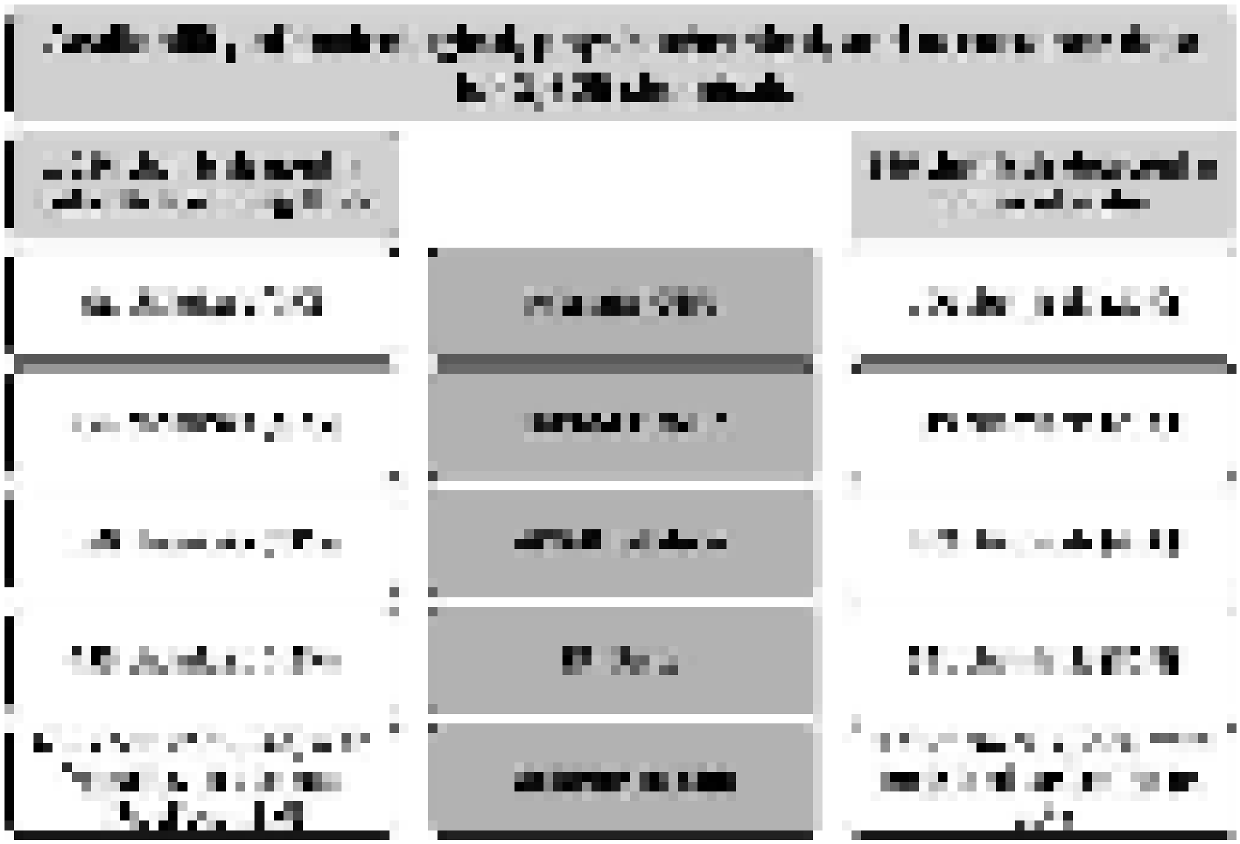

Figure 9-3. Overall representation of the selected toxicological, physicochemical, and occurrence data available for the 1,606 hydraulic fracturing-related chemicals identified by the EPA.

Overall, there is a clear paucity of chronic oral RfVs and OSFs for this list of chemicals, indicating that the majority of chemicals associated with hydraulic fracturing activity have not undergone significant toxicological assessment. QSAR-based toxicity estimates (TOPKAT LOAELs) were available for a larger number of these chemicals, and were often available for chemicals that lack chronic oral RfVs and OSFs. EPA's ACToR database offers additional toxicological data that may be useful for the hazard evaluation of these chemicals, although the quality and reliability of the data for these chemicals within ACToR was not evaluated here.

9.5 Hazard Identification of Hydraulic Fracturing Chemicals

This section focuses on the hazard identification of subsets of chemicals that were identified as being of particular interest in previous chapters of this report, or which otherwise may be of particular interest to risk assessors. For these chemicals, we summarize what is known about events that may lead to the entry of these chemicals into drinking water resources. We provide examples of recent studies that have reported these chemicals in drinking water resources, including examples in which these chemicals have been reported at concentrations exceeding MCLs. We then summarize the available toxicological data for these chemicals, including chronic oral RfVs, OSFs, cancer classifications, QSAR-based toxicity estimates (TOPKAT LOAELs), and the availability of relevant toxicological information from EPA's ACToR database—and indicate which chemicals are regulated by EPA as drinking water contaminates.

We focused on the following subsets of chemicals:

1. Chemicals used in hydraulic fracturing fluids (Chapter 5)
2. Organic chemicals that may be returned to the surface in produced water, including naturally occurring hydrocarbons such as BTEX (Chapter 7)
3. Inorganic chemicals that may be returned to the surface in produced water, including metals, inorganic ions, and technologically enhanced naturally occurring radioactive material (TENORM) (Chapter 7)
4. Methane in stray gas, which has been reported in drinking water resources in areas of hydraulic fracturing activity (Chapter 6)
5. Disinfection byproducts (DBPs) that may be formed from wastewater constituents (Chapter 8)
6. Banned chemicals reported in produced water, specifically organochlorine pesticides and polychlorinated biphenyls (PCBs).
7. Chemicals on EPA's consolidated list that were reported in both hydraulic fracturing fluids and produced water

The hazard identification for these subsets of chemicals is presented below.

9.5.1 Chemicals Used in Hydraulic Fracturing Fluids

Chapter 5 provided an overview of chemicals that are used in hydraulic fracturing fluids. These chemicals have the potential to enter drinking water resources through events such as spills of hydraulic fracturing fluids, injection of hydraulic fracturing fluids directly into groundwater, and leakoff of fluids into the formation. These chemicals may also persist in produced water, and may enter drinking water resources through spills or releases of produced water or inadequately treated wastewater.

Several recent field studies have detected chemicals that are commonly used in hydraulic fracturing fluids in groundwater near hydraulically fractured wells. In some cases, the origin of the chemicals could be clearly linked to hydraulic fracturing activity. For example, in Killdeer, North Dakota (Section 6.2.2.1), evidence strongly suggests a well blowout during hydraulic fracturing led to the contamination of a drinking water aquifer with tert-butyl alcohol, a degradation product of tert-butyl hydroperoxide used in hydraulic fracturing fluids at that site (U.S. EPA, 2015i). In groundwater monitoring wells in the Pavillion Field in Wyoming, Digiulio and Jackson (2016) reported detections of organic chemicals used in hydraulic fracturing fluids at that site, including 2-

butoxyethanol, naphthalene, 1,2,4-trimethylbenzene, diethylene glycol, methanol, ethanol, and isopropanol, likely as a result of shallow hydraulic fracturing in that region.

Other studies provide indirect evidence that chemical contaminants originated from hydraulic fracturing activity. For example, in the Marcellus Shale in Pennsylvania, Llewellyn et al. (2015) detected trace levels of 2-butoxyethanol in water wells near several hydraulically fractured wells, with multiple lines of evidence suggesting that the chemical originated from a surface spill or leak related to hydraulic fracturing activity. In northeastern Pennsylvania, Drollette et al. (2015) found trace concentrations of known constituents of hydraulic fracturing fluid in private residential groundwater wells, including di(2-ethylhexyl) phthalate, with evidence suggesting that the chemicals originated from known surface spills of hydraulic fracturing fluids. In the Barnett Shale, Texas, a survey of water quality in public and residential wells reported chemicals that are known to be used in hydraulic fracturing fluids, including methanol, ethanol, isopropanol, and propargyl alcohol, but it was not clear whether these chemicals originated from hydraulic fracturing activity or from other potential sources (Hildenbrand et al., 2015).

Table 9-2 shows the list of chemicals that were reported in at least 10% of disclosures nationally in the EPA FracFocus 1.0 project database (excluding water, quartz, and sodium chloride), and shows the noncancer toxicity data (chronic oral RfVs and TOPKAT LOAEL estimates) and ACToR data available for these chemicals.[1] Cancer information is provided in Table 9-3. Nine (26%) of these 34 chemicals have a chronic oral RfV available from at least one of the sources in Table 9-1. Chronic oral RfVs ranged from 0.002 mg/kg-day (propargyl alcohol) to 2 mg/kg-day (methanol and ethylene glycol). Critical effects for these chemicals include kidney/renal toxicity, hepatotoxicity, developmental toxicity (extra cervical ribs), reproductive toxicity, neurotoxicity, and decreased terminal body weight. Only one of these chemicals, sodium chlorite, is regulated in drinking water under the NPDWRs.

Of the 25 chemicals that lack chronic oral RfVs, 11 have high-confidence TOPKAT LOAEL estimates available. Of these, methenamine (~14% of disclosures) had the lowest TOPKAT LOAEL estimate, and choline chloride (~15% of disclosures) had the second lowest. All but five of these chemicals had at least some relevant toxicological data available on EPA's ACToR database.

[1] The analysis of the FracFocus 1.0 project database presented in this chapter did not exclude chemicals that lacked valid concentration data, in order to present a more inclusive analysis of the potential toxicity of chemicals used in hydraulic fracturing fluids. The chemical list and percent disclosures listed for each chemical is therefore slightly different that those shown in Chapter 5 (Table 5-3), which excluded chemicals lacking valid concentration data.

Table 9-2. Chemicals reported to FracFocus 1.0 from January 1, 2011 to February 28, 2013 in 10% or more disclosures, with the percent of disclosures for which each chemical is reported. Chronic oral RfVs, TOPKAT LOAEL estimates, and availability of ACToR data are shown when available.

Chemicals are ordered in the table, from high to low, based on their number of disclosures in the EPA FracFocus 1.0 project database. Water, quartz, and sodium chloride are excluded from this analysis. Asterisk (*) indicates chemicals that are regulated as drinking water contaminants under the NPDWRs.

CASRN = Chemical Abstract Service Registry Number; RfV = Reference value; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer-Reviewed Toxicity Value; HHBP = Human Health Benchmarks for Pesticides; QSAR = Quantitative structure-activity relationship; TOPKAT = Toxicity Prediction by Komputer Assisted Technology; ACToR = EPA's Aggregated Computational Toxicology Online Resource

[a] The FracFocus frequency of use data presented in this chapter is based on 35,957 FracFocus disclosures that were deduplicated, within the study time period (January 1, 2011 to February 28, 2013), and with ingredients that have a valid CASRN.

[b] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in this analysis include chronic oral reference doses (RfDs) from IRIS, PPRTV, and HHBP; chronic oral minimal risk levels (MRLs) from ATSDR; maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intake (TDI) from CICAD. See Section 9.4.1.

[c] Critical effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

[d] TOPKAT LOAEL: The LOAEL is the lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group. TOPKAT LOAELs were predicted using a QSAR-based software model, as described in Section 9.4.2. Values are rounded to 3 significant figures.

[e] Indicates the total number of data points available for a chemical in the relevant data classes on EPA's ACToR database, as described in Section 9.4.3.

Table 9-3 shows the chemicals reported in at least 10% of disclosures nationally in the EPA FracFocus 1.0 project database that are considered by at least one of the sources in Table 9-1 to be known, probable, or possible human carcinogens. Ethanol is classified as a "carcinogenic to humans" (Group 1) by IARC. Naphthalene is classified by IARC as "possibly carcinogenic to humans" (Group 2B), and is classified by RoC as "reasonably anticipated to be a human carcinogen," while IRIS classifies naphthalene as having inadequate data to assess carcinogenic potential. Neither chemical has an available OSF.

Table 9-3. List of OSFs and qualitative cancer classifications available for all carcinogenic chemicals reported to FracFocus 1.0 from January 1, 2011 to February 28, 2013 in 10% or more disclosures.

Includes all chemicals from Table 9-2 that are classified as known, probable, or possible human carcinogens by at least one of the sources in Table 9-1.

		OSF[a]		Qualitative cancer classification			
Chemical Name	**CASRN**	**OSF (per mg/kg-day)**	**Source of OSF**	**IRIS[b]**	**PPRTV[c]**	**IARC[d]**	**RoC[e]**
Ethanol	64-17-5					1	
Naphthalene	91-20-3			"Data are inadequate to assess human carcinogenic potential"		2B	RAHC

CASRN = Chemical Abstract Service Registry Number; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer Reviewed Toxicity Values; IARC = International Agency for Research on Cancer Monographs; RoC = National Toxicology Program 13th Report on Carcinogens

[a] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in this analysis include values from IRIS, PPRTV, HHBP, and CalEPA. See Section 9.4.1.

[b] IRIS assessments use EPA's 1986, 1996, 1999, or 2005 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[c] PPRTV assessments use EPA's 1999 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[d] The IARC summarizes the weight of evidence as to whether a contaminant is or may be carcinogenic using five weight of evidence classifications: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to its carcinogenicity to humans; Group 4: Probably not carcinogenic to humans. See glossary in Appendix G for details.

[e] The listing criteria in the 13th RoC Document are: Known = Known to be a human carcinogen; RAHC = Reasonably anticipated to be a human carcinogen.

In addition to evaluating chemicals that are frequently used in hydraulic fracturing fluids, we also evaluated the availability of toxicological data for subsets of chemicals that are used less frequently on a national basis (Figure 9-4). For this analysis, we binned the chemicals according to frequency of use as identified from the EPA FracFocus 1.0 project database (>10% of disclosures, 5-10% of disclosures, 1-5% of disclosures, <1% of disclosures, or unknown frequency of use), and evaluated the percentage of chemicals within each bin that have available chronic oral RfVs or OSFs, TOPKAT LOAEL estimates, and relevant data on ACToR. This analysis demonstrates that the availability of chronic oral RfVs and OSFs is low across all of these subsets of chemicals. Proportionately, the availability of chronic oral RfVs, OSFs, and data on ACToR is slightly higher for chemicals that are used in >10% of disclosures, compared to chemicals that are used less frequently.

Of the chemicals on the EPA's list that had frequency of use data available from the EPA FracFocus 1.0 project database, the majority were used in <1% of disclosures (n=480), suggesting that potential exposure to these chemicals is more likely to be a local issue rather than a national issue. Given that the analysis of the EPA FracFocus 1.0 project database presented in this chapter was based on 35,957 disclosures, a chemical used in <1% of wells nationally could still be used in several hundred wells. Chemicals used infrequently on a national basis could still be used more frequently within certain areas or counties, increasing the potential for local exposure to that chemical.

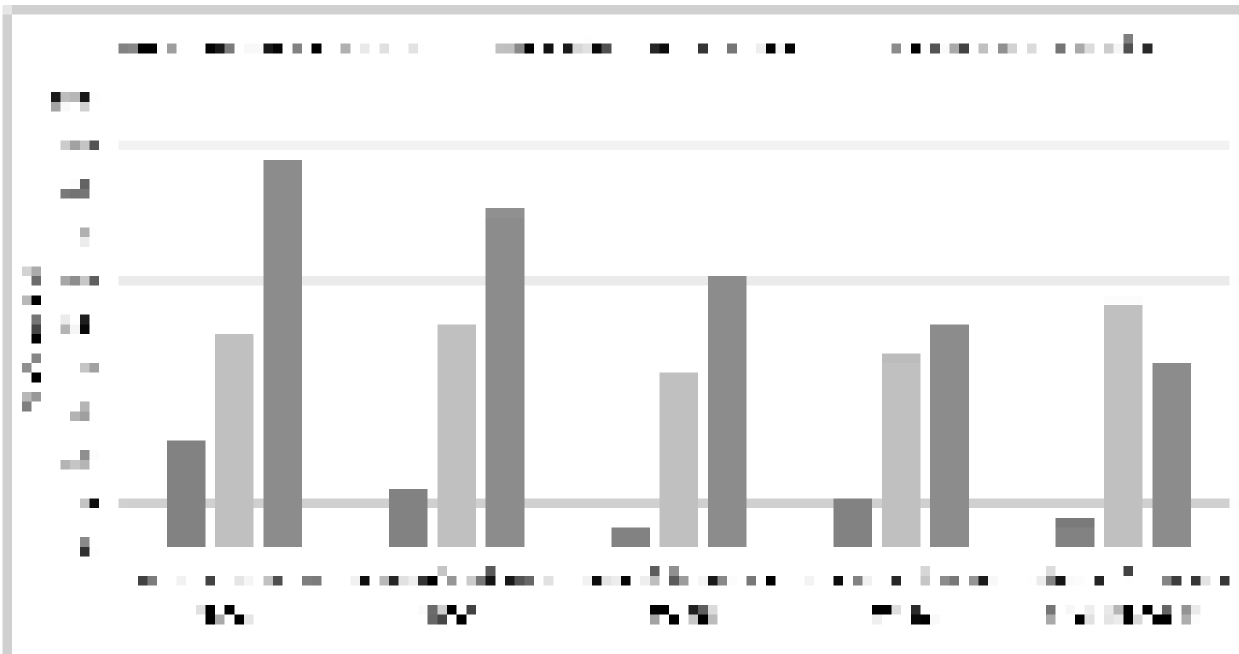

Figure 9-4. Availability of toxicity data (chronic oral RfVs/OSFs, TOPKAT LOAEL estimates, and relevant data on ACToR) for subsets of chemicals used at various frequencies in hydraulic fracturing fluids, as determined based on the number of disclosures in the EPA FracFocus 1.0 project database.

As described in Chapter 5, many of the chemicals used in hydraulic fracturing fluids can be classified as chemical mixtures. Among the most common chemical mixtures on EPA's list of chemicals are petroleum distillates (i.e., hydrocarbon solvents), which are complex mixtures of petroleum hydrocarbons.[1] Two of the most frequently used chemicals in Table 9-2 are petroleum distillates. (Petroleum) hydrotreated light distillates is a mixture of hydrocarbons having carbon numbers predominantly in the range of C9 through C16, and was reported as used in 67% of disclosures in the EPA FracFocus 1.0 project database. Heavy aromatic (petroleum) solvent naphtha is a mixture consisting predominantly of aromatic hydrocarbons in carbon fraction range of C9 through C16, and was reported as used in 21% of disclosures in the EPA FracFocus 1.0 project database. These petroleum distillates lack chronic oral RfVs or OSFs, and have little information available in ACToR. However, a methodology that describes the toxicity and derivation of surrogate

[1] Total petroleum hydrocarbons (TPH) is a term used to describe a large family of several hundred chemical compounds that originally come from crude oil. TPH is a mixture of chemicals, but they are all made mainly from hydrogen and carbon, called hydrocarbons. TPH are divided into groups of petroleum hydrocarbons that act alike in soil or water. These groups are called petroleum hydrocarbon fractions. Each hydrocarbon fraction contains many individual chemicals. Some chemicals that may be found in TPH are hexane, jet fuels, mineral oils, benzene, toluene, xylenes, naphthalene, and fluorene, as well as other petroleum products and gasoline components. Source: ATSDR (2011).

toxicity values for such mixtures was developed by the Total Petroleum Hydrocarbon Criteria Working Group (TPHCWG) (Edwards et al., 1997). This indicator/surrogate approach uses a combination of toxicity data and existing RfVs on individual compounds and fraction-specific mixtures. Examples of compounds present in each fraction include: toluene, ethylbenzene, and styrene (C5-C8) and isopropylbenzene (cumene), naphthalene, fluorene, pyrene, and methylnaphthalene (C9-C16). No data was available for consideration for C>16. Applying their methodology, the TPHCWG derived surrogate aliphatic and aromatic oral toxicity values for fractions in the C5-C8, C9-C16, and C17-C35 ranges. For aromatics, the toxicity ranking was C9-C16 and C17-C35 > C5-C8; and for aliphatics, the toxicity ranking was C9-C16 > C17-C35 > C5-C8. As reviewed by the TPHCWG, compounds above C20 are likely not volatile or soluble in groundwater and will remain at the release site and compounds above C35 are typically not likely to be bioavailable by the oral route of exposure. These surrogate toxicity values are not included in EPA's analysis in this report, but this methodology might be useful for risk assessors at sites where these petroleum distillates are used.

We additionally note that several of the frequently used chemicals in Table 9-2 are designated as being "generally recognized as safe" (GRAS) for use in food additives or food contact substances by the U.S. Food and Drug Administration (FDA). This includes hydrochloric acid, guar gum, sodium hydroxide, sodium chloride, potassium hydroxide, acetic acid, citric acid, choline chloride, carbonic acid dipotassium salt, ammonium chloride, and formic acid. Overall, 103 chemicals on EPA's list of chemicals used in hydraulic fracturing fluids have GRAS designations by the FDA. GRAS chemicals may be used by hydraulic fracturing industry operators in an effort to avoid more hazardous chemicals and minimizes concern in the public perception (Loveless et al., 2011). However, GRAS determinations are often specific to certain conditions as expressed in the FDA GRAS Notification Database and therefore do not indicate that the same chemical is safe for use in hydraulic fracturing fluids. For instance, formic acid is considered GRAS for specific use in paper food packaging materials (U.S. FDA, 2016), but has a chronic oral RfD of 0.9 mg/kg-day based on reproductive effects (U.S. EPA, 2010b). For human health risk assessment in areas of hydraulic fracturing activity, hazard and dose-response relations for these chemicals need to be assessed in the context of the use and levels that are likely to be encountered in an appropriate exposure scenario.

9.5.2 Organic Chemicals in Produced Water

Chapter 7 discussed the detection of volatile and semi-volatile organic chemicals in produced water. Many of these chemicals, including the BTEX chemicals and related hydrocarbons, occur naturally in hydrocarbon formations and are characteristic of produced water from oil and gas production wells in both conventional and unconventional reservoirs. Some of these chemicals have anthropogenic origins, such as di(2-ethylhexyl) phthalate, which does not occur naturally but has known use in hydraulic fracturing fluids. Naphthalene is an example of a chemical that may occur naturally in hydrocarbon formations but is also used frequently in hydraulic fracturing fluids (19% of disclosures in the EPA FracFocus 1.0 project database; Table 9-2). These chemicals have the potential to enter drinking water resources through events such as spills of produced water, mechanical integrity failures, infiltration into groundwater from produced water storage pits, and persistence in inadequately treated wastewater.

Several recent field studies have reported these organic constituents in surface water and groundwater in areas of hydraulic fracturing activity. For example, the BTEX chemicals, diesel-range organics, gasoline-range organics, and naphthalene were detected in groundwater monitoring wells in Pavillion Field, Wyoming, likely as a result of legacy contamination from leaking unlined production fluid storage pits (Digiulio and Jackson, 2016). BTEX chemicals were also found to be elevated above their respective MCLs following spills by the oil and gas industry in Colorado, and were reduced to lower concentrations following remediation (Gross et al., 2013). Ferrar et al. (2013) reported mean concentrations of the BTEX chemicals in effluent from a centralized waste treatment (CWT) facility in Pennsylvania ranged from about 2 to 46 μg/L, with significantly lower concentrations observed after oil and gas well operators were asked to stop discharging waste at this facility (Text Box 8-1). In a survey of 500 private and public water supply wells overlying and adjacent to the Barnett Shale in Texas, Hildenbrand et al. (2015) reported that benzene concentrations exceeded their MCL in all 34 wells where benzene was detected, while toluene, ethylbenzene, and xylenes were prevalent at trace levels; the authors noted that BTEX detections occurred at a high rate in an area that houses a large number of underground injection wells for drilling waste disposal, but it was not clear that these chemicals originated from hydraulic fracturing activity or from another potential source.

As there were a large number of organic chemicals identified on EPA's list, this section focuses on the toxicological evaluation of those organic chemicals that had measured concentration data available in Appendix E and had at least some toxicity data available from the sources in Table 9-1, TOPKAT, or ACToR (69 chemicals total).[1] There were an additional 46 organic chemicals that had measured concentration data in Chapter 7 or Appendix E that did not have any toxicity data available. Organic chemicals that lacked concentration data and are not discussed here.

For this subset of 69 organic chemicals, noncancer toxicity values (chronic oral RfVs and high confidence TOPKAT LOAEL estimates) and ACToR data availability are shown in Table 9-4, and cancer information (OSFs and qualitative cancer classifications) are shown in Table 9-5. Chronic oral RfVs were available for 31 of these chemicals, and ranged from 0.001 mg/kg-day (pyridine) to 0.9 mg/kg-day (acetone). Critical effects for these chemicals include kidney/renal toxicity, hepatotoxicity, neurotoxicity, reproductive toxicity (decreased maternal weight gain), developmental toxicity (decreased offspring body weight, fetal toxicity), and decreased terminal body weight. Six of the chemicals in Table 9-4 are regulated as drinking water contaminants under the NPDWRs: the BTEX chemicals (benzene, ethylbenzene, toluene, xylenes), benzo(a)pyrene, and di(2-ethylhexyl) phthalate.

Of the 38 chemicals in Table 9-4 that lack chronic oral RfVs, 10 have high-confidence TOPKAT LOAEL estimates available. Several of these had similarly low LOAEL estimates: benzo(g,h,i)perylene, indeno(1,2,3-cd)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, dibenz(a,h)anthracene, and N-nitrosodiphenylamine. Notably, 33 of the chemicals

[1] Note that chemical names presented in this chapter and in Appendix H sometimes differ from the chemical names presented with the concentration data in Appendix E. This is because Appendix E uses the chemical names provided by the original sources of chemical data, while this chapter and Appendix H use chemical names that were verified by EPA during the curation of the chemical list. See Appendix H for details on the curation of the chemical list.

in Table 9-4 were added to EPA's chemical list after the release of the external review draft (Text Box 9-2), and therefore were not included in the QSAR analysis (Section 9.4.2).

Table 9-4. List of a subset of organic chemicals that have been detected in produced water, with respective chronic oral RfVs, TOPKAT LOAEL estimates, and availability of ACToR data shown when available.

Includes organic chemicals that were identified on the EPA's list of chemicals in produced water (Appendix H) that have measured concentration data available in Appendix E and have at least some toxicity data available from the sources consulted by the EPA. Chemicals are ordered in the table from most toxic to least toxic based on chronic oral RfV. Chemicals without RfVs were ordered based on TOPKAT LOAEL, and then by number of data points on ACToR. *Indicates chemicals that are regulated as drinking water contaminants under the NPDWRs.

CASRN = Chemical Abstract Service Registry Number; RfV = Reference value; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer-Reviewed Toxicity Value; HHBP = Human Health Benchmarks for Pesticides; QSAR = Quantitative structure-activity relationship; TOPKAT = Toxicity Prediction by Komputer Assisted Technology; ACToR = EPA's Aggregated Computational Toxicology Online Resource

[a] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in this analysis include chronic oral reference doses (RfDs) from IRIS, PPRTV, and HHBP; chronic oral minimal risk levels (MRLs) from ATSDR; maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intake (TDI) from CICAD. See Section 9.4.1.

[b] Critical effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

[c] TOPKAT LOAEL: The LOAEL is the lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group. TOPKAT LOAELs were predicted using a QSAR-based software model, as described in Section 9.4.2. Values are rounded to 3 significant figures.

[d] Indicates the total number of data points available for a chemical in the relevant data classes on EPA's ACToR database, as described in Section 9.4.3.

Of the organic chemicals in produced water listed in Table 9-4, 17 have available OSFs and 23 are classified as known, probable, or possible carcinogens (Table 9-5). Benzidine and benzene were both classified as human carcinogens by IRIS, IARC, and RoC, with benzidine being the most potent carcinogen listed in Table 9-5 (OSF of 230 per mg/kg-day). Benzo(a)pyrine is classified as a human carcinogen by IARC, and as a probable human carcinogen by IRIS. The remaining chemicals were classified as probable or possible human carcinogens.

Table 9-5. List of OSFs and qualitative cancer classifications available for a subset of organic chemicals that have been reported in produced water.

Includes organic chemicals that were identified on EPA's list of chemicals in produced water (Appendix H) that have measured concentration data available in Chapter 7 or Appendix E (Table 9-4) and are classified as known, probable, or possible carcinogens. Chemicals that had OSFs available are ordered in this table from most potent (highest OSF) to least potent (lowest OSF).

CASRN = Chemical Abstract Service Registry Number; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer Reviewed Toxicity Values; HHBP = Human Health Benchmarks for Pesticides; CalEPA = California Environmental Protection Agency; IARC = International Agency for Research on Cancer Monographs; RoC = National Toxicology Program 13th Report on Carcinogens

[a] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in this analysis include values from IRIS, PPRTV, HHBP, and CalEPA. See Section 9.4.1.

[b] IRIS assessments use EPA's 1986, 1996, 1999, or 2005 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[c] PPRTV assessments use EPA's 1999 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[d] The IARC summarizes the weight of evidence as to whether a contaminant is or may be carcinogenic using five weight of evidence classifications: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to its carcinogenicity to humans; Group 4: Probably not carcinogenic to humans. See glossary in Appendix G for details.

[e] The listing criteria in the 13th RoC Document are: Known = Known to be a human carcinogen; RAHC = Reasonably anticipated to be a human carcinogen.

9.5.3 Inorganic Chemicals and TENORM in Produced Water

Chapter 7 discussed the detection of inorganic constituents such as metals, inorganic ions, and TENORM in produced water. Examples include barium, cadmium, chromium, copper, lead, manganese, nickel, zinc, and radium. In general, these chemicals are naturally occurring, and are characteristic of produced water from both conventional and unconventional reservoirs. These chemicals have the potential to enter drinking water resources through events such as spills of produced water, mechanical integrity failures, infiltration into groundwater from produced water storage pits, and persistence in inadequately treated wastewater.

The entry of inorganic constituents of produced water into drinking water resources has been documented in numerous studies. In Pennsylvania, elevated levels of barium and strontium have been observed in CWT effluent (PA DEP, 2015a), with effluent concentrations dropping after oil and gas well operators were asked to stop discharging waste at this facility (see Text Box 8-1 for details on temporal trends in wastewater management in Pennsylvania). Likewise, effluent concentrations at two publicly owned treatment words (POTWs) that had accepted Marcellus wastewater were found to have lower concentrations of bromide, chloride, barium, strontium, and sulfate after oil and gas well operators were asked to stop discharging waste at this facility in May 2011 (Ferrar et al., 2013). Effluents from POTWs and CWTs that handle Marcellus Shale wastewater have been found to have levels of radium-226 and radium-228 that exceed the MCL for radium and are significantly higher than typical background levels of radium in river water (PA DEP, 2015b). Radium-226 and radium-228 have been demonstrated to accumulate in sediments near the outfalls of CWTs and of POTWs that handle oil and gas wastewater from CWTs (PA DEP, 2015b; Warner et al., 2013a), and in sediments receiving effluent from landfills that accept oil and gas wastes (PA DEP, 2015b). In West Virginia, water samples collected downstream of a hydraulic fracturing wastewater injection facility had elevated specific conductance and total dissolved solids, elevated bromide, chloride, sodium, barium, strontium, and lithium concentrations, and different strontium isotope ratios compared to those found in upstream, background waters (Akob et al., 2016). In a survey of 500 groundwater wells overlying and adjacent to the Barnett Shale in Texas, Hildenbrand et al. (2015) reported a variety of metals and anions that are known produced water constituents at concentrations that sometimes exceeded primary or secondary MCLs, health advisory levels, or other suggested levels as provided in the EPA Drinking Water Standards, although it was not clear that these chemicals originated from nearby hydraulic fracturing activity or from other potential sources.

For the inorganic chemicals that were identified in produced water on EPA's chemical list, noncancer toxicity values (chronic oral RfVs) and ACToR data availability for these chemicals are shown in Table 9-6, and cancer information (OSFs and qualitative cancer classifications) are shown in Table 9-7. As shown in Table 9-6, chronic oral RfVs were available for 26 of these chemicals, ranging from 0.00002 mg/kg-day (phosphorus) to 1.6 mg/kg-day (nitrate). Critical effects for these metals include neurotoxicity, developmental and liver toxicity, hyperpigmentation and keratosis of the skin, and decrements in blood copper status and enzyme activity. Nineteen of the inorganic chemicals in Table 9-6 are regulated as drinking water contaminants under the NPDWR.

All but one of these inorganic chemicals had at least some relevant data available on EPA's ACToR database. However, none of the inorganic chemicals have TOPKAT LOAEL estimates available, as this QSAR model is only able to generate estimates for organic chemicals (Section 9.4.2).

Table 9-6. List of inorganics and TENORM reported in produced water, and respective chronic oral RfVs and OSFs when available.

Includes inorganic chemicals that were identified on EPA's list of chemicals in produced water (Appendix H). Chemicals are ordered from most toxic to least toxic based on chronic oral RfV. Chemicals without chronic oral RfVs were ordered in terms of the number of data points on ACToR. *Indicates chemicals are regulated as drinking water contaminants under the NPDWR.

CASRN = Chemical Abstract Service Registry Number; RfV = Reference value; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer-Reviewed Toxicity Value; CalEPA = California Environmental Protection Agency; CICAD = Concise International Chemical Assessment Documents; ACToR = EPA's Aggregated Computational Toxicology Online Resource

[a] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in this analysis include chronic oral reference doses (RfDs) from IRIS, PPRTV, and HHBP; chronic oral minimal risk levels (MRLs) from ATSDR; maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intake (TDI) from CICAD. See Section 9.4.1.

[b] Critical effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

[c] Indicates the total number of data points available for a chemical in the relevant data classes on EPA's ACToR database, as described in Section 9.4.3.

[d] CalEPA MADLs are in units of µg/day, while all other chronic oral RfVs in this table are in units of mg/kg-day.

OSFs were available for 4 of the inorganic chemicals reported in produced water, and 14 are classified as known or probable carcinogens (Table 9-7). OSFs ranged from 15 per mg/kg-day for cadmium to 0.0085 mg/kg-day for lead. Chromium (VI), arsenic, alpha particle, beta particle, radium-226, and radium-288 are all classified as known human carcinogens by all sources reporting in this table. Beryllium and cadmium are both classified as known human carcinogens by IARC and NTP, and as probable human carcinogens by EPA. Lead, cobalt, nickel, nitrate, and nitrite are classified by these sources as possible or probable human carcinogens.

Table 9-7. List of qualitative cancer classifications available for inorganics and NORM that were reported in produced water.

Includes inorganic chemicals that were identified on EPA's list of chemicals in produced water (Appendix H) that classified as known, probable, or possible carcinogens by at least one of the sources in Table 9-1. Chemicals that had OSFs available are ordered in this table from most potent (highest OSF) to least potent (lowest OSF).

[c] PPRTV assessments use EPA's 1999 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[d] The IARC summarizes the weight of evidence as to whether a contaminant is or may be carcinogenic using five weight of evidence classifications: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to its carcinogenicity to humans; Group 4: Probably not carcinogenic to humans. See glossary in Appendix G for details.

[e] The listing criteria in the 13th RoC Document are: Known = Known to be a human carcinogen; RAHC = Reasonably anticipated to be a human carcinogen.

9.5.4 Organochlorine Pesticides and Polychlorinated Biphenyls (PCBs) in Produced Water

EPA's list of chemicals detected in produced water includes several chemicals that have been banned from commercial use: specifically, organochlorine pesticides and Aroclor 1248, which is a commercial PCB mixture. These chemicals were reported by two of the sources used to compile EPA's chemical list (Appendix H): a technical report prepared by the Gas Technology Institute for the Marcellus Shale Coalition (MSC), which is a drilling industry trade group (Hayes, 2009); and a report by the New York State Department of Environmental Conservation (NYSDEC), which referenced the results of the MSC study (NYSDEC, 2011). These chemicals are listed in Table 9-8 along with their respective noncancer toxicity values (chronic oral RfVs and TOPKAT LOAELs) and availability of relevant toxicological information on ACToR. Cancer information (OSF or qualitative cancer classification) for these chemicals is listed in Table 9-9.

There is uncertainty about why organochlorine pesticides and PCBs were detected, as they are not used in hydraulic fracturing fluids and are not naturally occurring. The MSC study stated the banned substances were detected sporadically and at low concentrations, and suggested they may have originated from laboratory contamination. The NYSDEC report suggested that the banned substances may have been introduced to the shale or the water as a result of drilling or fracturing operations. It is possible that these chemicals were present as legacy contaminants in the source water used for hydraulic fracturing fluid formulation, or were mobilized from the environment near the well. Although these chemicals are notable for their high toxicity, the extent to which these chemicals may be detected in produced water from other hydraulic fracturing sites is not clear.

Chronic oral RfVs for these organochlorine pesticides ranged from 0.000013 mg/kg-day (Heptachlor epoxide) to 0.0005 mg/kg-day (heptachlor), and were all based on liver toxicity. All of these pesticides had TOPKAT LOAEL estimates, and all have relevant data available within EPA's ACToR database.). Heptachlor epoxide, heptachlor, and lindane are regulated as drinking water contaminants under the NPDWR.

Table 9-8. List of organochlorine pesticides and PCBs that were reported in produced water, and their respective chronic oral RfVs, TOPKAT LOAEL estimates, and availability of data in EPA's ACToR database.

Includes banned chemicals that were identified on EPA's list of chemicals in produced water (Appendix H). Chemicals are ordered from most toxic to least toxic based on chronic oral RfV. Chemicals without chronic oral RfVs were ordered in terms of the number of data points on ACToR. *Indicates chemicals that are regulated as drinking water contaminants under the NPDWRs.

CASRN = Chemical Abstract Service Registry Number; RfV = Reference value; IRIS = Integrated Risk Information System; QSAR = Quantitative structure-activity relationship; TOPKAT = Toxicity Prediction by Komputer Assisted Technology; ACToR = EPA's Aggregated Computational Toxicology Online Resource

[a] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in this analysis include chronic oral reference doses (RfDs) from IRIS, PPRTV, and HHBP; chronic oral minimal risk levels (MRLs) from ATSDR; maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intake (TDI) from CICAD. See Section 9.4.1.

[b] Critical effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

[c] TOPKAT lowest-observed-adverse-effect level (LOAEL): The LOAEL is the lowest exposure level at which there are biologically significant increases in frequency or severity of adverse effects between the exposed population and its appropriate control group. TOPKAT LOAELs were predicted using a QSAR-based software model, as described in Section 9.4.2.

[d] Indicates the total number of data points available for a chemical in the relevant data classes on EPA's ACToR database, as described in Section 9.4.3.

OSFs were available for 7 of the organochlorine pesticides that are classified as known, probable, or possible human carcinogens (Table 9-9). OSFs ranged from 17 per mg/kg-day (aldrin) to 0.34 per mg/kg-day (p,p'-DDE). Aldrin, dieldrin, heptachlor epoxide, heptachlor, beta-hexachlorocyclohexane, and p,p'-DDE are classified as probable or possible carcinogens. Lindane is classified as a known carcinogen by IARC, and as "reasonably anticipated to be a human carcinogen" by RoC.

Table 9-9. List of OSFs and qualitative cancer classifications available for organochlorine pesticides reported in produced water.

Includes banned chemicals that were identified on EPA's list of chemicals in produced water (Appendix H) that are classified as known, probable, or possible carcinogens by at least one of the sources in Table 9-1. Chemicals are ordered in this table from most potent (highest OSF) to least potent (lowest OSF).

[a] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in this analysis include values from IRIS, PPRTV, HHBP, and CalEPA. See Section 9.4.1.

[b] IRIS assessments use EPA's 1986, 1996, 1999, or 2005 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[c] PPRTV assessments use EPA's 1999 guidelines to establish descriptors for summarizing the weight of evidence as to whether a contaminant is or may be carcinogenic. See glossary in Appendix G for details.

[d] The IARC summarizes the weight of evidence as to whether a contaminant is or may be carcinogenic using five weight of evidence classifications: Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to its carcinogenicity to humans; Group 4: Probably not carcinogenic to humans. See glossary in Appendix G for details.

[e] The listing criteria in the 13th RoC Document are: Known = Known to be a human carcinogen; RAHC = Reasonably anticipated to be a human carcinogen.

9.5.5 Methane in Stray Gas

Chapter 6 discussed stray gas as a potential hazard in areas of hydraulic fracturing activity (Text Box 6-3). Stray gas refers to the phenomenon of natural gas (primarily methane, plus lesser amounts of ethane) migrating into shallow groundwater, into water wells, or to the surface (e.g., cellars, streams, or springs). As discussed in Chapter 6, some studies indicate an association between hydraulic fracturing activity and elevated methane concentrations in drinking water, while other studies did not find such a correlation. Potential pathways for migration of stray gas into aquifers include pathways along production wells with casing and/or cement issues, through naturally existing fractures, through induced fractures, or via a route that is some combination of these pathways.

Although ingestion of methane is not considered to be toxic, it has the potential to pose a physical hazard. Methane can accumulate to explosive levels when allowed to exsolve (degas) from groundwater in closed environments. High concentrations of methane may also displace oxygen and act as an asphyxiant (NIOSH, 2000), potentially causing suffocation, loss of consciousness, or symptoms such as headache and nausea. Methane is not a regulated drinking water contaminant. Methane does not have an RfV, OSF, or qualitative cancer classification available from any of the sources consulted by EPA, and did not have a high-confidence TOPKAT LOAEL estimate. Information on methane is available within the ACToR database.

9.5.6 Disinfection Byproducts (DBPs) Formed from Wastewater Constituents

Some of the inorganic constituents of hydraulic fracturing produced water, including chloride, bromine, iodine, and ammonium, can contribute to the formation of DBPs during wastewater treatment (Harkness et al., 2015; Parker et al., 2014). The entry of these constituents into drinking water resources—e.g., as a result of wastewater spills or from the discharge of inadequately treated hydraulic fracturing wastewater—can result in DBPs in finished drinking water from downstream drinking water treatment plants (States et al., 2013). DBPs may also be formed when hydraulic fracturing produced water is treated at a centralized or publicly owned treatment works, and may reach drinking water resources when the treated wastewater is discharged to surface water (Hladik et al., 2014). Currently, there are no data available on the concentrations of DBPs in finished drinking water as related to contributions of DBP precursors from hydraulic fracturing wastewater.

Regulated DBPs such as bromate, chlorite, haloacetic acids, and trihalomethanes are a small subset of the full spectrum of DBPs that include other chlorinated and brominated DBPs as well as nitrogenous and iodated DBPs. Long term exposure to these DBPs can result in an increased risk of cancer, anemia, liver and kidney effects, and central nervous system effects. Some of the unregulated DBPs may be more toxic than their regulated counterparts (Harkness et al., 2015; McGuire et al., 2014; Parker et al., 2014). In addition, brominated forms of DBPs are considered to be more cytotoxic, genotoxic, and carcinogenic than chlorinated species based on studies using rodents, various types of human cells, and a salmonella strain containing human P450 genes (McGuire et al., 2014; Parker et al., 2014; States et al., 2013; Krasner, 2009; Richardson et al., 2007). As with brominated DBPs, there is concern that some iodinated forms of DBPs are more cytotoxic and genotoxic than chlorinated species (McGuire et al., 2014; Parker et al., 2014; Krasner, 2009; Richardson et al., 2007), as evidenced by studies involving rodent research and human cell research (Plewa et al., 2010; Plewa and Wagner, 2009; Richardson et al., 2007). The MCLs (mg/L) for the regulated DBPs are: 0.01 for bromate, 1.0 for chlorite, 0.06 for haloacetic acid, and 0.08 for total trihalomethanes.

9.5.7 Chemicals Detected in Multiple Stages of the Hydraulic Fracturing Water Cycle

As mentioned in Section 9.3 above, there were a total of 77 chemicals on EPA's list that were identified as being used in hydraulic fracturing fluids and detected in produced water. The presence of these chemicals within both of these stages of the hydraulic fracturing water cycle may indicate that these chemicals persist after they are injected into the well. However, this is not necessarily the case, as some of these chemicals (e.g., BTEX, naphthalene, metals) also occur naturally in oil and gas reservoirs. Additionally, the EPA's list of chemicals used in hydraulic fracturing fluids and list of chemicals in produced water were compiled from different sets of sources, and does not provide a matched comparison between the chemicals used in hydraulic fracturing fluid and the chemicals present in produced water at a particular site. There may have been other chemicals in present in produced water that were not detected by these studies due to limitations of analytical chemistry. Thus, the EPA's composited chemical list cannot reliably be used to draw conclusions on the persistence of hydraulic fracturing chemicals following well injection.

Of the 77 chemicals identified in both hydraulic fracturing fluids and produced water, 45 have a chronic oral RfV or OSF available from at least one of the sources in Table 9-1. These 45 chemicals and their respective toxicity values are shown in Table 9-10, with frequency of use data from the EPA FracFocus 1.0 project database provided when available. Eleven of these chemicals are regulated as drinking water contaminants.

Table 9-10. List of 45 chemicals on EPA's list that were used in hydraulic fracturing fluids and detected in produced water and have an RfV or OSF available.

Frequency of use data from the EPA FracFocus 1.0 project database is provided when available. Chemicals with available data from the FracFocus 1.0 project database are ordered from high to low based on frequency of use. Chemicals without frequency of use data are ordered from most toxic to least toxic based on chronic oral RfV. *Indicates chemicals that are regulated as drinking water contaminants under the NPDWRs.

			Chronic oral RfVs[b]			OSFs[d]

CASRN = Chemical Abstract Service Registry Number; RfV = Reference value; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer-Reviewed Toxicity Value; HHBP = Human Health Benchmarks for Pesticides; ATSDR = Agency for Toxic Substances and Disease Registry; CalEPA = California Environmental Protection Agency; CICAD = Concise International Chemical Assessment Documents; QSAR = Quantitative structure-activity relationship; TOPKAT = Toxicity Prediction by Komputer Assisted Technology; ACToR = EPA's Aggregated Computational Toxicology Online Resource

[a] The FracFocus frequency of use data presented in this chapter is based on 35,957 FracFocus disclosures that were deduplicated, within the study time period (January 1, 2011 to February 28, 2013), and with ingredients that have a valid CASRN.

[b] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in this analysis include chronic oral reference doses (RfDs) from IRIS, PPRTV, and HHBP; chronic oral minimal risk levels (MRLs) from ATSDR; maximum allowable daily levels (MADLs) from CalEPA; and tolerable daily intake (TDI) from CICAD. See Section 9.4.1.

[c] Critical effect: The first adverse effect, or its known precursor, that occurs to the most sensitive species as the dose rate of an agent increases.

[d] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in this analysis include values from IRIS, PPRTV, HHBP, and CalEPA. See Section 9.4.1.

[e] CalEPA MADLs are in units of µg/day, while all other chronic oral RfVs in this table are in units of mg/kg-day.

9.6 Hazard Evaluation of Selected Subsets of Hydraulic Fracturing Chemicals Using Multi-Criteria Decision Analysis (MCDA): Integrating Toxicity, Occurrence, and Physicochemical Data

Based on the information presented in Section 9.5, it is clear that there are a variety of chemicals used in hydraulic fracturing fluids or detected in produced water that are known to be hazardous to human health. However, there are gaps in our understanding of the potential for human exposure to these chemicals. Although there are subsurface and surface pathways by which these chemicals may be introduced into drinking water resources—including spills, leaks, mechanical integrity failures, intersection of the fracture network with groundwater, or discharge of wastewater, as described in previous chapters of this report—there are significant limitations associated with the publicly available data on these potential impacts, and the potential for human exposure has not been systematically characterized. This makes it difficult to determine which chemicals are of the greatest concern for human exposure in drinking water, and creates a challenge for hazard evaluation.

Although exposure assessment data are limited, some of the chemicals identified by EPA have other data available that might provide preliminary insight into relative hazard potential. This includes data on toxicity, frequency of use in hydraulic fracturing fluids, detected concentrations in produced water, and data on physicochemical properties. By integrating these types of data, we can place the severity of potential impacts (i.e., the toxicity of specific chemicals) into the context of factors that affect the likelihood of impacts (i.e., frequency of use, environmental fate and transport).

Multi-criteria decision analysis (MCDA) is one possible approach that can be used to facilitate data integration. MCDA is a well-established decision support tool, which is used to integrate multiple lines of evidence to develop an overall ranking or classification (Hristozov et al., 2014; Mitchell et al., 2013b; Huang et al., 2011; Linkov et al., 2011). Using MCDA, a problem is approached by dividing it into smaller criteria that need to be evaluated; the criteria are each analyzed individually, and then combined to provide an integrated evaluation. This approach is structured yet flexible, and offers a transparent means of combining information to provide weight of evidence and insight into a complex problem. MCDA has gained increasing popularity as an environmental decision-making tool (Huang et al., 2011). A recent publication by Yost et al. (In Press) described the use of an MCDA framework to evaluate the hazard potential of chemicals associated with hydraulic fracturing.

Here, to demonstrate one possible method for exploring the potential hazards of these chemicals, we use an adaptation of the MCDA framework developed by Yost et al. (In Press) to analyze and rank selected subsets of chemicals that have data available.[1] Chemicals were assigned scores based on toxicity, occurrence, and physicochemical properties that describe transport in water. These scores were then combined to develop a relative ranking of chemicals based on hazard potential.

The MCDA scores provide a preliminary evaluation of hazard potential, and serve as a qualitative metric for making comparison between chemicals when exposure assessment data is limited or unavailable. This analysis is not intended to define whether or not a chemical will present a human health hazard or indicate that one chemical is safer than another, and should not be used in place of

[1] Yost et al. (In Press) used the MCDA framework to analyze and rank the hazards of chemicals used in hydraulic fracturing fluids, using data from the FracFocus 1.0 project database as the metric of occurrence. This chapter uses that same framework for the analysis of chemicals used in hydraulic fracturing fluids. For chemicals detected in produced water, this chapter modifies the MCDA framework by using measured concentration in produced water as the metric of occurrence.

site-specific data on chemical exposures. An overview of the MCDA framework and selection of chemicals for inclusion in the MCDA is described below.

9.6.1 Overview of the MCDA Framework for Hazard Evaluation

The MCDA framework employed in this chapter was designed specifically to fit the scope of EPA's hydraulic fracturing study (Yost et al., In Press). A basic schematic of the model is shown in Figure 9-5, and the methods for assigning scores are outlined below. Under the MCDA framework, each chemical was assigned three scores:

1. A Toxicity Score;
2. An Occurrence Score; and
3. A Physicochemical Properties score.

The three scores were each standardized based on the highest and lowest respective score within the given subset of chemicals, and then summed to develop a Total Hazard Potential Score for each chemical. The Total Hazard Potential Scores reflect a relative ranking of each chemical within the given subset of chemicals, and offer a means of making comparisons between chemicals.

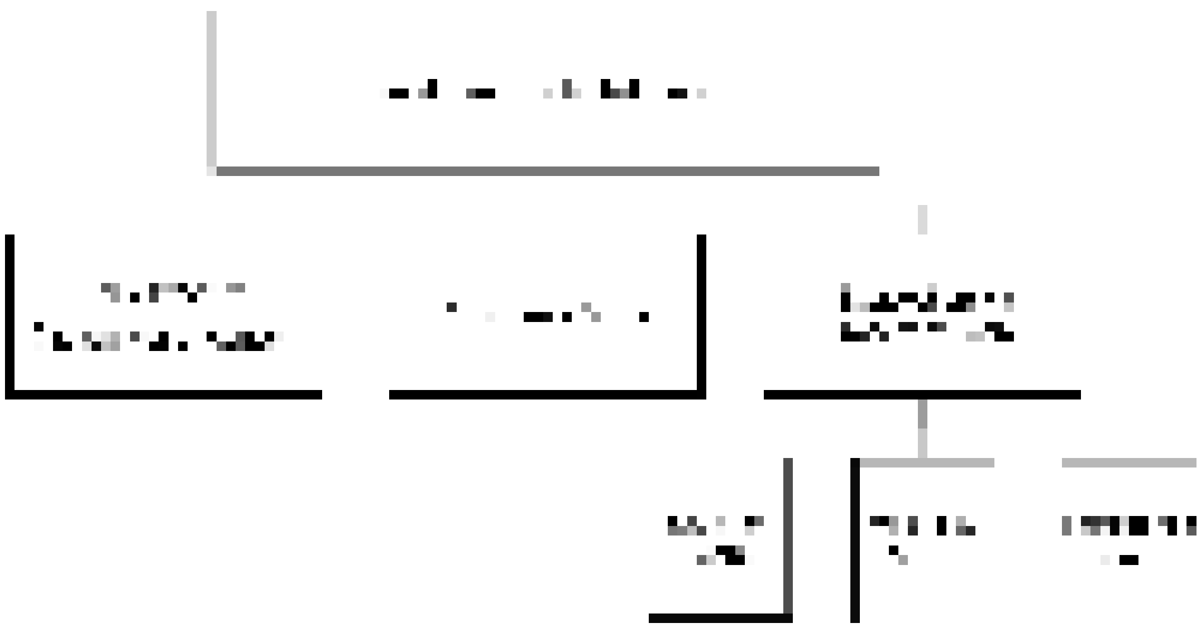

Figure 9-5. Overview of the MCDA framework for hazard evaluation.
Source: Yost et al. (In Press).

9.6.2 Selection of Chemicals for Hazard Evaluation in the MCDA Framework

From the overall list of 1,606 chemicals identified in this assessment, subsets of chemicals were selected for hazard evaluation in the MCDA framework if they had sufficient data for inclusion, using an adaptation of the criteria outlined by Yost et al. (In Press). Specifically, chemicals were selected if they had the following information available:

1. Had a chronic oral RfV or OSF from a US federal source (IRIS, PPRTV, ATSDR, HHBP);
2. Had available data on frequency of use in hydraulic fracturing fluids (data available from the EPA FracFocus 1.0 project database) or measured concentrations in produced water (data available from Appendix E)[1]; and
3. Had data on physicochemical properties available from EPI Suite.

The rationale for applying these criteria is as follows:

1. Federal toxicity values generally undergo more extensive peer review compared to other sources of toxicity values, and are based on the best available scientific information. For this reason, EPA generally prefers to apply RfVs and OSFs from US federal sources for human health risk assessment.
2. Data on frequency of use (in hydraulic fracturing fluids) or measured concentration (in produced water) provide a metric to help assess the likelihood of chemical occurrence in the hydraulic fracturing water cycle.
3. Information on physicochemical properties enables estimation of the likelihood a chemical will be transported in water.

Chemicals used in hydraulic fracturing fluids and chemicals detected in produced water were evaluated separately using the MCDA framework. To explore the different types of toxicity values identified by EPA, two versions of the MCDA were performed on each of these subsets of chemicals: a noncancer MCDA, in which the Toxicity Score is calculated using chronic oral RfVs; and a cancer MCDA, in which the Toxicity Score is calculated using OSFs. For chemicals used in hydraulic fracturing fluids, the noncancer MCDA was repeated for specific subsets of chemicals used in three states that have a significant amount of hydraulic fracturing activity: Texas, Pennsylvania, and North Dakota. Thus, seven iterations of the MCDA were performed: 1-4) noncancer MCDAs for chemicals used in hydraulic fracturing fluids on a national or state-specific basis, 5) a cancer MCDA for chemicals used in hydraulic fracturing fluids, 6) a noncancer MCDA for chemicals detected in produced water, and 7) a cancer MCDA for chemicals detected in produced water.

In total, 42 chemicals used in hydraulic fracturing fluid and 29 chemicals detected in produced water had sufficient information available for inclusion in noncancer MCDAs (Figure 9-6), while 10 chemicals used in hydraulic fracturing fluid and 7 chemicals detected in produced water had sufficient information available for inclusion in cancer MCDAs (Figure 9-7).

[1] Chemicals in produced water were considered for the MCDA if they had average or median measured concentrations from any of the tables in Appendix E. Chemicals with only a maximum or minimum concentration listed in Appendix E were not considered for the MCDA.

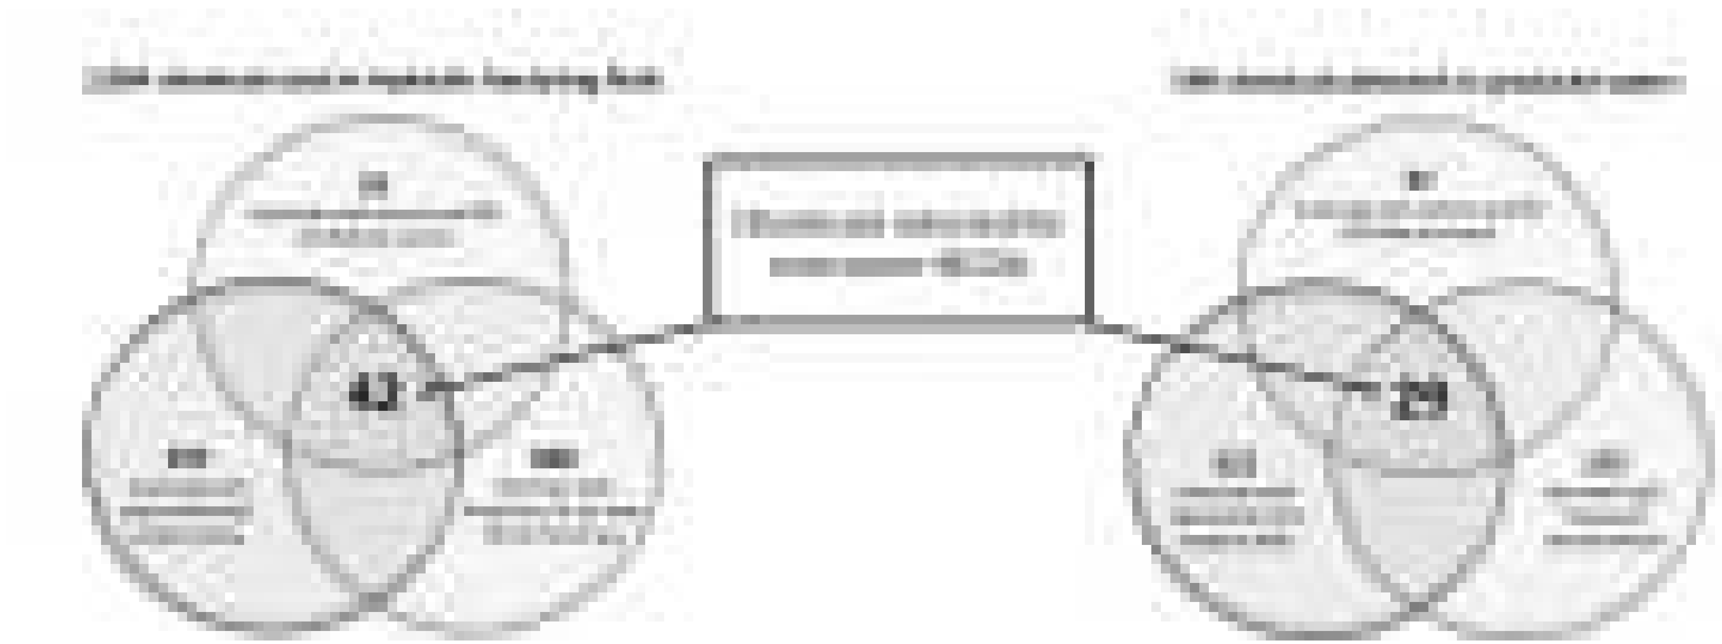

Figure 9-6. The subsets of chemicals selected for hazard evaluation using the noncancer MCDA framework included 42 chemicals used in hydraulic fracturing fluids and 29 chemicals detected in produced water.

For chemicals used in hydraulic fracturing fluids, subsets of these chemicals were also considered in state-specific analyses for Texas (36 chemicals), Pennsylvania (20 chemicals), and North Dakota (21 chemicals).

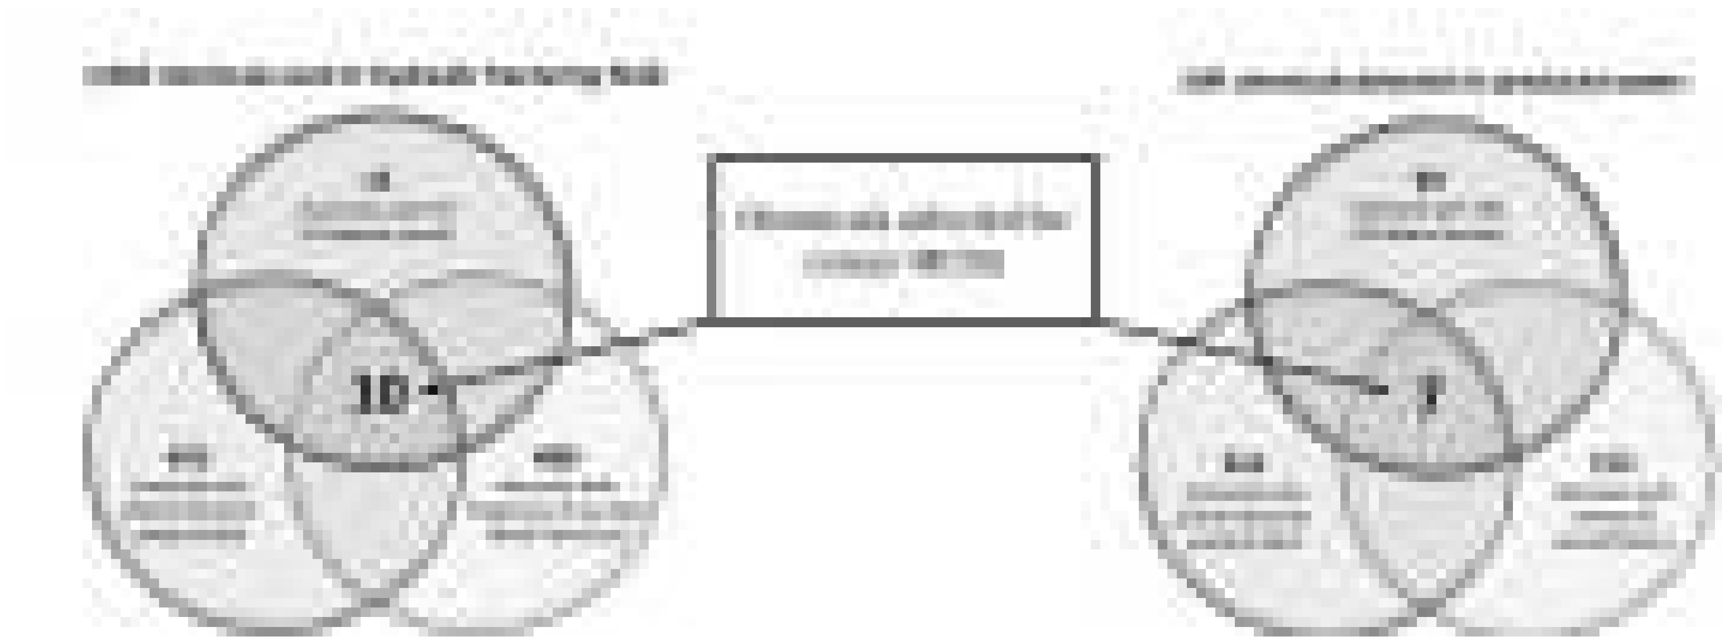

Figure 9-7. The subsets of chemicals selected for hazard evaluation using the cancer MCDA framework included 10 chemicals used in hydraulic fracturing fluids, and 7 chemicals detected in produced water.

9.6.3 Calculation of MCDA Scores

For each iteration of the MCDA, chemicals were assigned scores based on toxicity, occurrence, and physicochemical properties according to the protocol outlined by Yost et al. (In Press). These scores were then standardized to the highest and lowest score within the given subset of chemicals, and then summed to determine a total score and relative ranking for each chemical. The methods used to assign each score and calculate a total score are outlined below.

9.6.3.1 Toxicity Score (Noncancer MCDA)

For each noncancer MCDA, Toxicity Scores were calculated based on chronic oral RfVs from US federal sources (IRIS, PPRTV, ATSDR, and HHBP). If a chemical had a chronic oral RfV available from more than one of these sources, a single value was selected in this order, as described in Section 9.4: HHBP (pesticides), IRIS, PPRTV, ATSDR. Toxicity Scores for the noncancer MCDA were then assigned based on a relative ranking. Within each suite of chemicals considered in this analysis (chemicals used in hydraulic fracturing fluids, or chemicals detected in produced water), RfVs were ranked based on quartiles, and each chemical was assigned a Toxicity Score of 1 to 4 (Table 9-11). Chemicals in the lowest quartile received the highest Toxicity Score, as these chemicals have lower RfVs than other chemicals (i.e., may have lower thresholds for toxicity).

9.6.3.2 Toxicity Score (Cancer MCDA)

For each cancer MCDA, Toxicity Scores were calculated based on OSFs from US federal sources (IRIS, PPRTV, and HHBP). If a chemical had an OSF available from more than one of these sources, a single value was selected in this order, as described in Section 9.4: HHBP (pesticides), IRIS, PPRTV. Toxicity Scores for the cancer MCDA were assigned based on a relative ranking. Within each suite of chemicals considered in this analysis (chemicals used in hydraulic fracturing fluids, or chemicals detected in produced water), OSFs were ranked based on quartiles, and each chemical was assigned a Toxicity Score of 1 to 4 (Table 9-11). Chemicals in the highest quartile received the highest Toxicity Score, as these chemicals have higher OSFs than other chemicals (i.e., are associated with a higher increased risk of cancer per unit of exposure).

9.6.3.3 Occurrence Score

For each of the noncancer and cancer MCDAs, an Occurrence Score was calculated based on the frequency or concentration at which each chemical was reported within the hydraulic fracturing water cycle. For chemicals used in hydraulic fracturing fluids, the Occurrence Score was based on the number of well disclosures for each chemical in the EPA FracFocus 1.0 project database. For chemicals detected in produced water, the Occurrence Score was based on the average or median measured concentration reported in Appendix E. If an average or median concentration of a chemical was reported by multiple studies in Appendix E, the highest of these reported average or median concentrations was used for this calculation. Once a value was determined for each chemical, Occurrence Scores were then assigned based on a relative ranking. Within each suite of chemicals considered in this analysis (chemicals used in hydraulic fracturing fluids, or chemicals detected in produced water), chemical occurrence was ranked based on quartiles, with each chemical assigned an Occurrence Score of 1 to 4 (Table 9-11).

9.6.3.4 Physicochemical Properties Score

For each of the noncancer and cancer MCDAs, a Physicochemical Properties Score was calculated based upon inherent physicochemical properties that describe the likelihood that a chemical will be transported in water. The total Physicochemical Properties Score was calculated as the sum of three subcriteria scores: a Mobility Score, a Volatility Score, and a Persistence Score. The Mobility Score was assessed based upon three physicochemical properties that describe chemical solvency in water: the octanol-water partition coefficient (K_{ow}), the soil adsorption coefficient (K_{oc}), and aqueous solubility. The Volatility Score was assessed based on the Henry's law constant, which describes partitioning of a chemical between water and air. The Persistence Score was assessed based on estimated half-life in water, which describes how long a chemical will remain in water before it is degraded.

For input into the MCDA, experimentally measured physicochemical property values (provided in EPI Suite) were used whenever available. Otherwise, estimated values from EPI Suite were used. To classify these values and assign a score, these numerical values were compared against threshold values (Table 9-11). Each chemical was assigned a Mobility Score, Volatility Score, and Persistence Score (each on a scale of 1 to 4), which were then summed to calculate the Physicochemical Properties Score. The threshold values in Table 9-11 are based upon previously published values employed by existing exposure assessment models, including the EPA's Design for the Environment Alternatives Assessment Criteria for Hazard Evaluation (U.S. EPA, 2011b), the EPA's Pollution Prevention (P2) Framework (U.S. EPA, 2012i), and a peer-reviewed publication by Mitchell et al. (2013b). More details on the Physicochemical Properties Score calculation are provided in the Chapter 9 Annex, Section 9.8.1.

9.6.4 Total Hazard Potential Score

Within each iteration of the MCDA, the three criteria scores (Toxicity, Occurrence, Physicochemical Properties) were each standardized to the dataset by scaling to the highest and lowest respective score within the given subset of chemicals. The following equation was used:

$$S_{x\_final} = (S_x - S_{min}) / (S_{max} - S_{min})$$

in which S_x is the raw score for a particular chemical, S_{max} is the highest observed raw score within the set of chemicals, and S_{min} is the lowest observed raw score within the set of chemicals. S_{x_final} is the standardized score for the chemical. Each standardized score (Toxicity, Occurrence, or Physicochemical Properties) falls on a scale of 0 to 1, and represents a relative ranking within the given subset of chemicals.

The standardized Toxicity Score, Occurrence Score, and Physicochemical Properties Score were summed to calculate a Total Hazard Potential Score for each chemical. The Total Hazard Potential Scores fall on a scale of 0 to 3, with higher scores indicating chemicals that may be more likely to affect drinking water resources. Examples of the Total Hazard Potential Score calculation can be found in the Chapter 9 Annex, Section 9.8.2.

Table 9-11. Thresholds used for developing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score in this MCDA framework.
Adapted from Yost et al. (In Press).

Criteria	Sub-criteria	Value	Score			
			1	2	3	4
Toxicity (Noncancer MCDA)	NA	Chronic oral RfV (mg/kg-day)	>3rd quartile	>2nd quartile to ≤3rd quartile	>1st quartile to ≤2nd quartile	≤1st quartile
Toxicity (Cancer MCDA)	NA	OSF (per mg/kg-day)	<1st quartile	≥1st quartile to <2nd quartile	≥2nd quartile to <3rd quartile	≥3rd quartile
Occurrence	NA	Frequency of use (% of disclosures in EPA's FracFocus 1.0 project database) <u>or</u> Measured concentration in produced water (µg/L; Appendix E)	<1st quartile	≥1st quartile to <2nd quartile	≥2nd quartile to <3rd quartile	≥3rd quartile
Physico-chemical Properties	Mobility	Log K_{OW}	>5	>3 to ≤5	>2 to ≤3	≤2
		Log K_{OC}	>4.4	>3.4 to ≤4.4	>2.4 to ≤3.4	≤2.4
		Aqueous solubility (mg/L)	<0.1	≥0.1 to <100	≥100 to <1000	≥1000
	Volatility	Henry's law constant	$>10^{-1}$	$>10^{-3}$ to $\leq 10^{-1}$	$>10^{-5}$ to $\leq 10^{-3}$	$\leq 10^{-5}$
	Persistence	Half-life in water (days)	<16	≥16 to <60	≥60 to <180	≥180

9.6.5 MCDA Results

For each iteration of the MCDA, we first present the data used for input into the MCDA, including data on toxicity, occurrence, and physicochemical properties. We then present the results of each MCDA, which show a relative ranking of chemicals based on integration of these data. Lastly, we discuss the key limitations of this MCDA approach, which is intended as a preliminary analysis only.

9.6.5.1 Results: Noncancer MCDA for Chemicals Used in Hydraulic Fracturing Fluids

A total of 42 chemicals used in hydraulic fracturing fluids were evaluated in a noncancer MCDA (Table 9-12). Chronic oral RfVs within this suite of chemicals range from 0.001–20 mg/kg-day, with (E)-crotonaldehyde having the lowest chronic oral RfV and 1,2-propylene glycol having the highest. These RfVs were derived based on health effects including immune system effects, changes in body weight, changes in blood chemistry, cardiotoxicity, neurotoxicity, liver and kidney toxicity, and reproductive and developmental toxicity. The total UFs used in the derivation of these chronic oral RfVs (Table 9-12) reflect varying degrees of confidence surrounding the data sets for these chemicals. Three of the chemicals with the lowest chronic oral RfVs [(E)-crotonaldehyde, propargyl alcohol, benzyl chloride] have total UFs of 3000, indicating a relatively large amount of uncertainty in these values. Comparatively, chemicals such as benzene, acrylamide, and dichloromethane also have low chronic oral RfVs, but with much less uncertainty reflected in the values.

Figure 9-8 presents the results of a noncancer MCDA for these 42 chemicals in hydraulic fracturing fluids. Of these 42 chemicals, propargyl alcohol received the highest overall Total Hazard Potential Score. Propargyl alcohol was reported in 33% of disclosures nationally in the EPA FracFocus 1.0 project database, making it one of the most widely used chemicals that was considered in this analysis. It has physicochemical properties that are conducive to transport in water, and a low RfV. Given these properties, propargyl alcohol received the highest overall ranking based on hazard potential across all of the metrics that were considered in the MCDA.

Several of the other chemicals that received high Occurrence Scores also received among the highest Total Hazard Potential Scores, including 2-butoxyethanol, naphthalene, 1,2,4-trimethylbenzene, N,N-dimethylformamide, and formaldehyde (reported in 23%, 19%, 13%, 9%, and 7% of disclosures, respectively). Methanol, ethylene glycol, and formic acid (73%, 47%, and 11% of disclosures, respectively) received lower Total Hazard Potential Scores as a result of having higher RfVs. Likewise, didecyldimethylammonium chloride and dodecylbenzenesulfonic acid (8% and 7% of disclosures, respectively) received lower Total Hazard Potential Scores as a result of having higher RfVs and more hydrophobic properties.

The other chemicals that received high Toxicity Scores (i.e., had low chronic oral RfVs) received moderate to high Total Hazard Potential Scores overall. Acrylamide was reported in only 1% of disclosures, but has physicochemical properties that are very conducive to transport in water, and therefore received one of the highest overall Total Hazard Potential Scores. 1,2,4-Trimethylbenzene, benzyl chloride, and epichlorohydrin (13%, 6%, and 1% of disclosures in the EPA FracFocus 1.0 project database, respectively) scored slightly lower than acrylamide with regards to physicochemical properties. Other chemicals, including 1,2,3-trimethylbenzene, 1,3,5-trimethylbenzene, (E)-crotonaldehyde, benzene, dichloromethane, aniline, furfural, and 2-(Thiocyanomethylthio)benzothiazole, received lower overall scores because they are used more infrequently (the trimethylbenzenes were reported in <1% of disclosures, and the rest reported in <0.1% of disclosures).

9.6.5.2 Results: Noncancer MCDA for Chemicals Used in Hydraulic Fracturing Fluids (State-specific analysis for Texas, Pennsylvania, and North Dakota)

To investigate the extent of regional differences and examine the applicability of the MCDA model at the regional scale, we repeated the noncancer MCDA for hydraulic fracturing fluids for subsets of chemicals used in three representative states that have a significant amount of hydraulic fracturing activity: Texas, Pennsylvania, and North Dakota. The chemicals used in these state-specific analyses are subsets of the chemicals used nationally, and are indicated in Table 9-12. Some of the chemicals considered in the national analysis were not included in the state-specific analyses because they were not disclosed to FracFocus 1.0 as used in these states.

Results are presented in Figure 9-9 (Texas), Figure 9-10 (Pennsylvania), and Figure 9-11 (North Dakota). By comparing these results to each other and to the national noncancer MCDA (Figure 9-8), it is evident that there are some regional differences in the Total Hazard Potential Scores, although many chemicals were commonly used and received similar overall rankings.

Methanol, ethylene glycol, and 2-butoxyethanol were among the most frequently reported chemicals in all three state-specific analyses, while other chemicals differed distinctly between states. For instance, propargyl alcohol was frequently reported in Texas (39% of disclosures) and Pennsylvania (58% of disclosures), but not North Dakota (1% of disclosures). Likewise, naphthalene was reported frequently in Texas (14% of disclosures) and North Dakota (43% of disclosures), but not in Pennsylvania (1% of disclosures). The most toxic chemicals (occurring in the lowest quartile of chronic oral RfVs) common among all three states include propargyl alcohol, benzyl chloride, acrylamide, and 1,2,4-trimethylbenzene. Other chemicals receiving high Toxicity Scores in these states include epichlorohydrine (Texas and Pennsylvania), 1,3,5-Trimethylbenzene (Texas and Pennsylvania), 1,4-dioxane (North Dakota), naphthalene (North Dakota), benzene, aniline, and 1,2,3-Trimethylbenzene (Texas).

Overall, in Texas, propargyl alcohol received the highest possible Total Hazard Potential Score, with acrylamide receiving the second highest score. In Pennsylvania, propargyl alcohol also received the highest possible Total Hazard Potential Score, with 2-butoxyethanol receiving the second highest score. In North Dakota, 2-butoxyethanol received the highest Total Hazard Potential Score, with naphthalene receiving the second highest score.

The results of these state-specific MCDAs support the concept presented in Chapter 5 that there is no single hydraulic fracturing fluid formulation, and that the chemicals of most potential concern will vary between regions or even between wells.

Table 9-12. Data on the selected subset of chemicals in hydraulic fracturing fluids used for input into a noncancer MCDA.
Chemicals within the table are ordered from most toxic to least toxic based on chronic oral RfV.

CASRN = Chemical Abstract Service Registry Number; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer Reviewed Toxicity Values; ATSDR = Agency for Toxic Substances and Disease Registry; HHBP = Human Health Benchmarks for Pesticides; K_{OW} = octanol-water partitioning coefficient; K_{OC} = soil adsorption coefficient

[a] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in the MCDA include chronic oral reference doses (RfD) from IRIS, PPRTV, and HHBP; and chronic oral minimal risk levels (MRLs) from ATSDR.

[b] The FracFocus frequency of use data presented in this chapter is based on 35,957 FracFocus disclosures that were deduplicated, within the study time period (January 1, 2011 to February 28, 2013), and with ingredients that have a valid CASRN.

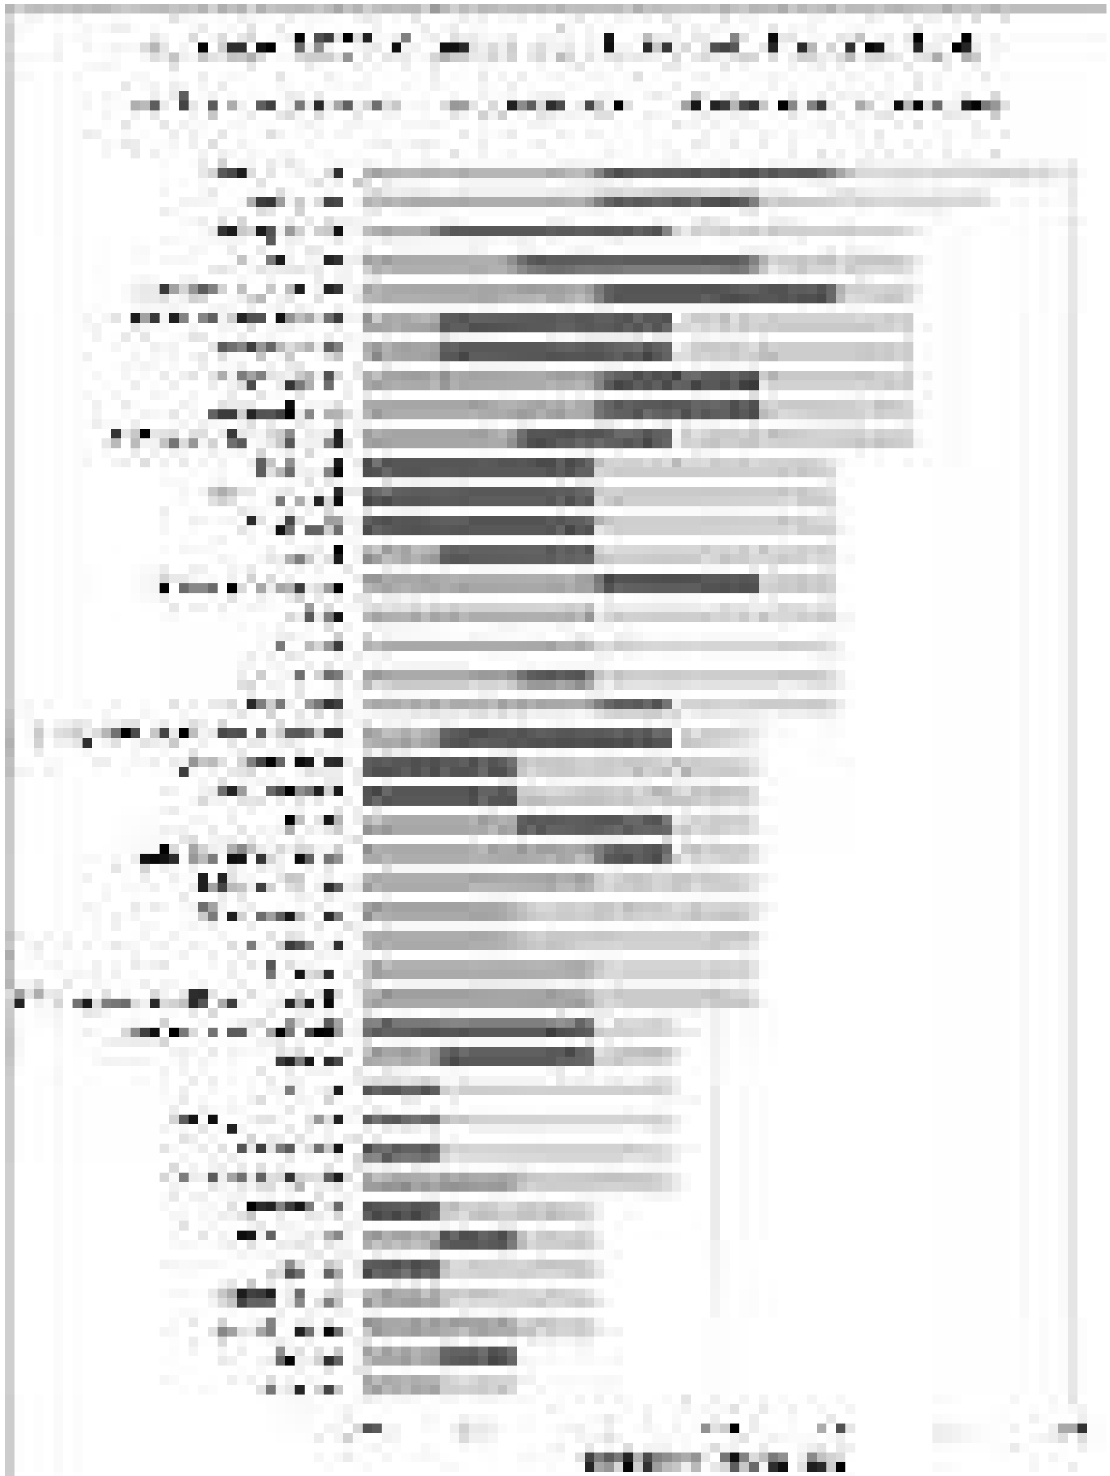

Figure 9-8. Noncancer MCDA results for 42 chemicals used in hydraulic fracturing fluids (national analysis), showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

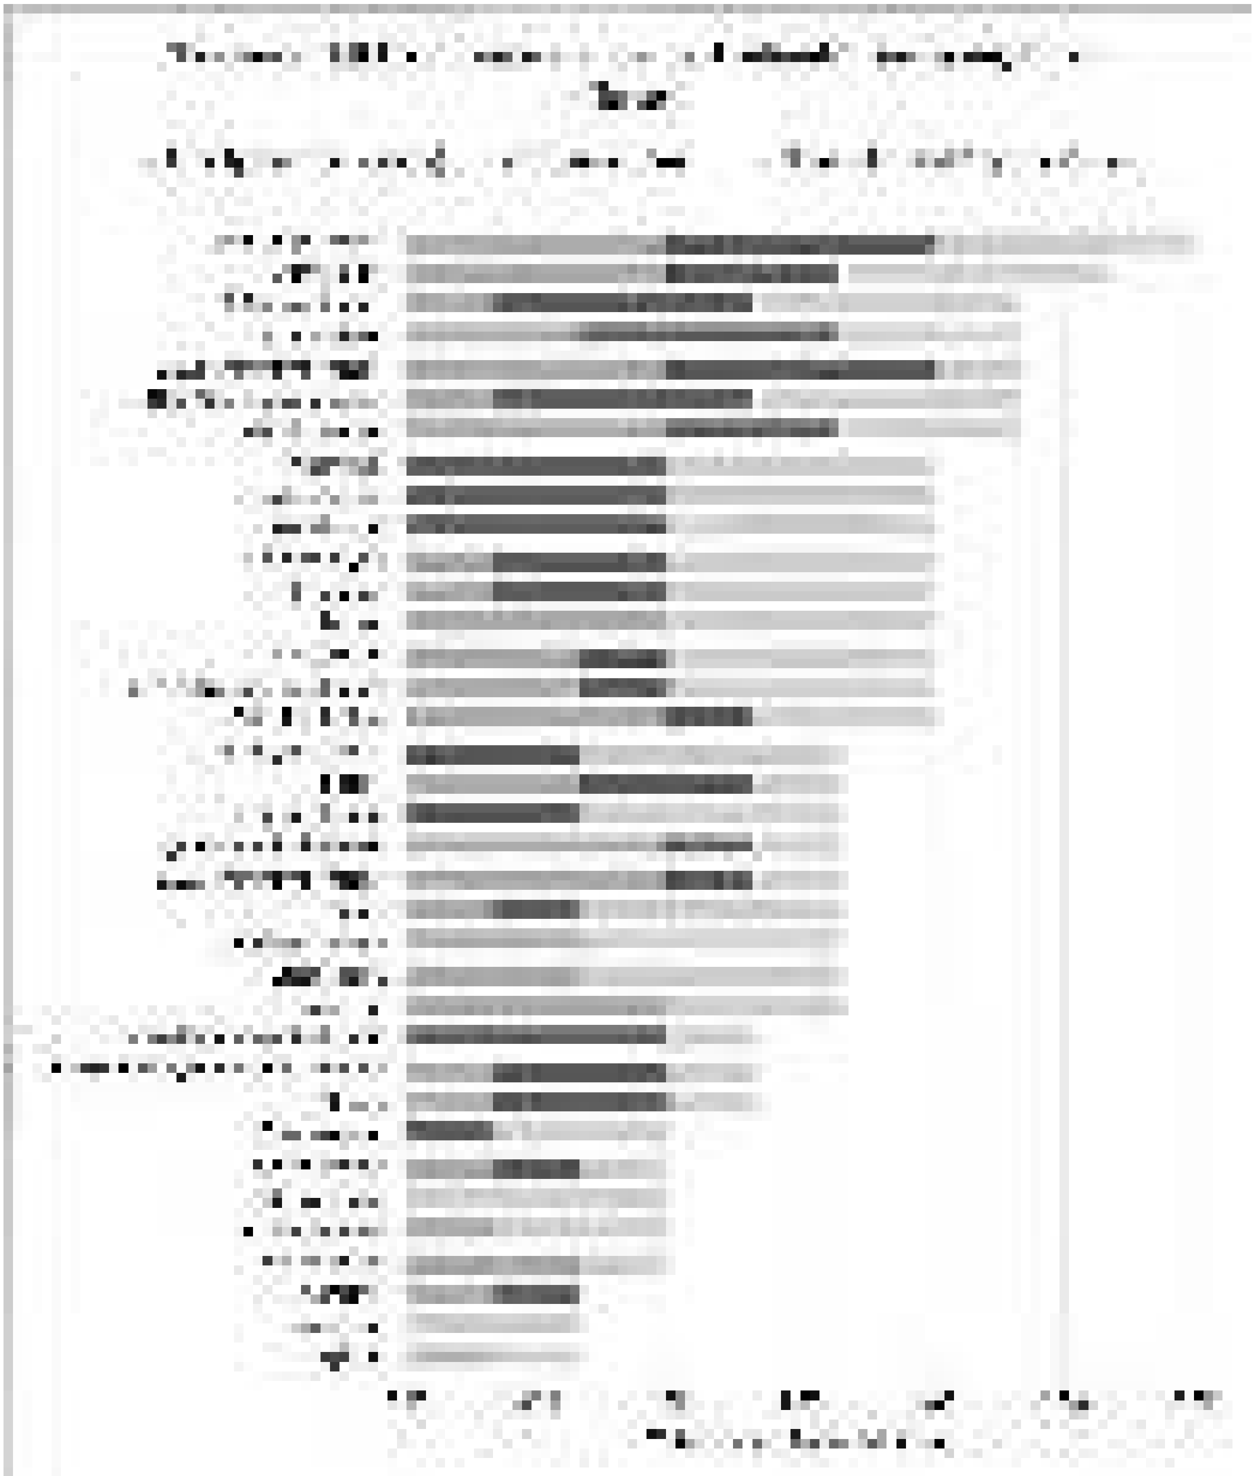

Figure 9-9. Noncancer MCDA results for 36 chemicals used in hydraulic fracturing fluids in Texas (state-specific analysis), showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

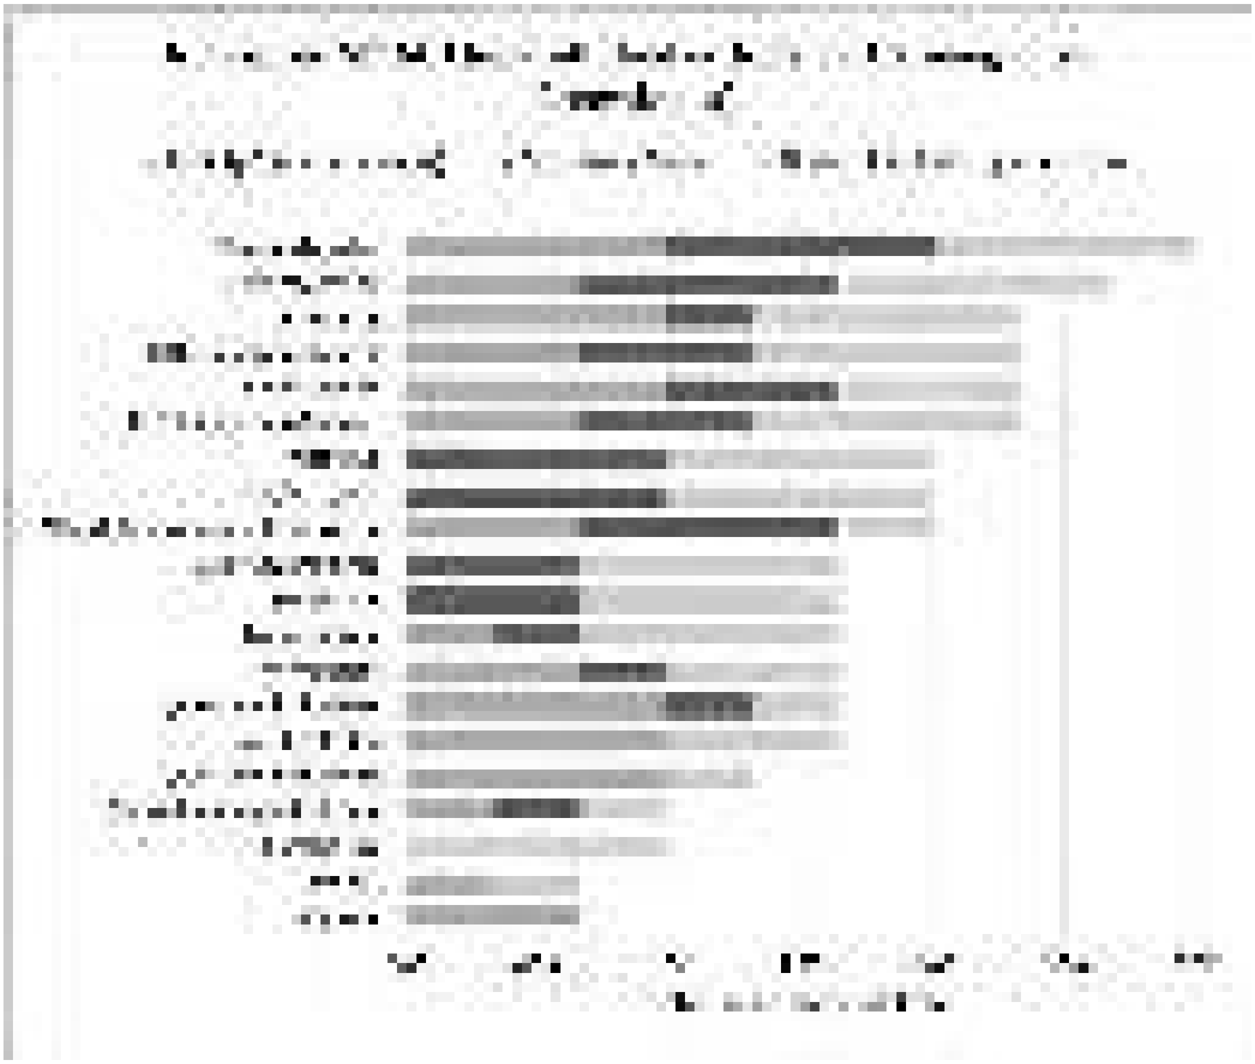

Figure 9-10. Noncancer MCDA results for 20 chemicals used in hydraulic fracturing fluids in Pennsylvania (state-specific analysis), showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

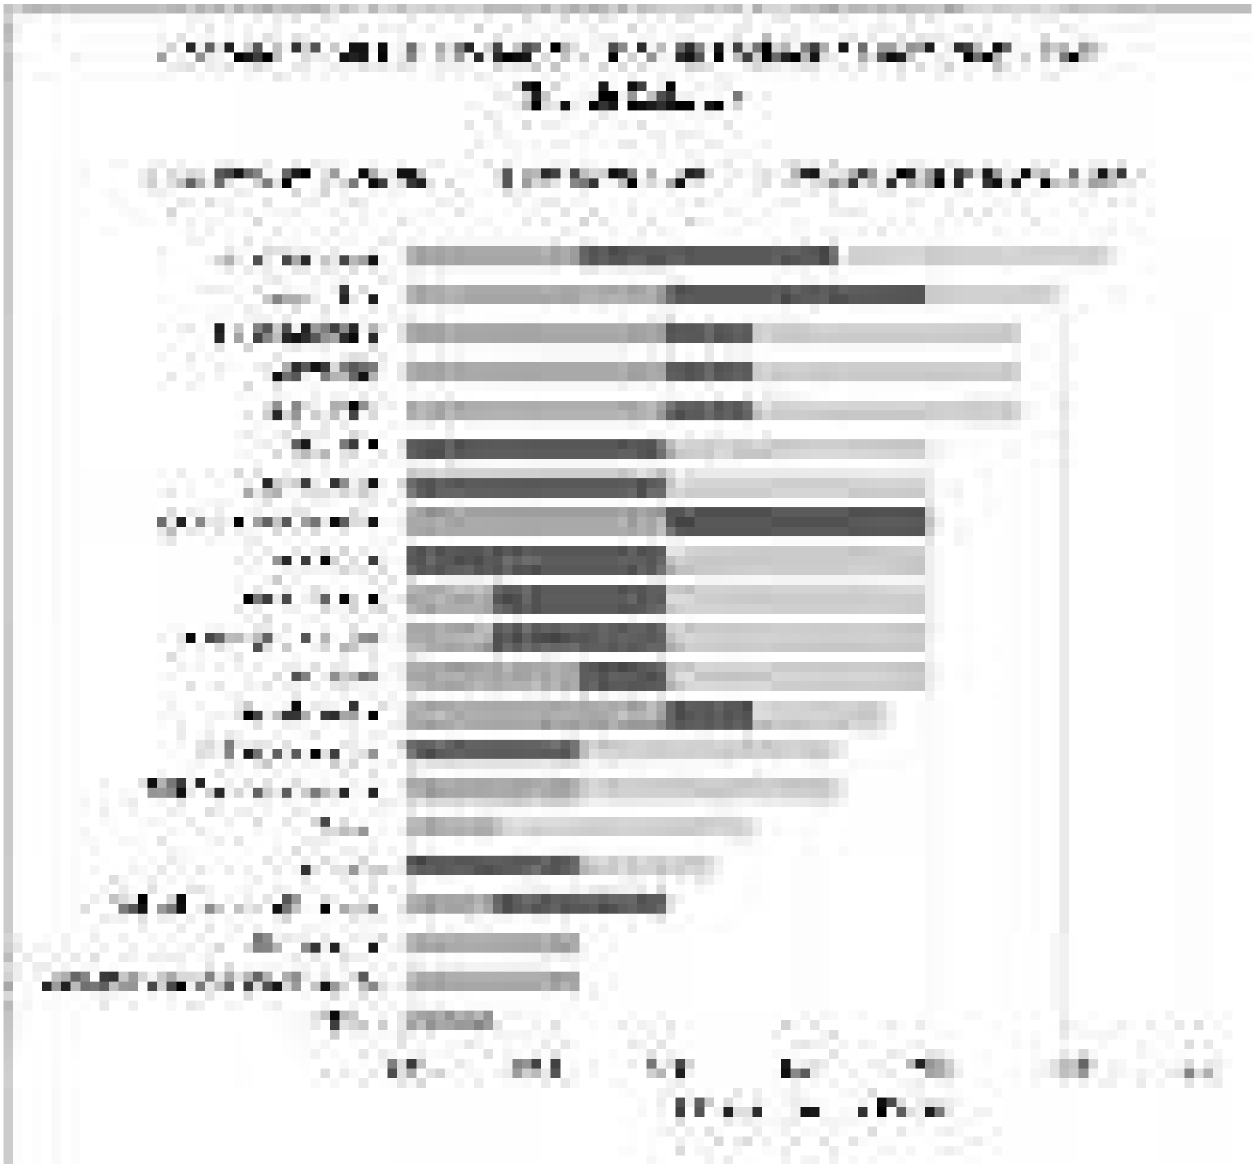

Figure 9-11. Noncancer MCDA results for 21 chemicals used in hydraulic fracturing fluids in North Dakota (state-specific analysis), showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

9.6.5.3 Results: Cancer MCDA for Chemicals Used in Hydraulic Fracturing Fluids

A total of 10 chemicals used in hydraulic fracturing fluids were evaluated in a cancer MCDA (Table 9-13). OSFs for these chemicals ranged from 0.002 to 3 per mg/kg-day, with quinoline having the highest OSF, and dichloromethane having the lowest. Benzene is the only one of these chemicals that is classified as a known human carcinogen by at least one of the sources in Table 9-1, while the other chemicals in this subset are classified as probable carcinogens in humans (Appendix Table G-1e).

Figure 9-12 presents the results from the cancer MCDA for chemicals used in hydraulic fracturing fluids. Of the 10 chemicals that were considered in this analysis, acrylamide received the highest Total Hazard Potential Score. Acrylamide has an OSF of 0.5 per mg/kg-day, which is one of the higher OSFs in this suite of chemicals, and has physicochemical properties that are highly conducive to transport in water. Acrylamide was reported in 1% of disclosures nationally in the EPA FracFocus 1.0 project database. This nevertheless places acrylamide in the top quartile in terms of frequency of use, as none of the chemicals within this subset were used with great frequency on a national basis.

Bis(2-chloroethyl)ether and quinoline, which are the two most potent carcinogens considered in the analysis and received high Toxicity Score, received the second and third highest Total Hazard Potential Scores within this suite of chemicals. Bis(2-chloroethyl)ether was reported in 0.7% of disclosures, while quinoline was reported in 0.02% of disclosures. Both are expected to be readily transported in water.

In addition to acrylamide, the other two chemicals receiving high Occurrence Scores were benzyl chloride and epichlorohydrin (6% and 1% of disclosures, respectively). These two chemicals both received moderate Total Hazard Potential Scores. Benzyl chloride has an OSF of 0.17 per mg/kg-day, while epichlorohydrine has an OSF of 0.0099 per mg/kg-day. Both received lower Physicochemical Properties Scores relative to other chemicals in this analysis, due in part to volatility.

Table 9-13. Data on the selected subset of chemicals in hydraulic fracturing fluids used for input into a cancer MCDA.
Chemicals within the table are ordered from most potent to least potent based on OSF.

CASRN = Chemical Abstract Service Registry Number; IRIS = Integrated Risk Information System; K_{OW} = octanol-water partitioning coefficient; K_{OC} = soil adsorption coefficient

[a] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in the MCDA include values from IRIS, PPRTV, and HHBP.

[b] The FracFocus frequency of use data presented in this chapter is based on 35,957 FracFocus disclosures that were deduplicated, within the study time period (January 1, 2011 to February 28, 2013), and with ingredients that have a valid CASRN.

[c] IRIS lists the OSF for benzene as a range from 0.015 to 0.055 per mg/kg-day. For input into the MCDA, we used the high end of this range (0.055 per mg/kg-day).

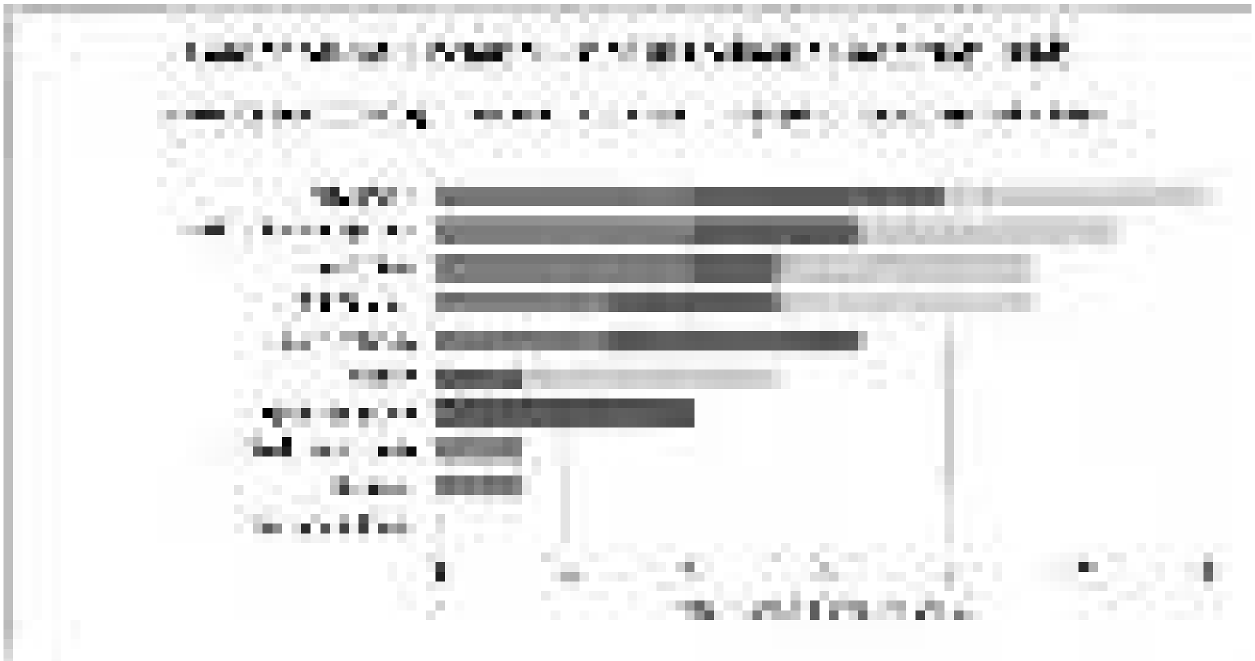

Figure 9-12. Cancer MCDA results for 10 chemicals used in hydraulic fracturing fluids, showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

9.6.5.4 Results: Noncancer MCDA for Chemicals in Produced Water

A total of 29 chemicals detected in produced water were evaluated in a noncancer MCDA (Table 9-14). Of these 29 chemicals, 13 were also included in the noncancer MCDA for hydraulic fracturing fluids. Chronic oral RfVs within this suite of chemicals range from 0.001 to 0.9 mg/kg-day, with pyridine having the lowest chronic oral RfV, and acetone having the highest. Chronic oral exposure to these chemicals may induce a variety of adverse outcomes, including immune system effects, changes in body weight, changes in blood chemistry, pulmonary toxicity, neurotoxicity, liver and kidney toxicity, and reproductive and developmental toxicity. The total UFs used in the derivation of these chronic oral RfVs (Table 9-14) reflect varying degrees of confidence surrounding the data sets for these chemicals.

Figure 9-13 presents the results of a noncancer MCDA for these 29 chemicals detected in produced water. Benzene, pyridine, and naphthalene received the highest Total Hazard Potential Scores, followed by 2-methylnaphthalene. These four chemicals all received high Toxicity Scores and high Occurrence Scores (with maximum average concentrations of 1500 μg/L, 413 μg/L, 238 μg/L, and 1362 μg/L in Barnett, Marcellus, or Powder River Basin produced water, respectively), but received moderate to low Physicochemical Property Scores.

Table 9-14. Data on the selected subset of chemicals detected in produced water used for input into a noncancer MCDA.
Chemicals within the table are ordered from most toxic to least toxic based on chronic oral RfV.

[a] Reference value (RfV): An estimate of an exposure for a given duration to the human population (including susceptible subgroups) that is likely to be without an appreciable risk of adverse health effects over a lifetime. RfVs considered in the MCDA include chronic oral reference doses (RfD) from IRIS, PPRTV, and HHBP; and chronic oral minimal risk levels (MRLs) from ATSDR.

[b] From Appendix E.

[c] Di(2-ethylhexyl) phthalate is listed under the name bis(2-ethylhexyl) phthalate in Appendix Table E-11.

[d] Chlorobenzene is listed under the name chloro-benzene in Appendix Table E-13.

[e] o-Cresol is listed under the name 2-methylphenol in Appendix Table E-11.

[f] Cumene is listed under the name isopropylbenzene in Appendix Table E-11.

[g] Dibutyl phthalate is listed under the name dibutyl-n-phthalate in Appendix Table E-11.

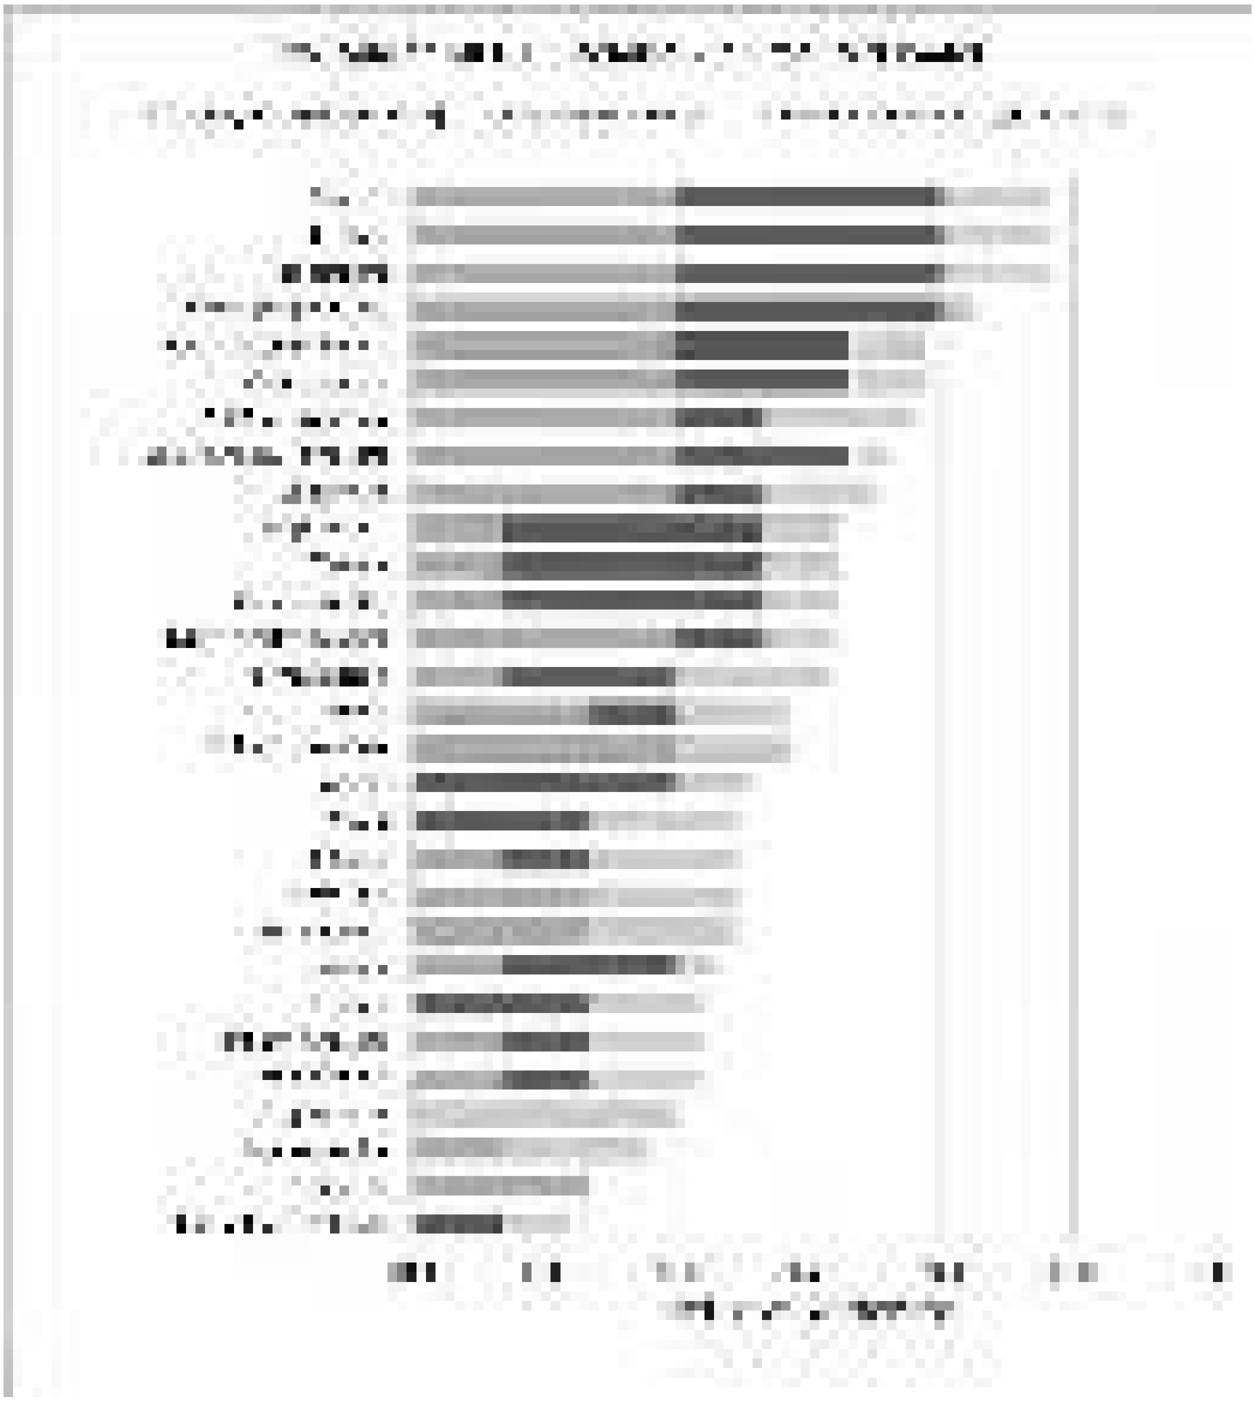

Figure 9-13. Noncancer MCDA results for a subset of 29 chemicals detected in produced water, showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.

Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

The other chemicals that received high Toxicity Scores were 1,2,4-trimethylbenzene, 1,3,5-trimethylbenzene, chloroform, 2,4,-dimethylphenol, tributyl phosphate, di(2-ethylhexyl) phthalate, and chlorobenzene. These chemicals received moderate Total Hazard Potential Scores, as all were detected at lower concentrations compared to other chemicals considered in this analysis and are expected to have moderate transport in water.

The other chemicals that received high Occurrence Scores are ethylbenzene, toluene, xylenes, and carbon disulfide, which were detected at maximum average concentrations of 2010 µg/L, 760 µg/L, 360 µg/L, and 400 µg/L in Barnett, Marcellus, or Powder River Basin produced water. These chemicals received moderate Total Hazard Potential Scores, as all have as all have higher chronic oral RfVs relative to many of the other chemicals in the hazard evaluation, and are all expected to have moderate transport in water relative to the other chemicals.

9.6.5.5 Results: Cancer MCDA for Chemicals in Produced Water

A total of 7 chemicals reported in produced water were evaluated in a cancer MCDA (Table 9-15). OSFs within this suite of chemicals ranged from 7.3 to 0.0049 per mg/kg-day, with benzo(a)pyrene having the highest OSF and N-nitrosodiphenylamine having the lowest. Of these 7 chemicals, benzene and 1,4-dioxane were also included in the cancer MCDA for chemicals used in hydraulic fracturing fluids. Benzene and benzo(a)pyrene are both classified by at least one of the sources in Table 9-1 as a known human carcinogen, while the other chemicals as classified as likely or probable carcinogens in humans (Appendix G: Tables G-1e and G-2e).

Figure 9-14 presents the results of a cancer MCDA for these 7 chemicals in hydraulic fracturing fluids. Benzene and benzo(a)pyrene tied for highest Total Hazard Potential Scores. Of these, benzene was detected at the highest average concentrations in produced water (1500 µg/L in Power River Basin produced water), while benzo(a)pyrene were detected at lower average concentrations (6.7 µg/L in Barnett shale produced water). Benzo(a)pyrine and 1,2-diphenylhydrazine were the most potent carcinogens within this suite of chemicals and received high Toxicity Scores.

The other chemical that received a high Occurrence Score was di(2-ethylhexyl) phthalate, which was detected at an average concentration of 210 µg/L in Barnett Shale produced water. It received a moderate Total Hazard Potential Score because it is hydrophobic and not expected to be readily transported in water.

Table 9-15. Data on the selected subset of chemicals detected in produced water used for input into a cancer MCDA.
Chemicals within the table are ordered from most potent to least potent based on OSF.

		Cancer-specific toxicity (OSF)[a]		Occurrence (concentration in produced water)[b]		Mobility			Volatility	Persistence

CASRN = Chemical Abstract Service Registry Number; IRIS = Integrated Risk Information System; PPRTV = Provisional Peer-Reviewed Toxicity Values; K_{OW} = octanol-water partitioning coefficient; K_{OC} = soil adsorption coefficient

[a] Oral slope factor (OSF): An upper-bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime oral exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per mg/kg-day, is generally reserved for use in the low dose region of the dose response relationship, that is, for exposures corresponding to risks less than 1 in 100. OSFs considered in the MCDA include values from IRIS, PPRTV, and HHBP.

[b] From Appendix E.

[c] IRIS lists the OSF for benzene as a range from 0.015 to 0.055 per mg/kg-day. For input into the MCDA, we used the high end of this range (0.055 per mg/kg-day).

[d] Di(2-ethylhexyl) phthalate is listed under the name bis(2-ethylhexyl) phthalate in Appendix Table E-11.

Figure 9-14. Cancer MCDA results for 7 chemicals detected in produced water, showing the Toxicity Score, Occurrence Score, and Physicochemical Properties Score for each chemical.
Chemicals are ordered from high to low based on Total Hazard Potential Score. See Section 9.6.4 for details on the calculation.

9.6.6 Limitations and Uncertainty of the MCDA Framework

While this MCDA framework provides a simple and transparent tool for exploring the relative hazard potential of chemicals in the hydraulic fracturing water cycle, it is intended only as a preliminary analysis. It is important to acknowledge the limitations of this analysis, as well as the limitations of the parameters that were used for input in the MCDA.

Chronic oral RfVs and OSFs were selected for the MCDA because they are a primary focus of the toxicological evaluation presented in this chapter. We were interested in placing these values in the context of variables that may impact the likelihood of human exposure. These toxicity values were available for a relatively small fraction of chemicals on EPA's list, which limited the number of chemicals considered in the MCDA.

The FracFocus 1.0 data used in the MCDA does not represent a complete record of hydraulic fracturing chemical usage in the United States, as described in more detail in Chapter 5 and in Section 9.3.1. Frequency of use also does not reflect the volume or concentration of chemical usage, and therefore is an incomplete metric for potential exposure. The EPA FracFocus 1.0 project database provides data on the maximum concentration of chemicals in additives and in hydraulic fracturing fluid, as discussed in Section 5.4, but we elected not to use this data in the MCDA because reported concentrations for each chemical varied widely between disclosures (see Table 5-5 and volume estimates in Figure 5-5), making it difficult to determine a chemical concentration to use in an MCDA. Additionally, many chemicals in the EPA FracFocus 1.0 project database did not have valid concentration data; for instance, the maximum concentrations of a chemical in additive often added up to greater than 100%. We therefore elected to focus on frequency of use as a general metric of chemical occurrence in the hydraulic fracturing water cycle.

The produced water concentrations used in the MCDA are based on the compilation of data presented in Appendix E. While this data reflects the findings of recent studies, it does not represent a complete record of chemicals present in produced water, as described in more detail in Chapter 7 and in Section 9.3.2. Concentrations in produced water also do not necessarily reflect the concentrations in treated wastewater, drinking water wells, or residuals in soil or sediment. Concentrations of these chemicals in treated wastewater or well water would likely be more dilute compared to concentrations in produced water. Concentrations in soils or sediments may be higher, particularly for hydrophobic chemicals.

The physicochemical properties from EPI Suite used in the MCDA are useful for making comparison across chemicals, but these values are also subject to uncertainty. Many of the values used in the MCDA were estimated by EPI Suite, and therefore are subject to the inherent limitations of the EPI Suite model (Section 5.8). Chemical fate and transport will be also influenced by environmental and site-specific conditions, which are outside the scope of this analysis. For instance, the half-lives used to develop the Physicochemical Properties Score are estimated values that assume aerobic conditions, and thus may underestimate the expected half-life under anaerobic conditions (e.g., in a groundwater contaminant plume). If chemicals are present in a mixture, as inevitably occurs in hydraulic fracturing fluids and in the subsurface environment, fate and transport will be influenced by changes in solubility or degradation resulting from interactions with other chemicals.

There are also fundamental limitations with regards to the scope of the MCDA. The chemicals used in these analyses may not be representative of chemicals at a specific field site. The analysis only examined organic chemicals, as EPI Suite is not able to estimate physicochemical properties of inorganic chemicals. Additionally, the physicochemical properties used in the MCDA were chosen specifically to reflect chemical transport in water, and therefore do not highlight the potential hazards of hydrophobic or volatile chemicals. Hydrophobic chemicals may serve as long-term sources of pollution by sorbing to soils or sediments at contaminated sites, and volatile chemicals may be hazardous when inhaled. This analysis also does not attempt to address bioavailability or toxicokinetics, which may be influenced by physicochemical properties such as log K_{ow}. For instance, chemicals with log K_{ow} of 2-4 tend to absorb well through biological membranes, while chemicals with log K_{ow} > 4 tend not to absorb well, and those with log K_{ow} of 5-7 tend to bioconcentrate (U.S. EPA, 2012i).

9.6.7 Application of the MCDA Framework for Preliminary Hazard Evaluation

The MCDA framework presented here is intended as a preliminary analysis, and illustrates one possible method for integrating data to explore potential hazards. By combining multiple lines of data, we can stratify chemicals according to estimated hazard potential, and gain preliminary insight into those chemicals that may be of more concern than others to drinking water resources.

Researchers may find this approach useful in their efforts to explore the potential hazards of chemicals present at specific field sites, particularly in instances when exposure assessment data is not available. The MCDA framework is flexible, and could be adapted to incorporate site-specific data on chemical usage, different types of toxicity data, as well as other variables that may be of interest for risk assessment. For instance, rather than focusing on RfVs and OSFs from US federal sources, one could choose to derive the Toxicity Score using other sources of relevant toxicity information. Additionally, one could choose to perform this analysis using different physicochemical property inputs, to highlight chemical interactions with different environmental media (e.g., hydrophobic or volatile chemicals). Researchers could also choose to apply different weights to each of the three criteria considered in this analysis (toxicity, occurrence, physicochemical properties), to reflect expert judgement of each variable's relative importance.

9.7 Synthesis

The overall objective of this chapter was to identify and provide information on the toxicological properties of chemicals used in hydraulic fracturing and of hydraulic fracturing wastewater constituents, and to evaluate the potential hazards of these chemicals for drinking water resources. Toward this end, the EPA developed a list of 1,606 chemicals that are reported to be associated with hydraulic fracturing, separating them into subsets based on whether they were reported to have been used in hydraulic fracturing fluids (1,084 chemicals total) or detected in produced water (599 chemicals total). To evaluate the potential hazards of these chemicals, the EPA compiled chronic oral RfVs, OSFs, and qualitative cancer classifications from selected federal, state, and international sources that met the EPA's criteria for consideration in this assessment. This toxicological information was used to conduct an initial identification of the potential human health hazards associated with several subsets of chemicals identified as being of particular interest in previous chapters of this report. Finally, in order to illustrate how data integration could be used to explore potential hazards, an MCDA framework was used to evaluate selected subsets of chemicals based on toxicity, environmental occurrence, and physicochemical properties affecting chemical transport in water.

9.7.1 Summary of Findings

A major finding of this chapter was that chronic oral RfVs and OSFs were not available for the majority of chemicals that the EPA has identified as being associated with hydraulic fracturing activity, indicating that the majority of these chemicals have not undergone significant toxicological evaluation. Similarly, there have been several recent peer-reviewed studies that have attempted to gather toxicological information for subsets of chemicals that are used in hydraulic fracturing fluids, and they have found that many of these chemicals do not have toxicity values available (Elliott et al., 2016; Wattenberg et al., 2015; Stringfellow et al., 2014; Colborn et al., 2011). Taken together, this suggests a potentially significant knowledge gap exists with respect to the scientific community's understanding of the potential human health impacts of these chemicals. With the limited availability of toxicity values, risk assessment is difficult, and potential impacts on drinking water resources may not be assessed adequately. This lack of toxicity values is not unique to the hydraulic fracturing industry; in fact, it has been estimated that there are tens of thousands of chemicals in commercial use that have not undergone significant toxicological evaluation (Judson et al., 2009).

There are a variety of chemicals associated with hydraulic fracturing known to be hazardous to human health. Chronic oral RfVs or OSFs from the sources considered by the EPA in this assessment were available for 98 (9%) of the 1,084 chemicals used in hydraulic fracturing fluids, and 120 (20%) of the 599 chemicals detected in hydraulic fracturing produced water. Potential hazards associated with chronic oral exposure to these chemicals include carcinogenesis, immune system effects, changes in body weight, changes in blood chemistry, cardiotoxicity, neurotoxicity, liver and kidney toxicity, and reproductive and developmental toxicity. Methane is not considered to be toxic when ingested, but may accumulate to explosive levels or act as an asphyxiant. DBPs formed during wastewater treatment can contribute to an increased risk of cancer, anemia, liver and kidney effects, and central nervous system effects, with brominated forms of DBPs considered to be more cytotoxic, genotoxic, and carcinogenic than chlorinated species.

To assess the toxicity of chemicals that lack chronic oral RfVs and OSF, risk assessors will need to turn towards alternative data sources. This chapter explored two alternative data sources that may provide useful information. QSAR-based toxicity estimates—specifically, rat chronic oral LOAEL estimates generated using TOPKAT—were available for many of the chemicals that lacked chronic oral RfVs and OSFs from the sources considered in this assessment, and may be used to rank chemicals based on toxicity when other data are not available. Additionally, many of these chemicals have information available on the EPA's ACToR database, which is an online data warehouse designed to consolidate large and disparate amounts of chemical data. The information available in the ACToR data warehouse ranges from the selected RfVs and OSFs discussed in this assessment, which have undergone extensive peer review, to toxicological data that have undergone little-to-no peer review.

When considering the potential impact of chemicals on drinking water resources and human health, it is important to consider exposure as well as toxicological properties. As discussed in previous chapters of this report and highlighted in this chapter, events such as spills, leaks from storage pits, and discharge of inadequately treated wastewater have led to the entry of hydraulic fracturing-related chemicals into drinking water resources. In some instances, chemical concentrations in surface water or groundwater were in exceedance of MCLs, indicating their presence at levels that could impact human health. While these studies demonstrate the potential entry of these chemicals into drinking water resources, there is a lack of systematic studies examining actual human exposures to these chemicals in drinking water as a result of hydraulic fracturing activity.

In the absence of exposure assessment data, the MCDA framework presented in this chapter provides a preliminary analysis of the relative hazard potential of these chemicals. In this context, occurrence and physicochemical property data were used as metrics to estimate the likelihood that a chemical could reach and impact drinking water, and toxicity data was used as a metric for the potential severity of an impact. This analysis highlighted several chemicals that may be more likely than others to reach drinking water and create a toxicological hazard. Of the chemicals used in hydraulic fracturing fluids that were considered in this analysis, chemicals such as propargyl alcohol stood out as having high potential toxicity, high frequency of use, and physicochemical properties that are conducive to transport in water. Of the chemicals in produced water, chemicals such as benzene, pyridine, 2-methylnaphthalene, and naphthalene stood out as having high potential toxicity, high concentrations in produced water, and physicochemical properties that are conducive to transport in water.

9.7.2 Factors Affecting the Frequency or Severity of Impacts

There are multiple pieces of information that could be taken into account when evaluating the frequency and severity of impacts that these chemicals may have on drinking water resources. This includes knowledge of the chemicals used at a given site, the toxicological and physicochemical properties of these chemicals, the amount of fluid being used and recovered, the likelihood of mechanical integrity failures, the likelihood of spills and other unintentional releases, and the efficiency of chemical removal during wastewater treatment. The MCDA presented in this chapter incorporated parameters that may impact the likelihood of chemical exposure, including frequency of use, measured concentration, and transport in water, and was used to stratify and rank chemicals based on relative hazard potential. However, it should be considered only as a preliminary analysis, and should not be used in place of local data on the concentrations and volumes of chemicals in areas of hydraulic fracturing activity.

Analysis of the chemicals used in hydraulic fracturing fluids indicated that the majority of chemicals on the EPA's list are used in <1% of wells nationally (Figure 9-4). Therefore, potential exposure to the majority of these chemicals is more likely to be a local issue, rather than a national one. Given that the analysis of the EPA FracFocus 1.0 project database presented in this chapter was based on 35,957 disclosures, a chemical used in <1% of wells nationally could still be used in several hundred wells. Chemicals used infrequently on a national basis could still be used more frequently within certain areas or counties, increasing the potential for local exposure to that chemical.

As an example of how an infrequently used chemical could have local impacts, consider (E)-crotonaldehyde, which had one of the lowest chronic oral RfVs among the chemicals considered in the noncancer MCDA for hydraulic fracturing chemicals, and was reported in approximately 0.06% of disclosures in the EPA FracFocus 1.0 project database. If the EPA FracFocus 1.0 project database is a representative sample of all of the wells across the country, then the likelihood of (E)-crotonaldehyde contamination on a national scale is limited. However, this in no way diminishes the likelihood or potential severity of (E)-crotonaldehyde contamination at sites where this chemical is used.

This is in contrast with frequently used chemicals such as methanol. Methanol was reported in 73% of wells in the EPA FracFocus 1.0 project database, and was the most frequently used chemical considered in the noncancer MCDA for chemicals used in hydraulic fracturing fluids. Methanol is soluble and relatively mobile in water, but has a higher chronic oral RfV compared other chemicals considered in this analysis. Therefore, methanol may be expected to have a higher exposure potential on a national basis compared to other chemicals, with a moderate hazard potential due to its relatively high RfV.

Even if no chemicals were added to hydraulic fracturing fluids, there is still a potential for impacts from constituents naturally present in the subsurface which could be brought to the surface in produced water. As described in Section 9.5, many of the naturally occurring chemicals in produced water—e.g., organic chemicals (e.g., BTEX and related hydrocarbons), metals, anions, and TENORM—are hazardous to human health and have been reported in drinking water resources as a result of hydraulic fracturing activity, sometimes at concentrations exceeding MCLs. The constituents of produced water that contribute to the formation of DBPs, specifically bromide, chloride, iodine, and ammonium, are naturally occurring and are characteristic of wastewater from hydraulically fractured wells.

Overall, contamination of drinking water resources depends on site-, chemical-, and fluid-specific factors (Goldstein et al., 2014), and the exact mixture and concentrations of chemicals at a site will depend upon the geology and the chemicals used in the oil and gas extraction processes. Therefore, potential hazard and risk considerations are best made on a site-specific, well-specific basis.

9.7.3 Uncertainties

There are notable uncertainties in the chemical and toxicological data limiting a comprehensive assessment of the potential health impacts of hydraulic fracturing on drinking water resources.

For human health risk assessment, a significant data gap is the lack of chronic oral RfVs and OSFs from sources meeting the EPA's criteria for inclusion in this report. For instance, of the 34 chemicals (excluding water, quartz, and sodium chloride) that were reported in ≥10% of disclosures in the EPA FracFocus 1.0 project database, 9 chemicals have chronic oral RfVs available, and none have OSFs (Table 9-2). Without reliable and peer reviewed toxicity values, comprehensive hazard evaluation and hazard identification of chemicals is difficult, and the ability to consider the potential cumulative effects of exposure to chemical mixtures in hydraulic fracturing fluid or produced water may be limited. Although there are other potential sources of toxicity information for many of these chemicals, some of it may be limited or of lesser quality. Consequently, potential impacts on drinking water resources and human health may not be assessed adequately.

An equally significant data gap is the lack of exposure assessment data for drinking water resources in areas of hydraulic fracturing activity. As discussed in Text Box 9-1, data on exposure potential is a critical component of the risk assessment process, and is necessary for risk characterization. In the absence of exposure assessment information, the MCDA framework presented in this chapter may be useful for exploring the potential hazards of hydraulic fracturing-related chemicals, but should be considered as a preliminary analysis only. The MCDA presented in this chapter considered only a small subset of chemicals that had data available, was limited in scope, and may not be representative of the chemicals that are present at a specific field site. It should be emphasized that this MCDA framework represents just one method that can be used to integrate chemical data for hazard evaluation, and is readily adaptable to include different variables, different weights for the variables, and site-specific considerations.

There is also uncertainty surrounding the EPA's list of chemicals associated with hydraulic fracturing activity. As discussed in Section 5.4 and Section 9.3.1, there is incomplete information available on chemicals used in hydraulic fracturing fluids due to industry use of CBI as well as incomplete reporting of chemical use. For instance, the EPA's analysis of the FracFocus 1.0 project database found that approximately 11% of ingredients were reported as CBI, and that more than 70% of FracFocus 1.0 disclosures contained at least one CBI ingredient. There may also be regional limitations in the disclosures submitted to FracFocus 1.0, as 78% of chemical disclosures in came from five states, and 47% were from Texas (U.S. EPA, 2015a). Despite these limitations, FracFocus remains the most complete source for tracking hydraulic fracturing chemical usage in the United States, and therefore was the best available source for the hazard evaluation in this chapter. Although the sources used to compile the chemical list represented the best available data at the time of this study, it is possible that some of these chemicals are no longer used at all, and many of these chemicals may only be used infrequently. Therefore, it may be possible that significantly fewer than 1,084 chemicals are currently used in abundance. As practices evolve, it is likely that chemicals are used or will be used that are not included on this chemical list. Having a better understanding of the chemicals and formulations, including those that are CBI, along with their frequency of use and volumes, would greatly benefit risk assessment and risk management decisions.

Additionally, the list of produced water chemicals identified in this chapter is almost certainly incomplete. As discussed in Chapter 7, chemicals and their metabolites may go undetected because they were not included in the analytical methodology, or because an analytical methodology was not available. Chemical analysis of produced water can also be challenging because high levels of dissolved solids in produced water and wastewater can interfere with chemical detection. As a result, there are likely chemicals of concern in produced water that have not been detected or reported, and are not included on the chemical list presented in this report.

9.7.4 Conclusions

The EPA identified 1,606 chemicals associated with the hydraulic fracturing water cycle, including 1,084 chemicals used in hydraulic fracturing fluids, and 599 chemicals detected in produced water. Toxicity-based chronic oral RfVs and/or OSFs from sources meeting selection criteria were not available for the majority (89%) of the chemicals on this total list. Thirty-seven percent of chemicals on the EPA's list that are used in hydraulic fracturing fluids lack data on their frequency of use. Current understanding of the chemical composition of produced water is constrained by analytical chemistry limitations and by the likelihood that chemical composition will vary between wells. A limited number of studies have detected these chemicals in surface water, groundwater, or well water near areas of hydraulic fracturing activity, suggesting the potential for human exposure; however, actual human exposures to these chemicals in drinking water resources has not been well characterized. Given the large number of chemicals used or detected in various stages of the hydraulic fracturing water cycle, as well as the large number of hydraulically fractured wells nationwide, this missing chemical information represents a significant data gap.

While it remains challenging to fully understand the toxicity and potential public health impacts of these chemicals for drinking water resources, the toxicological data, occurrence data, and physicochemical data compiled in this report provide a resource for assessing the potential hazards of chemicals in the hydraulic fracturing water cycle. The MCDA framework presented here illustrates one method for integrating these data for a preliminary hazard evaluation, which may be useful when exposure assessment data are not available. While the analysis in this chapter is constrained to the assessment of chemicals on a national scale, this approach is readily adaptable for use on a regional or site-specific basis.

This collection of data provides a tool to inform decisions about protection of drinking water resources. Stakeholders may use these results to prioritize chemicals for hazard assessment or for determining future research priorities. Industry may use this information to prioritize chemicals for replacement with less toxic, persistent, and mobile alternatives.

9.8 Annex

9.8.1 Calculation of Physicochemical Property Scores (MCDA Hazard Evaluation)

Section 9.6.3 describes how Physicochemical Properties Scores for the noncancer and cancer MCDAs were calculated based on three subcriteria which affect the likelihood that a chemical will be transported in water: mobility, volatility, and persistence. Calculation of these subcriteria scores was performed as described by Yost et al. (In Press), as follows:

9.8.1.1 Mobility Score

Chemical mobility in water was assessed based upon three physicochemical properties that describe chemical solvency in water: the octanol-water partition coefficient (K_{OW}), the soil adsorption coefficient (K_{OC}), and aqueous solubility. K_{OW} describes the partitioning of a chemical between water and a carbon-based media (octanol), while K_{OC} described the partitioning of a chemical between water and organic carbon in soil. K_{OW} and K_{OC} are generally represented on a logarithmic scale. Aqueous solubility is the maximum amount of a chemical that will dissolve in water in the presence of pure chemical. Chemicals with low K_{OW}, low K_{OC}, or high aqueous solubility are more likely to solubilize and move with water, and therefore were ranked as having greater potential to affect drinking water resources.

For input into the MCDA, we used experimentally measured values (provided in EPI Suite) whenever available. Otherwise, we used the following estimated values from EPI Suite: log K_{OW} estimated using the KOWWIN™ model, log K_{OC} estimated using the KOCWIN™ Sabljic molecular connectivity method, and aqueous solubility estimated using the WSKOWWIN™ model. Using the thresholds designated in Table 9-11, each of these properties was assigned a score of 1-4. The highest of these three scores (K_{OW}, K_{OC}, or solubility) was designated as the Mobility Score for each chemical.

9.8.1.2 Volatility Score

Chemical volatility was assessed based on the Henry's law constant, which is the ratio of the concentration of a chemical in air to the concentration of that chemical in water. Chemicals with low Henry's law constants are less likely to leave water via volatilization, and were therefore ranked as having greater potential to affect drinking water resources.

For input into the MCDA, we used experimentally measured values (provided in EPI Suite) whenever available. Otherwise, we used Henry's Law constants that were estimated using the EPI Suite HENRYWIN™ model, which generates values using two different methods (group contribution and bond contribution); the lower of these two estimated values was used as input into the MCDA.

Using the thresholds designated in Table 9-11, the Henry's law constant for each chemical was assigned a score of 1-4. This value was designated as the Volatility Score for each chemical.

9.8.1.3 Persistence Score

Chemical persistence was assessed based on estimated half-life in water, which describes how long a chemical will persist in water before it is transformed or degraded. Chemicals with longer half-lives are more persistent, and were therefore ranked as having greater potential to impact drinking water resources.

EPI Suite estimates biodegradation time using the BIOWIN™ 3 model, which provides an indication of a chemical's environmental biodegradation rate in relative terms (e.g., hours, days, weeks, etc.), assuming aerobic conditions. These BIOWIN3 estimates are converted to numerical half-life values for use in EPI Suite's Level III Fugacity model. For input into the MCDA, we used the same estimated half-life in water that is used in the Level III Fugacity model. Using the thresholds designated in Table 9-11, the half-life in water of each chemical was assigned a score of 1-4. This value was designated as the Persistence Score for each chemical.

9.8.1.4 Total Physicochemical Properties Score

For each chemical, the Mobility Score, Volatility Score, and Persistence Score (each on a scale of 1 to 4) were summed to calculate a total Physicochemical Properties Score. Higher Physicochemical Properties Scores indicate chemicals that are more likely to be transported in water, with a maximum possible score of 12.

9.8.2 Example of MCDA Score Calculation

The methods used for MCDA score calculation are described in Section 9.6.3. For an example of how the MCDA scores were calculated, consider benzene, which was included in both the noncancer MCDA (national analysis) and cancer MCDA for chemicals used in hydraulic fracturing fluids. This demonstrates how MCDA scores were calculated for benzene for these two different analyses.

9.8.2.1 Score Calculation for Benzene in Noncancer MCDA for Hydraulic Fracturing Fluids

- **Toxicity Score (Noncancer):** Benzene has a chronic oral RfV of 0.004 mg/kg-day (source: IRIS). Across the 42 chemicals that were considered in the noncancer MCDA (national analysis), chronic oral RfVs ranged from 0.001 mg/kg-day [(E)-crotonaldehyde] to 20 mg/kg-day (1,2-propylene glycol). The chronic oral RfV of benzene falls in the lowest (most toxic) quartile of these chemicals, and therefore benzene was assigned a Toxicity Score of 4. When the results were standardized to the highest Toxicity Score (4) and lowest Toxicity Score (1) within the set of chemicals, benzene was calculated to have a final Toxicity Score of 1, as follows:

$$1 = (4 - 1) / (4 - 1)$$

- **Occurrence Score:** Benzene was used in 0.006% of wells nationally. For the 42 chemicals considered in the national noncancer MCDA, frequency of use ranged from 73%

(methanol) to 0.003% (furfural) of wells nationally. Benzene falls in the lowest quartile with regards to frequency of use, and therefore benzene was assigned an Occurrence Score of 1. When the results were standardized to the highest Occurrence Score (4) and lowest Occurrence Score (1) within the set of chemicals, benzene was calculated to have a final Occurrence Score of 0, as follows:

$$0 = (1 – 1) / (4 – 1)$$

- **Physiochemical Properties Score:** Benzene received a Mobility Score of 4 (log K_{OW} = 2.13; log K_{OC} = 1.75; solubility = 2000 mg/l), a Volatility Score of 2 (Henry's law constant = 0.00555), and a Persistence Score of 2 (half-life in water = 37.5 days). This sums to a Total Physicochemical Properties Score of 8. Within the 42 chemicals considered in the national noncancer MCDA, several chemicals received Total Physicochemical Properties Scores of 9, which was the highest observed score. Cumene received a Total Physicochemical Properties Scores of 6, which was the lowest score. When the results were standardized to the highest (9) and lowest (6) of these scores, benzene was calculated to have a final Total Physicochemical Properties Scores of 0.67, as follows:

$$0.67 = (8 – 6) / (9 – 6)$$

- **Total Hazard Potential Score (Noncancer MCDA):** For benzene, the Toxicity Score (1), Occurrence Score (0), and Physicochemical Properties Score (0.67) were summed to calculate a Total Hazard Potential Score of 1.67. The relative contribution of the three criteria scores to this total score is depicted as a graphic in Figure 9-8.

9.8.2.2 Score Calculation for Benzene in Cancer MCDA for Hydraulic Fracturing Fluids

- **Toxicity Score (Cancer):** Benzene has an OSF of 0.055 per mg/kg-day (source: IRIS). Within the entire set of 10 chemicals that was considered in the cancer MCDA, OSFs ranged from 3 (quinoline) to 0.002 (dichloromethane) per mg/kg-day. The OSF of benzene falls in the second quartile of these scores, and therefore was assigned a Toxicity Score of 2. When the results were standardized to the highest Toxicity Score (4) and lowest Toxicity Score (1) within the set of chemicals, benzene was calculated to have a final Toxicity Score of 0.33, as follows:

$$0.33 = (2 – 1) / (4 – 1)$$

- **Occurrence Score:** As described in the noncancer MCDA above, benzene was used in 0.006% of wells nationally. This was the lowest frequency of use among the 10 chemicals that were considered in the cancer MCDA, with benzyl chloride (used in 6% of wells) having the highest. Benzene therefore falls in the lowest quartile with regards to frequency of use, and was assigned an Occurrence Score of 1. When the results were standardized to the highest Occurrence Score (4) and lowest Occurrence Score (1) within the set of chemicals, benzene was calculated to have a final Occurrence Score of 0, as follows:

$$0 = (1 - 1) / (4 - 1)$$

- **Physiochemical Properties Score:** As described in the noncancer MCDA above, benzene received a Total Physicochemical Properties Score of 8. Within the 10 chemicals that were considered in the cancer MCDA, all chemicals either received a Total Physicochemical Properties Score of 8 or 9. When the results were standardized to these high and low scores, benzene was calculated to have a final Total Physicochemical Properties Scores of 0 as follows:

$$0 = (8 - 8) / (9 - 8)$$

- **Total Hazard Potential Score (Cancer MCDA):** The Toxicity Score (0.33), Occurrence Score (0), and Physicochemical Properties Score (0) were summed to calculate a Total Hazard Potential Score of 0.33. The relative contribution of the three criteria scores to this total score is depicted as a graphic in Figure 9-12.

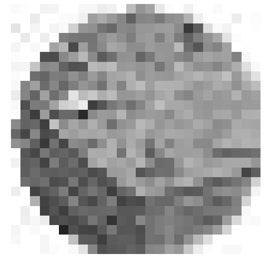
Chapter 10. Synthesis



This page is intentionally left blank.

10. Synthesis

Introduction

The goals of this report were to assess the potential for activities in the hydraulic fracturing water cycle to impact the quality or quantity of drinking water resources, and to identify factors affecting the frequency or severity of those impacts. Overall, we conclude activities in the hydraulic fracturing water cycle can impact drinking water resources under some circumstances. Impacts can range in frequency and severity, depending on the combination of hydraulic fracturing water cycle activities and local- or regional-scale factors. The following combinations of activities and factors are more likely than others to result in more frequent or more severe impacts:

- Water withdrawals for hydraulic fracturing in times or areas of low water availability, particularly in areas with limited or declining groundwater resources;
- Spills during the management of hydraulic fracturing fluids and chemicals or produced water that result in large volumes or high concentrations of chemicals reaching groundwater resources;
- Injection of hydraulic fracturing fluids into wells with inadequate mechanical integrity, allowing gases or liquids to move to groundwater resources;
- Injection of hydraulic fracturing fluids directly into groundwater resources;
- Discharge of inadequately treated hydraulic fracturing wastewater to surface water resources; and
- Disposal or storage of hydraulic fracturing wastewater in unlined pits, resulting in contamination of groundwater resources.

These conclusions are based on cases of identified impacts and other data, information, and analyses presented in this report. Cases of impacts were identified for all stages of the hydraulic fracturing water cycle. Identified impacts generally occurred near hydraulically fractured oil and gas production wells and ranged in severity, from temporary changes in water quality to contamination making private drinking water wells unusable. The inherent characteristics of groundwater resources make them more vulnerable to impacts from activities in the hydraulic fracturing water cycle compared to surface water.

We see the identification of factors affecting the frequency or severity of impacts, and uncertainties and data gaps in this report as particularly useful for decision makers. Factors often can be managed, changed, or used to identify areas for specific monitoring or modification of practices. Thus, in the short-term, information on factors can help decision makers reduce current vulnerabilities of drinking water resources to activities in the hydraulic fracturing water cycle. In the longer term, reducing the uncertainties and filling the data gaps could enhance science-based decisions to protect drinking water resources in the future.

The purpose of this chapter is to synthesize for decision makers the information on factors, uncertainties, and data gaps presented in this assessment. In Section 10.2, we focus on factors increasing or decreasing the frequency or severity of impacts at each stage of the hydraulic fracturing water cycle. In Section 10. 3, we discuss major uncertainties and data gaps identified in this assessment. Finally, in Section 10.4, we discuss potential uses for this assessment.

10.1 Factors Affecting the Frequency or Severity of Impacts

10.1.1 Water Acquisition

Groundwater and surface water resources serve as both sources of water for hydraulic fracturing and public and private drinking water supplies. Thus, water withdrawals for hydraulic fracturing can impact the quantity or quality of drinking water resources under certain circumstances. Since, by definition, every water withdrawal affects water quantity, we focused in this assessment not on all water withdrawals per se, but rather on those with the potential to limit the availability of drinking water or alter its quality. Whether a withdrawal has this potential depends upon a combination of factors at the local scale. Factors can either increase or decrease the frequency or severity of impacts. In this section on water acquisition, we combine our discussion of frequency and severity because all of the factors we discuss in this section affect both frequency and severity in a similar fashion (i.e., either increase both frequency and severity, or decrease both frequency and severity).

10.1.1.1 Frequency and Severity

The local balance between water withdrawals and water availability is the most important factor determining whether water acquisition impacts are likely to occur or be severe. Impacts are more likely to be frequent or severe where or when hydraulic fracturing water withdrawals are relatively high and water availability is low. In contrast, the same amount of water withdrawn can have a negligible effect if withdrawn in an area of—or at a time of—higher water availability. For this reason, it is important not to focus solely on the amount withdrawn, but the balance between water withdrawals and availability in place and time.

For this assessment, we developed county-level estimates of water use (i.e., water withdrawals) for hydraulic fracturing, which were then compared to an index of readily available fresh water. This readily available fresh water index included unappropriated surface water and groundwater, and appropriated water potentially available for purchase (Tidwell et al., 2013) (Text Box 4-2).[1] In the majority of counties where hydraulic fracturing takes place, hydraulic fracturing water use was less than 1% of this index of readily available fresh water. We did find, however, a small number of counties with higher percentages. There were 45 counties out of the almost 400 surveyed where hydraulic fracturing water use was above 10% of the index. Of these counties, 35 exceeded 30%, and 17 of these counties had hydraulic fracturing water use exceeding the index. All of the counties in this latter category are located in Texas.

[1] In the western United States, water is generally allocated by the principle of prior appropriation—that is, first in time of use is first in right. New development must use unappropriated water or purchase appropriated water from vested users. In the index of readily available fresh water, it was assumed 5% of appropriated irrigated water could be purchased. See Text Box 4-2 for more details about this analysis.

This does not mean impacts to drinking water quantities occurred or will occur in these counties, nor does it mean that impacts did not or will not occur in counties with relatively low percentages. To truly determine whether impacts occurred, water withdrawals and availability need to be compared at the scale of the drinking water resource. For instance, groundwater withdrawals for hydraulic fracturing could affect water levels in nearby private water wells. As a national assessment, we could not often examine impacts at this local scale, although we did cite studies of local impacts where available. Nevertheless, our county level assessment does point to places where the potential for impacts is higher. This information may be useful to focus efforts on reducing the fresh water demand of hydraulic fracturing.

Beyond our county level assessment, we conclude that declining groundwater resources are particularly vulnerable to water quantity and quality impacts from withdrawals. Groundwater recharge rates can be low, and groundwater withdrawals are exceeding recharge in areas of the country (Konikow, 2013). When withdrawals exceed recharge, the result is declining water levels. For this reason, water levels in some aquifers in the United States have declined substantially over the last century (Konikow, 2013). Although irrigated agriculture is often the dominant user of groundwater, hydraulic fracturing withdrawals now also contribute to declining groundwater levels in some areas (e.g., southern Texas; Steadman et al., 2015; Scanlon et al., 2014b) Cumulative groundwater withdrawals can also impact water quality by mobilizing chemicals, such as uranium, from naturally occurring sources in the surrounding rock into the groundwater (DeSimone et al., 2014).

In certain instances, state and local governments have encouraged or mandated the use of surface water in place of groundwater, as evidenced in both Louisiana and North Dakota. In 2008, the state of Louisiana asked oil and gas companies to switch from groundwater to surface water to mitigate stress on the Carrizo-Wilcox aquifer, a critical source of drinking water in the region. Likewise, the state of North Dakota requested the oil industry obtain water from the Missouri river system, and not from stressed groundwater sources. By contrast, surface water availability is limited in other regions and cannot provide an alternative source of water (e.g., western Texas).

Among surface water sources, small streams are particularly vulnerable to impacts. This is the case across the country, even in the eastern United States where surface water is generally more plentiful. An EPA study of the Susquehanna River Basin in northeastern Pennsylvania found that the smallest streams (with less than 10 mi^2 of contributing area–i.e., the watershed area drained by the stream) would be the most likely to be impacted from water withdrawals in the absence of protective passby flows; see discussion below and U.S. EPA (2015e).[1] While the amount of contributing area varies by geographic location due to differences in runoff, the finding that the smallest streams are the most vulnerable to withdrawals holds across all landscapes.

Not only does water availability vary from one location to another, but it can also vary temporally at a given location, often due to variations in precipitation. Because of this dynamic, long-term or seasonal drought can increase the frequency or severity of impacts from withdrawals by decreasing water availability. The EPA study of the Susquehanna River Basin found even larger streams (up to

[1] Passby flows are low stream flow thresholds below which withdrawals are not allowed.

600 mi^2 of contributing area) would be vulnerable to impacts at times of drought, again absent passby flows (U.S. EPA, 2015e). Dry conditions can also stress groundwater supplies by simultaneously increasing water demand (e.g., irrigation water demand increases in dry conditions) while also decreasing groundwater recharge. Much of the western United States has experienced extended periods of drought over the last decade. Climate change is likely to exacerbate these conditions in certain locations (Meixner et al., 2016).

Conversely, there are factors that can reduce the frequency or severity of impacts. Reuse of hydraulic fracturing wastewater (i.e., produced water managed for reuse, treatment and discharge, or disposal), for example, can reduce demands on fresh water resources.[1] Reuse does not appear to be driven by water scarcity, but rather by the cost of disposal. Operators are likely to dispose of wastewater when it is less expensive than reuse. For instance, greater reuse of wastewater occurs in the Marcellus Shale in Pennsylvania than in the Barnett Shale in Texas, even though water availability is generally higher in the Marcellus region (Figure 10-1). The general lack of disposal wells in Pennsylvania means disposing of wastewater requires trucking to Ohio or other locations with disposal wells. Because of this expense, operators reuse substantial proportions of their wastewater, in contrast to the Barnett Shale where disposal wells are readily available.

The reuse of wastewater to offset fresh water use in hydraulic fracturing is often limited by the amount of wastewater available. The volume of produced water from a single well can be relatively small compared to the volume needed to fracture a well (Figure 10-1a). This means produced water would need to be aggregated from multiple wells to equal the volume needed to hydraulically fracture an additional well. For instance, it would take 10 wells to make enough water to fracture an 11th well if, as has been shown in the Marcellus Shale in Pennsylvania, produced water volumes are 10% of injected volumes (Figure 10-1a). Thus, reuse is a factor that can reduce fresh water demand, but not eliminate it in most cases. Nevertheless, even a marginal decline in fresh water demand can make a difference in the frequency or severity of impacts.

The use of brackish groundwater is also a factor reducing fresh water demand, in some cases to a much greater degree than reuse. In the Permian Basin in western Texas, for instance, brackish water makes up 30 to 80% of water used for hydraulic fracturing, and 20% in the Eagle Ford Shale in southern Texas (Nicot et al., 2012). Our county level estimates suggest brackish water availability could entirely meet current hydraulic fracturing water demand in Texas and many other locations.[2] In 35 counties nationally, hydraulic fracturing water use equaled or exceeded 30% of an index of fresh water availability; when brackish water and wastewater were considered in addition to fresh water availability, only two counties equaled or exceeded 30% (Text Box 4-2).

[1] Hydraulic fracturing wastewater is produced water that is managed using practices that include, but are not limited to, reuse in subsequent hydraulic fracturing operations, treatment and discharge, and injection into disposal wells. The term is being used in this study as a general description of certain waters and is not intended to constitute a term of art for legal or regulatory purposes (see Chapter 8 and Appendix J, the Glossary, for more detail).

[2] Brackish water for the purposes of this analysis ranged from 3,000 to 10,000 ppm of total dissolved solids (TDS), and from 50 to 2,500 ft (15-760 m) below the surface (Tidwell et al., 2013). (See Text Box 4-2 for more details.)

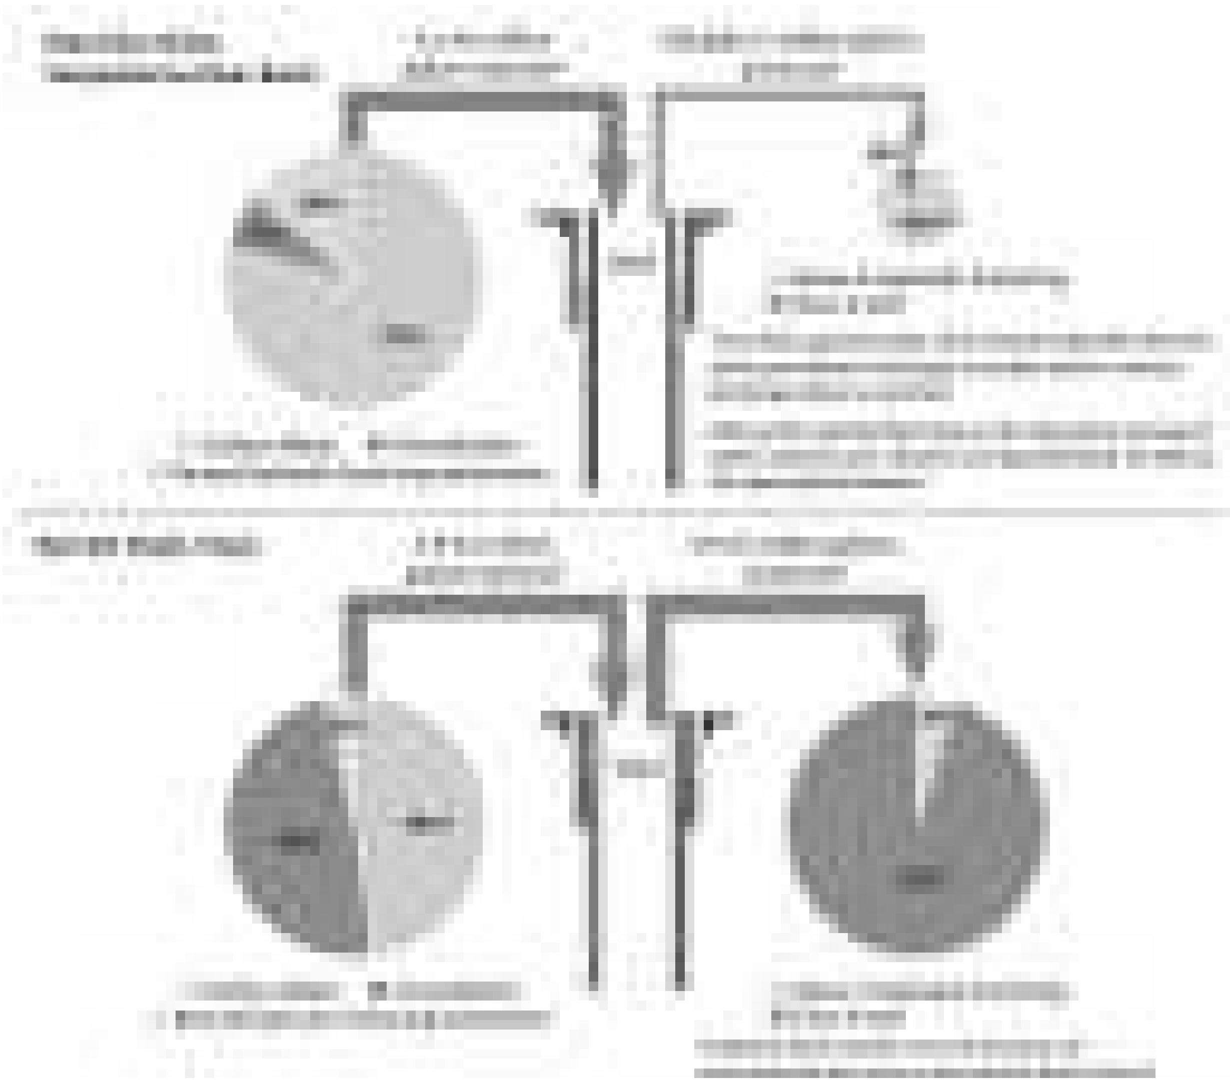


Figure 10-1. Water budgets representative of practices in (top) the Marcellus Shale in the Susquehanna River Basin in Pennsylvania and (bottom) the Barnett Shale in Texas.

Pie size and arrow thickness represent the relative volume of water as it flows through the hydraulic fracturing water cycle. Water budgets illustrative of typical water management practices in the Marcellus Shale in the Susquehanna River Basin between approximately 2008 and 2013 and the Barnett Shale in Texas between approximately 2011 and 2013. They do not represent any specific well. Sources for the top figure (a) Tables 4-1 and 4-2 (SRBC, 2016)—note, surface water, groundwater, and reuse values of 92%, 8%, and 16% in table normalized to 79%, 7%, 14%, respectively, for this chart (this was done to represent reuse on the same chart as surface water and groundwater—in the original tabular values, reuse is expressed as a percentage of total water used, and surface water and groundwater are expressed in percentages relative to each other); (b) Appendix Table B-5 (U.S. EPA, 2015a); (c) Table 7-2 (Ziemkiewicz et al., 2014)—note: produced water volumes estimated from percentages applied to volumes injected, and value from the West Virginia portion of the Marcellus Shale used in this chart since it was the longest term measurement of produced water volumes; (d) Figure 8-4 (PA DEP, 2015a) and Table 8-6 (Ma et al., 2014; Shaffer et al., 2013). Sources for the bottom figure: (e) Tables 4-1 and 4-2 (Nicot et al., 2014; Nicot et al., 2012)—note, surface water, groundwater, and reuse values of 50%, 50%, and 5% in the tables normalized to 48%, 48%, and 4%, respectively, for this chart (see reason for this above); (f) Appendix Table B-5 (U.S. EPA, 2015a; Nicot et al., 2012; Nicot et al., 2011)—note: see median value for Fort Worth Basin; (g) Table 7-2 (Nicot et al., 2014); (h) Table 8-6 (Nicot et al., 2012)—note, percentage going to disposal wells estimated by subtracting reuse values from 100%.

Finally, passby flows can be a factor reducing the frequency or severity of surface water impacts. Passby flows are low stream flow thresholds below which withdrawals are not allowed. This management practice has been shown to be protective of streams from over-withdrawals in the Susquehanna River Basin in northern Pennsylvania (U.S. EPA, 2015e). This is likely most important for protecting aquatic life in smaller streams, but may also aid in protecting drinking water supplies.

10.1.2 Chemical Mixing and Produced Water Handling

Like water acquisition, activities in the chemical mixing and produced water handling stages of the hydraulic fracturing water cycle can impact drinking water in some instances. We combine our discussion of the two stages here because activities in these stages both affect drinking water resources primarily through spills. The chemical mixing stage encompasses management of fluids on the well pad to create hydraulic fracturing fluid. Chemicals are mixed with a base fluid, typically water, and then injected into the production well. After the pressure is released post-fracturing, produced water flows from the well and needs to be collected and managed in the produced water handling stage.

Chemical mixing and produced water handling activities can impact drinking water resources through spills of chemicals used to make hydraulic fracturing fluid, hydraulic fracturing fluid itself, or produced water reaching surface water or groundwater.[1] There is some information on spill frequencies—although limited—and spill severities are most often uncharacterized. Nevertheless, we could identify factors affecting the frequency or severity of impacts from chemical mixing or produced water spills. In the section below, we discuss these factors, with those affecting frequency first, followed by those affecting severity. We discuss each of the factors individually, but spill events in reality exhibit combinations of these factors. These factors can interact to increase or decrease the frequency or severity of a spill beyond the effect of an individual factor.

10.1.2.1 Frequency

An impact on the quality of a drinking water resource from a spill first depends on a spill occurring. Most spill frequency estimates are of spills in total, and not the subset reaching drinking water resources. Spill estimates from three states (Colorado, North Dakota, and Pennsylvania) ranged from 0.4 to 12.2 reported spills per 100 hydraulically fractured wells (Appendix C.4).[2] The estimates from Pennsylvania and Colorado included hydraulic fracturing chemicals, fluids, and produced water; while the North Dakota estimate was based on spills of hydraulic fracturing chemicals and fluids only.[3] Spill rates can also be expressed on a per-active-well basis. This may be

[1] In Chapter 5 and elsewhere in this assessment, the chemicals added to the base fluid (most often water) and proppant (most often sand) are referred to as "additives" since this is the term used in FracFocus. Here, this chapter simply refers to them as "chemicals." It does this to discuss chemicals in a unified manner in this combined section on chemical mixing and produced water.

[2] Since most wells are not reported hydraulically fractured in databases, these estimates used spudded, completed, or installed wells as proxies for hydraulically fractured wells. (See Appendix Section C.4 for more detail.)

[3] These estimates from Pennsylvania and Colorado also included spills of diesel fuel and drilling muds, which could not be separated out from the total frequency estimate even though they were generally out-of-scope of this assessment (diesel fuel was in scope if used in hydraulic fracturing fluid).

more appropriate for produced water spills since they can occur years or even decades after hydraulic fracturing. An analysis of North Dakota produced water spills found there were approximately 5 to 7 spills of produced water per 100 active wells between 2010 and 2015 (Appendix E.5). We conclude from these data that spills do occur in both the chemical mixing and produced water stages of the hydraulic fracturing water cycle, generally in the range of 1 to 10% of hydraulically fractured or active wells.

Not all spills, however, reach and therefore impact a drinking water resource. In U.S. EPA (2015m), 32 of the 457 (7%) spills characterized were reported to have reached surface water or groundwater. The California Office of Emergency Services estimated 18% of produced water spills reached waterways between January 2009 and December 2014 (CCST, 2015b). It is unclear if this estimate included groundwater, or was limited to surface water. If, however, roughly 5 to 20% of spills reach surface water or groundwater (encompassing the U.S. EPA and California estimates above), we would expect a spill to occur and reach a drinking water resource at approximately 0.05 to 2% of active or hydraulically fractured wells.[1] This estimate of spills reaching drinking water resources would be broadly consistent with estimates from the limited number of published studies addressing this topic (e.g., Brantley et al., 2014; Gross et al., 2013).[2] If a 0.05 to 2% frequency rate is applied to the estimates of approximately 275,000 to 370,000 new wells hydraulically fractured nationally between 2000 and part of 2013 and 2000 and part of 2014, respectively (Chapter 3), we would expect roughly 140 to 7,400 spills to reach a drinking water resource during this almost 14-to-15 year time-period. This would be approximately 10 to 500 spills per year reaching a drinking water resource, dividing by the respective time periods. This large range reflects the high uncertainty of these estimates and the lack of data on this topic.

Despite the data limitations and uncertainties surrounding estimates of spills, we can with more certainty identify factors likely affecting the frequency of spills reaching drinking water resources. These factors include spill characteristics, encompassing the volume of the chemical spilled; factors related to the environmental fate and transport of the spill, such as properties of the chemical spilled and characteristics of the site where the spill occurred; and finally, factors related to spill prevention and response.

Everything else being equal, a larger volume spill will be more likely to reach a drinking water resource than a smaller spill (U.S. EPA, 2015m). On-site spills in the chemical mixing and produced water handling stages are typically in the hundreds of gallons (U.S. EPA, 2015m). Larger spills, though less common, do occur. Well blowouts, pipeline leaks, and impoundment failures are sources of some of the largest individual spill volumes. Well blowouts were responsible for the

---

[1] Estimated by multiplying the 1 to 10% spill rate for active or hydraulically fractured wells by 5% to 20% for spills reaching drinking water, and then reconverting to a percentage by multiplying by 100.

[2] Brantley et al. (2014) estimated approximately 0.4 to 0.8 spills per 100 hydraulically fractured wells reached surface water in Pennsylvania between 2008 to September 2013. These were spills of 400 gal (1,514 L) or more, containing hydraulic fracturing chemicals, fluids, or produced water. This might be an underestimate of spills reaching surface water since spill volumes were limited to only 400 gal (1,514 L) or more. In estimate of the frequency of spills reaching groundwater, Gross et al. (2013) examined oil and produced water spills between July 2010 and July 2011 in Weld County, Colorado. They counted 77 such spills reaching groundwater, approximately 0.4% of the nearly 18,000 active wells in the county.

highest volume spills on average in 2015 in North Dakota. In Bradford County, Pennsylvania, a well blowout resulted in a spill of approximately 10,000 gal (38,000 L) of produced water into a tributary of Towanda Creek, a state designated trout fishery. The largest volume spill identified in this assessment occurred in North Dakota, where approximately 2.9 million gal (11 million L) of produced water spilled from a broken pipeline and impacted surface water and groundwater. Though relatively rare compared to smaller volume spills, these types of spills are more likely to reach—and therefore impact—a drinking water resource because they are of larger volumes.

By this same principle, produced water spills are more likely to impact drinking water resources than chemical mixing spills. In an analysis of on-site spills, the median volume of produced water spills was approximately twice as large as that in the chemical mixing stage (990 versus 420 gal, or 3,750 versus 1,590 L; U.S. EPA (2015m)). Additionally, offsite, large pipeline spills of produced water can occur. It is possible that spills of produced water are larger, in part, because they are less likely to be stopped as quickly as spills in the chemical mixing stage. Spills in the chemical mixing stage are likely to occur when people are on-site, and so the spills can be quickly addressed. In contrast, spills of produced water may occur when no one is on-site or, in the case of pipelines, near the off-site location of the spill. This may delay a response, allowing larger volumes to spill, increasing the likelihood of the spill reaching a drinking water resource.

Properties of the chemicals spilled also affect the frequency of impacts. We identified or estimated chemical and physical properties for almost half of the chemicals used in hydraulic fracturing fluids between 2006 and 2013 (455 of the 1,084 chemicals). These were individual organic chemicals, not inorganic chemicals, polymers, or mixtures. Volatility, solubility, and hydrophobicity/hydrophilicity are three properties, among others, affecting whether a spill reaches a drinking water resource (hydrophobic chemicals tend to repel or fail to mix with water, while hydrophilic chemicals tend to mix with water). The vast majority of organic chemicals in hydraulic fracturing fluid do not readily volatilize or evaporate, meaning these chemicals tend to remain in water if spilled. These chemicals also vary widely in their solubility and hydrophobicity/hydrophilicity, defying a general characterization. Nevertheless, of the 20 chemicals most frequently used according to our analysis of FracFocus, most are highly soluble and hydrophilic, meaning they will be mobile if spilled (Chapter 5). For example, methanol, isopropanol, and ethylene glycol are all likely to travel quickly through the environment. Thus, these chemicals may more frequently reach drinking water because of two unrelated, yet compounding factors: relatively high frequency of use in hydraulic fracturing operations and relatively high mobility in the environment.

Site characteristics are also an important factor determining whether a spill reaches a drinking water resource (Figure 10-2). Site characteristics facilitating infiltration to groundwater are of particular concern, since spills into groundwater are more likely to have severe impacts than those into surface water (discussed in the severity section below). More permeable, sandier soils allow greater infiltration of spilled fluids, whereas less permeable soils with more clay content can greatly slow infiltration. More permeable rock also facilitates infiltration and movement of spills through preferential flow paths—for example, in fractured or karst bedrock. Thus, sandier soils and more permeable rock can increase the potential for spills to reach groundwater.

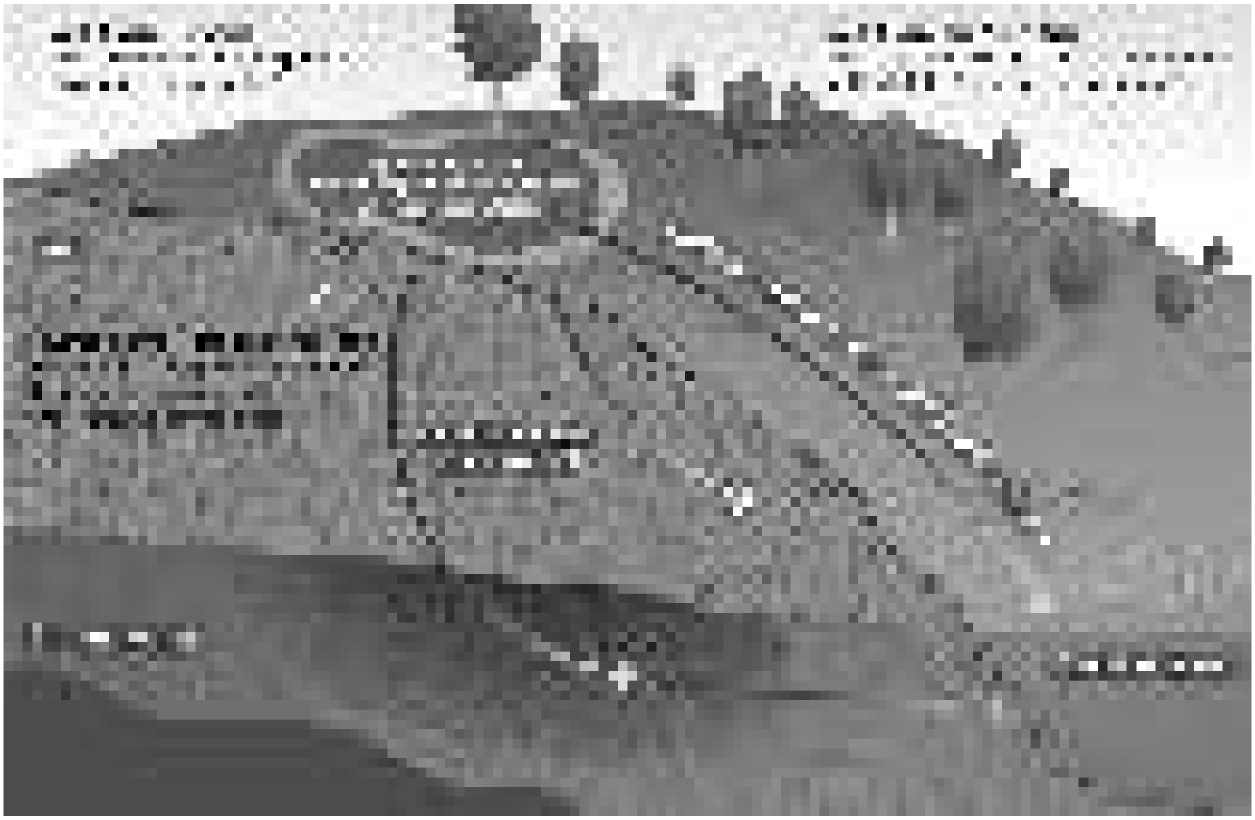

Figure 10-2. Fate and transport schematic for a spill of chemicals, hydraulic fracturing fluid, or produced water.

Schematic shows the potential paths, transport processes, and factors governing potential impacts of spills to drinking water resources.

There are spill prevention and response factors that reduce the frequency of impacts to drinking water resources from spills. Spill containment systems include primary, secondary, and emergency containment systems. Primary containment systems are the storage units, such as tanks or totes. Secondary containment systems, such as liners and berms installed during site set-up, are intended to contain spilled fluids until they can be cleaned up. Emergency containment systems, such as berms, dikes, and booms, can be implemented temporarily in response to a spill. Remediation is the action taken to clean up a spill and its affected environmental media. One of the most commonly reported remediation activities is the removal of spilled fluid and/or affected media, typically soil (U.S. EPA, 2015m). Other remediation methods include the use of absorbent material, vacuum trucks, flushing the affected area with water, and neutralizing the spilled material (U.S. EPA, 2015m). It was beyond the scope of this assessment to evaluate the implementation and efficacy of spill prevention practices and spill response activities.

10.1.2.2 Severity

In addition to frequency, there are also factors affecting the severity of an impact on a drinking water resource from a spill. For a given concentration, a larger volume spill will be more severe than a smaller spill (see frequency section above for discussion of spill volumes). In addition to volume, the concentration and toxicity of the chemicals reaching a drinking water resource affect severity, as well as site characteristics.

A spill with higher chemical concentrations will be more severe than a more dilute spill of equal volume. In the chemical mixing stage, chemicals are stored in concentrated form on-site, prior to diluting with a base fluid. Approximately 3,000 to 30,000 gal (11,000 to 114,000 L) of chemicals are used per well on average, with up to twice that amount stored on site. If multiple wells are fractured per site, tens to hundreds of thousands of gallons of chemicals are likely stored in containers at a single site during the hydraulic fracturing of these wells. These storage containers are a relatively frequent source of spills during the chemical mixing stage. Spills from these storage containers, even if low in volume, may be severe if they reach a drinking water resource because they often contain concentrated chemicals.

In the produced water handling stage, the severity of impacts from a spill also increases with higher concentrations, especially if the spill reaches groundwater (see site characteristics below). Produced water can vary substantially in chemical concentrations, including total dissolved solids (TDS), metals, radioactive isotopes, and organic chemicals. Within the Marcellus Shale, for example, produced water can range in TDS from less than 1,500 mg/L to over 300,000 mg/L (Rowan et al., 2011). By comparison, the average salinity concentration for seawater is 35,000 mg/L. The more concentrated the produced water, the more likely impacts will be severe if a spill reaches a drinking water resource. When a spilled fluid has greater concentrations of TDS than groundwater, the higher-density fluid can move downward through the groundwater resource. Depending on the flow rate and other properties of the groundwater, impacts from produced water spills can last for years.

In addition to concentration, the toxicity of chemicals affects the severity of the impact if they enter a drinking water resource. There were 37 chemicals listed in 10% or more of all FracFocus disclosures between January 1, 2011 and February 28, 2013. Of these 37 chemicals, nine had chronic oral reference values meeting the criteria used in this assessment. [1] These nine chemicals are associated with health effects including liver toxicity, kidney toxicity, developmental toxicity, reproductive toxicity, and/or carcinogenesis. Chemicals used in hydraulic fracturing fluids and detected in produced water will vary from site to site, so human health hazards are best evaluated on a site-specific basis. Nevertheless, the multi-criteria decision analysis (MCDA) presented in Chapter 9 highlighted certain chemicals that may have greater hazard potential. Propargyl alcohol, 2-butoxyethanol, and N,N-dimethylformamide are three such chemicals having relatively greater hazard potential in the MCDA based on toxicity, frequency of use in hydraulic fracturing fluids, and mobility in water.

Many of the chemicals in produced water are also known or suspected to cause cancer and/or non-cancer health effects in humans. Associated health effects include liver toxicity, kidney toxicity, neurotoxicity, reproductive and developmental toxicity, and carcinogenesis, based on the produced

[1] The analysis of toxicity presented in Chapter 9 included chemicals regardless of accompanying concentration data in FracFocus, and therefore listed 37 chemicals that were reported in 10% or more disclosures. Comparatively, Chapter 5 listed 35 chemicals that had valid concentration data from FracFocus and were reported in 10% of more disclosures.

water chemicals having chronic oral reference values meeting the criteria used in this assessment. Benzene, pyridine, and naphthalene are three of the chemicals highlighted in the MCDA as having relatively greater hazard potential based on toxicity, measured concentrations in produced water, and mobility in water.

We did not evaluate trends in chemical use by toxicity (e.g., the trends in the use of less toxic chemicals). However, a more recent study of FracFocus data evaluated disclosures dating from March 9, 2011, to April 13, 2015 (Dayalu and Konschnik, 2016; Konschnik and Dayalu, 2016). When compared to the list of 1,084 chemicals used in hydraulic fracturing operations between 2005 and 2013 compiled for this assessment (Appendix H), an additional 263 chemicals were identified (Chapter 5). Only one of these 263 chemicals was reported in more than 1% of disclosures. This comparison of chemical lists does not address potential shifts in volumes of chemicals used, but it does suggest that a shift to new types of chemicals–less toxic or otherwise–did not occur between 2013 and early 2015.

Finally, site characteristics also affect the severity of the impact. Spills into groundwater are likely to be more severe than spills into surface water, everything else being equal. This is not to say that spills into surface water cannot be severe, especially in the immediate vicinity of the spill. For instance, a tank overflowed on a well site in Kentucky spilling fluid into a nearby stream at concentrations sufficient to kill fish in the area (Papoulias and Velasco, 2013). Chemicals can also associate with stream sediments, forming a source of long-term contamination (e.g., radium). In general, however, surface water dilutes a spilled chemical much more rapidly than groundwater. Groundwater often moves slowly between areas of recharge and discharge. Groundwater movement can be as slow as one foot per year or even one foot per decade (Alley et al., 1999). Because of this dynamic, chemicals from multiple spills can accumulate over time in groundwater. Multiple chemical mixing and produced water spills, even if individually small, may impact a groundwater resource in aggregate. Additionally, groundwater contamination may not be as readily apparent as that in surface water because of the need to install monitoring wells to detect contamination in groundwater. Lastly, groundwater can be difficult and expensive to remediate, adding to the severity of impacts if spills reach groundwater (Alley et al., 1999).

10.1.3 Well Injection

Like the water acquisition, chemical mixing, and produced water handling stages, activities in the well injection stage of the hydraulic fracturing water cycle can affect drinking water resources in some instances. The well injection stage involves the injection of hydraulic fracturing fluids through the production well and into the targeted rock formation at sufficient pressure to fracture the rock. There are two fundamental pathways outlined in this assessment by which activities in the well injection stage have the potential to affect drinking water resource quality. They are: (1) fluid (meaning, liquid or gas) movement into a drinking water resource through defects or deficiencies in the production well casing and/or cement; and (2) fluid movement into a drinking water resource through the fracture network. The fluids potentially affecting drinking water resources include hydraulic fracturing fluids, hydrocarbons (including methane gas), and naturally occurring brines. The drinking water resources impacted directly in this stage are almost always groundwater resources, rather than surface water.

Though we could not in this assessment quantify an overall frequency of groundwater quality impacts from the well injection stage, we can describe factors which make impacts more or less frequent or more or less severe, as we did for other stages. We describe these factors below, first with frequency and then severity. Within the frequency discussion, we address factors by each pathway type.

10.1.3.1 Frequency

Pathway #1: Fluid movement into a drinking water resource through defects or deficiencies in the production well casing and/or cement.

To reach and then fracture the production zone, an oil or gas well must first be drilled and constructed down through the subsurface rock formations, often containing an overlying drinking water resource. Since the well passes through the drinking water resource, this means defects or deficiencies in the production well can lead to unintended movement of fluid into the drinking water resource. This can occur regardless of the vertical separation between the drinking water and the production zone.

The relatively brief hydraulic fracturing phase will likely impose the highest stresses to which the well will be exposed during its entire life. If the well cannot withstand the stresses experienced during hydraulic fracturing, the casing or cement can fail, resulting in the loss of mechanical integrity and the unintended movement of fluids into the surrounding environment.

A few studies have estimated rates of mechanical integrity failure of production wells resulting in the loss of *all* barriers protecting the groundwater or in contamination of groundwater in areas with hydraulic fracturing activity (Table 10-1). The estimates are all approximately equal to or less than 1% of wells drilled or hydraulically fractured over varying time frames. For most of these estimates, it is not possible to tell whether failures occurred during hydraulic fracturing or at some other point in the well's life, with the exception of the EPA's Well File Review (U.S. EPA, 2015n). If the failure rate from the Well File Review (0.5%) is applied to the estimates of 275,000 to 370,000 new wells hydraulically fractured nationally between 2000 and part of 2013 and 2000 and part of 2014, respectively (Chapter 3), we would expect roughly 1,370 to 1,850 mechanical integrity failures during this time-period (almost 14 to 15 years). Dividing by each time period yields approximately 100 to 125 mechanical integrity failures per year on average, resulting in the loss of all barriers protecting the groundwater during hydraulic fracturing. These estimates also have a high degree of uncertainty like the spills estimates. This not only stems from the lack of certainty about failure rates, but also uncertainties surrounding the estimates of the number of wells hydraulically fractured (Chapter 3). These are likely low estimates because they do not include mechanical integrity failures occurring outside of the hydraulic fracturing process (e.g., during the production phase), nor do they consider failures in re-fractured wells.

Table 10-1. Literature estimates of mechanical integrity failure rates resulting in contamination of groundwater or failure of all well barriers, potentially exposing the groundwater.

Citation	Mechanical Integrity Failure Rate (%)	Geographic Scope	Key Findings & Description of Mechanical Integrity Failure[a,b]
Fleckenstein et al. (2015)	0.06	Colorado-Wattenberg Field	An overall catastrophic failure rate of 0.06% was found for 16,828 wells studied (out of 17,948 total wells) drilled in the Wattenberg Field between 1970 and 2013. The timing of the failures was unknown, but most of the failures occurred in the older wells. The Wattenberg Formation is 4,400 ft (1,300m) below surface and typically is hydraulically fractured. A catastrophic failure was considered to have occurred when there was contamination of drinking water aquifers (i.e., the presence of thermogenic gas in a drinking water well) and evidence of a well defect such as exposed intermediate gas formations or casing leaks.
Considine et al. (2012)	0.06	Pennsylvania	Two wells were cited between 2008 and 2011 by PA DEP for causing methane migration into an aquifer. In this same time period, 3,533 wells were drilled.
Brantley et al. (2014)	0.12–1.1	Pennsylvania	Based on positive determination letters (PDLs) for violations that occurred between 2008 and 2012, Brantley et al. estimated between 7 and 64 problematic unconventional wells contaminated 85 properties. Since PDLs are tied to drinking water wells and not gas wells, Brantley et al. made assumptions about how many unconventional gas wells were represented by each PDL. This equates to problematic unconventional gas wells compromising approximately 0.1 to 1% of the 6,061 wells spudded between 2008 and 2012.[c] Not all of these PDLs may be due to mechanical integrity failures–they could also be due to other causes, such as spills, or methane migration from natural or other anthropogenic sources.
Vidic et al. (2013)	0.25	Pennsylvania	Of the 6,466 wells studied, 16 received notices regarding contamination of groundwater with gas or other fluids from the PA DEP associated with incidents that occurred between 2008 and 2013.

Citation	Mechanical Integrity Failure Rate (%)	Geographic Scope	Key Findings & Description of Mechanical Integrity Failure[a,b]
U.S. EPA (2016c)	0.5	National	In an estimated 0.5% of the approximately 28,500 hydraulic fracturing jobs surveyed, a failure occurred during hydraulic fracturing, such that there was no additional barrier between the annular space with fluid and the protected drinking water resource. While it could not definitively be determined whether fluid movement into the protected drinking water resource occurred, in these cases, all of the protective barriers intended to prevent such fluid migration had failed, leaving the groundwater source vulnerable to contamination.

[a] Note: While some information is available on the age of the wells studied, it is unclear whether the failure occurred during the hydraulic fracturing event, with the exception of the U.S. EPA (2016c) study. In that study, the failures occurred during hydraulic fracturing.

[b] While the Pennsylvania studies did not specifically identify whether the wells were involved in hydraulic fracturing operations, a significant portion of Pennsylvania's recent oil and gas activity is in the Marcellus Shale; therefore, many of the wells in these studies were most likely used for hydraulic fracturing.

[c] Spudding refers to starting the well drilling process by removing rock, dirt, and other sedimentary material with the drill bit (U.S. EPA, 2013f).

Not all wells are equally likely to lose mechanical integrity; instead, there are factors that make some wells more likely to experience a mechanical integrity failure than others. Well design and construction are two such factors. First, a primary element of well design is the placement of at least one additional layer of casing (besides the production casing) from the surface through the lowest depth of the drinking water resource. This additional casing provides redundancy if the production casing fails. In a study of 731 saltwater injection wells in the Williston Basin in North Dakota, Michie and Koch (1991) found the risk of aquifer contamination from leaks into the drinking water resource was 7 in 1,000,000 injection wells if a surface casing, in addition to the production casing, was set deep enough to cover the drinking water resource. The risk increased to 6,000 per 1,000,000 wells (or 6 in 1,000) if this additional casing was not set deeper than the bottom of the drinking water resource.

Second, fully cementing casing(s) through the entire drinking water resource affects the frequency of impacts. Uncemented sections of surface casing increase the frequency of fluid leaks from the well that can reach groundwater (Fleckenstein et al., 2015; Watson and Bachu, 2009). The EPA's Well File Review estimated that a portion of the protected groundwater resource identified by well operators was uncemented in 3% of the wells surveyed (U.S. EPA, 2015n). With approximately 25,000 to 30,000 new wells hydraulically fractured a year (Chapter 3), this percentage means 750 to 900 of the wells used in hydraulic fracturing operations annually might lack this protection. Adding re-fractured wells would increase the estimate of wells lacking this protection. Knowing the depth of the groundwater resource at the point of drilling and then setting and cementing casings below the lowest part of the drinking water resource can reduce the frequency or likelihood of an impact.

Third, the well's casing, cement, and components need to be designed and constructed to withstand the stresses applied to the well during hydraulic fracturing. In an example of inadequate well construction, hydraulic fracturing of a gas well with insufficient and improperly placed cement in Bainbridge Township, Ohio led to gas contamination of 26 domestic water supply wells and an explosion in the basement of one of the nearby homes. This was due in part to a failure to cement through the over-pressured gas formations and proceeding with the fracturing operation without adequate cement (ODNR, 2008). In another case, casings at an oil well near Killdeer, North Dakota, ruptured in 2010 following a pressure spike during hydraulic fracturing, allowing fluids to escape to the surface. Brine and tert-butyl alcohol were detected in two nearby water wells. Following an analysis of potential sources, the only potential source consistent with the conditions observed in the two impacted water wells was the ruptured well (U.S. EPA, 2015i).

In addition to well design and construction, the degradation or corrosion of well components can also increase the frequency of impacts to drinking water quality. Older wells exhibit more integrity problems as cement and casings age. The EPA's Well File Review estimated at least 10% of the wells represented in the national survey were greater than five years old at the time of hydraulic fracturing. Hydraulic fracturing or re-fracturing older wells has the potential to increase the frequency of casing or cement failures allowing unintended fluid migration into drinking water resources.

Confirming well mechanical integrity can reduce the frequency of water quality impacts. Pressure testing the casing used for hydraulic fracturing prior to the job can help detect problematic casing—and provide an opportunity to make needed repairs if necessary. Monitoring the annular space behind the casing used for hydraulic fracturing during the hydraulic fracturing job can detect well component failure in real time and signal for an immediate shut down. Based on the EPA's Well File Review study, casing pressure testing occurred at slightly less than 60% of the approximately 28,500 hydraulic fracturing jobs represented in that time frame (primarily 2009-2010) and annulus monitoring took place during slightly more than 50% of these same jobs, implying these activities did not always occur (U.S. EPA, 2016c). It is unclear whether the frequency of these practices have changed since this time period.

Pathway #2: Fluid movement into a drinking water resource through the fracture network.

The other potential pathway for fluid movement into a drinking water resource is through the fracture network. This could occur indirectly if the fracture network extends to a nearby well or its fracture network, or to another permeable subsurface feature, such as natural fractures or faults, which then allow the fluid to reach an underground drinking water resource. It could also occur directly by the fracture network extending out of the production zone into a drinking water resource, or hydraulic fracturing into a drinking water resource itself.[1] Key factors affecting the frequency of this pathway are the presence, distance, and condition of nearby wells; and the vertical

[1] Hereafter, fractures extending out of the production zone are referred to as "out-of-zone" fractures, consistent with Chapter 6.

separation distance and the characteristics of the intervening rock between the production zone and the drinking water resource.

Nearby wells (often called offset wells) can be a pathway for fluid movement, with hydraulic fracturing fluid from one production well moving through the subsurface and entering another nearby oil or gas well or its fracture network. These events are commonly referred to as "well communication events" or "frac hits." The communication event might simply be registered as an increase in pressure in the nearby well; yet there is also the possibility of damage to the nearby well or its components, causing a surface spill or a subsurface release of fluids. The EPA's Well File Review found 1% of the wells represented in the study experienced a frac hit, and the EPA spills report identified 10 spills attributed to well communication events (U.S. EPA, 2015m, n). It is unknown whether any fluid reached a drinking water resource from these spills. Where active nearby wells exist, operators of those wells can shut them in temporarily during the nearby hydraulic fracturing to reduce the possibility of spills or damage to their wells, and therefore, the potential for drinking water resource contamination.

The distance to the nearby well can affect the frequency of these communication events. In one study, the likelihood of a frac hit was less than 10% in hydraulically fractured wells more than 4,000 ft (1,219 m) apart, while nearly 50% in wells less than 1,000 ft (300 m) apart (Ajani and Kelkar, 2012). Distance was measured from the mid-point of each horizontal lateral. Thus, the closer the nearby wells, the more likely a communication event.

If nearby wells are in good condition and can withstand an increase in pressure, then an impact is unlikely to occur. However, if the nearby well is not able to withstand the pressure of the fluid, well components may fail and allow fluid to move into a drinking water resource. Because of this, nearby older or abandoned wells are of particular concern. In older wells near a hydraulic fracturing operation, plugs and cement may have degraded over time; in some cases, abandoned wells may never have been plugged properly. This can be a significant issue in areas with legacy (i.e., historic) oil and gas exploration. A Pennsylvania Department of Environmental Protection (PA DEP) report cited three cases where migration of natural gas had been caused by well communication events via old, abandoned wells (PA DEP, 2009c). In Tioga County, Pennsylvania, following hydraulic fracturing of a shale gas well, an abandoned well nearby produced a 30 ft (9 m) geyser of brine and gas for more than a week (Dilmore et al., 2015). Various studies estimate the number of abandoned wells in the United States to be significant. For example, the Interstate Oil and Gas Compact Commission (IOGCC, 2008) estimates that approximately 1 million wells were drilled in the United States prior to a formal regulatory system, and the status and location of many of these wells are unknown. Hydraulic fracturing operators can reduce the possibility of impacts by identifying nearby wells, and if necessary, plugging or otherwise addressing deficiencies in these wells.

If nearby wells serve as a pathway, fluid movement can bypass layers of intervening rock. In the absence of this pathway, however, vertical distance and the intervening rock between the production zone and the drinking water resource are factors affecting the possible movement of fluid into a drinking water resource. The extension of fractures out of the oil and/or gas production zone can—and does—occur. Examples have been reported in Greene County, Pennsylvania (Hammack et al., 2014); at the Killdeer site in Dunn County, North Dakota (U.S. EPA, 2015i); and in other wells within the Bakken Shale (Arkadakskiy and Rostron, 2013; Arkadakskiy and Rostron, 2012; Peterman et al., 2012). In a study across several major shale formations, Davies et al. (2012) found upward vertical fracture growth was often on the order of tens-to-hundreds of feet. One percent of the fractures had a fracture height greater than 1,148 ft (350 m), and the maximum fracture height among all of the data reported was 1,929 ft (588 m). This would suggest that substantial vertical separation could preclude out-of-zone-fractures from directly reaching the drinking water resource, although these measurements were only conducted in shale formations and the extension of fractures is not the only way the drinking water resource could be contaminated from out-of-zone fractures (see below). A modeling study also suggests fractures are unlikely to extend from the production zone directly to a shallow drinking water resource in a deep Marcellus-like environment (Kim and Moridis, 2015).

Not all fracturing occurs, however, with substantial vertical separation between the production zone and the drinking water resource (Figure 10-3). The EPA's Well File Review found that 20% of wells used for hydraulic fracturing had less than 2,000 ft (600 m) between the shallowest point of fracturing and the base of the protected groundwater resource (U.S. EPA, 2015n). In coalbed methane (CBM) plays, typically shallower than shale gas plays, these separation distances can be smaller. For example, in the Raton Basin of southern Colorado and northern New Mexico, approximately 10% of CBM wells have less than 675 ft (206 m) of separation between the production zone and the depth of local water wells. In certain areas of the basin, this distance is less than 100 ft (31 m) (Watts, 2006). Many of these areas are shallower in depth, and fracture growth has been shown to be primarily horizontal, rather than vertical, at less than 2,000 ft (600 m) from the surface (Fisher and Warpinski, 2012). Nevertheless, the possibility of an out-of-zone fracture reaching a drinking water resource is more likely in a setting with less vertical separation than with more.

Even if an out-of-zone fracture does not extend into a drinking water resource, it could connect to other permeable subsurface features, such as natural fractures or faults, which could then connect to a drinking water resource. Thus, properties of the intervening rock can also make this pathway more or less frequent or likely. For instance, in the Pavillion gas field in Wyoming, there are no laterally-continuous confining layers to prevent upward movement of fluids into the groundwater (Digiulio and Jackson, 2016). While flow of subsurface fluids generally tends to be downward, local areas of upward flow have been observed (Digiulio and Jackson, 2016).

There are cases of hydraulic fracturing without vertical separation between the drinking water resource and the production zone (Figure 10-3). The co-location of the oil or gas formation with the drinking water resource is the factor affecting the frequency of an impact in these cases. Directly fracturing into a drinking water resource causes an impact because it changes the quality of the resource by introducing hydraulic fracturing fluids. The EPA's Well File Review found an estimated 0.4% of the wells represented in the study had perforations used for hydraulic fracturing shallower than the base of the protected groundwater resource, as reported by well operators (U.S. EPA, 2015n). The EPA's Well File Review did not examine these instances by formation type. This practice may be concentrated in locations in western states, especially in CBM plays. Examples include the Raton Basin in Colorado (U.S. EPA, 2015k), the San Juan Basin of Colorado and New

Mexico (U.S. EPA, 2004a), and the Powder River Basin of Montana and Wyoming (Dahm et al., 2011; ALL Consulting, 2004; U.S. EPA, 2004a). This is a concern in the short term (should there be people using these drinking water resources currently) and the long term (if drought or other conditions necessitate the future use of these drinking water resources). For the most part in this chapter, we focused on factors which can be managed, changed, or used to identify areas to target monitoring efforts. In this situation, hydraulic fracturing directly into a drinking water resource would need to cease if it was decided the resulting impacts to drinking water resource quality were unacceptable.

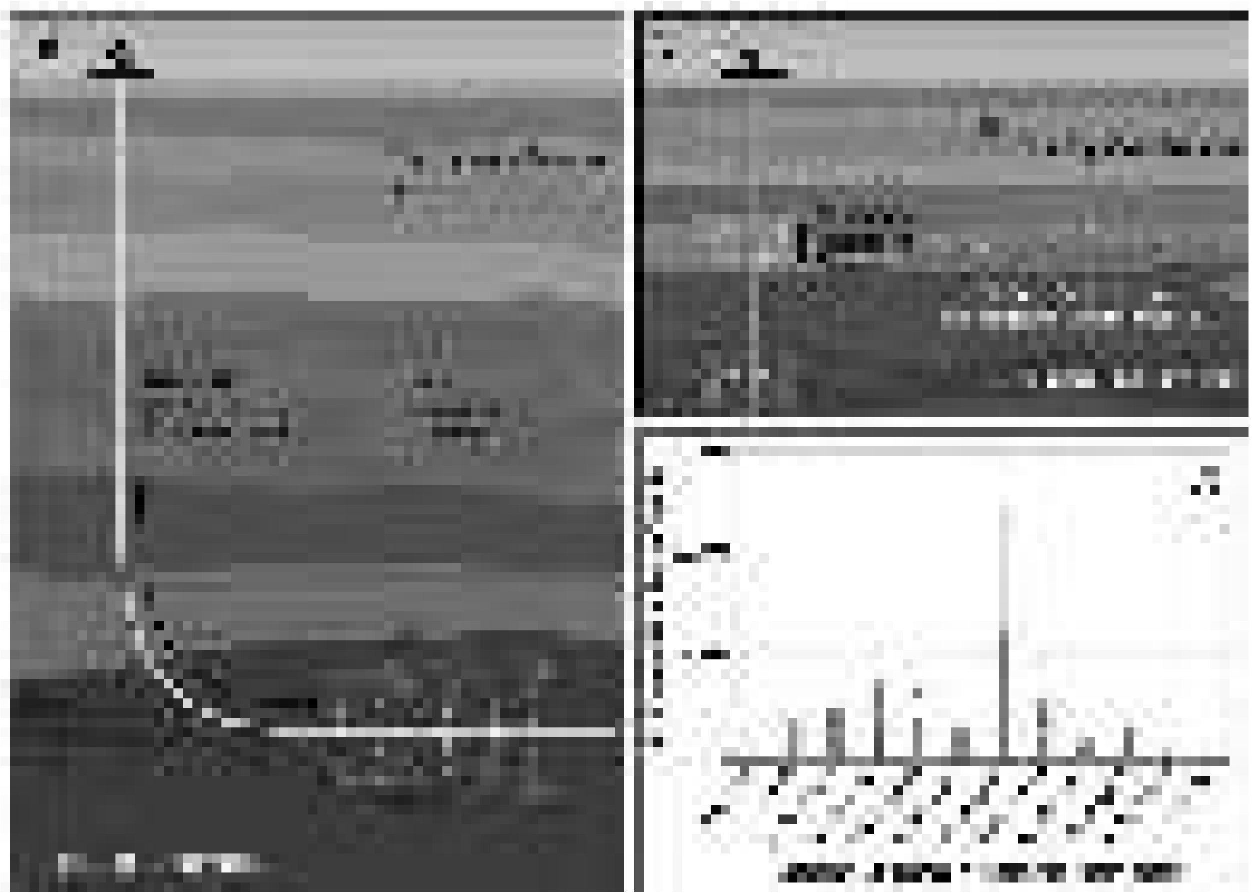

Figure 10-3. Separation in measured depth between drinking water resources and hydraulically fractured intervals in wells.

In panel (a), the oil- and gas-bearing formation (dark gray) being hydraulically fractured is much deeper than the depth where drinking water resources (light blue) exist, and hence a comparatively large separation distance exists. In panel (b), there are two oil- and gas-bearing formations (dark gray and grayish blue) being hydraulically fractured. The shallower formation has no separation distance, because the water also contained in this formation is a drinking water resource. Panel (b) also shows another subsurface drinking water zone at a shallower depth (light blue). Multiple groundwater zones of varying qualities can exist between the production zone and the surface. These two panels depict end-member cases of separation distance: from large separation distances to no separation distance. The graph in panel (c) illustrates the distribution of separation distances among the approximately 23,000 oil and gas production wells hydraulically fractured by nine service companies between 2009 and 2010 (U.S. EPA, 2015n). Error bars in the panel (c) display 95% confidence intervals.

Lastly, the presence of gas, as opposed to liquids, in the subsurface may be a factor affecting the frequency of impacts from fluid movement via defects or deficiencies in the well (pathway #1), or through the fracture network (pathway #2). The low density of gas compared to liquids makes it buoyant, which creates an upward drive toward the surface. Thus, gas found in the subsurface, such as methane, can exploit pathways in a well (such as along a well lacking mechanical integrity), or in the surrounding rock (such as induced or naturally occurring fractures). If a pathway exists and gas is present, it can reach groundwater used for drinking. Consequently, gases could be more likely to contaminate drinking water resources than liquids (Li et al., 2016a).

10.1.3.2 Severity

The well injection chapter (Chapter 6) focused primarily on the potential for impacts to occur and factors affecting frequency. By contrast, we have little-to-no information on factors affecting the severity of impacts for this stage of the hydraulic fracturing water cycle. Severity would likely be affected by the chemical composition of the fluid entering the drinking water resource; the volume of the fluid; the duration in which that volume is delivered; and the concentration of the fluid and its specific components, among other factors. Logically, the relatively simple pathway of a mechanical integrity failure might result in the highest fluid volume delivered to a drinking water resource over a short period of time—e.g., contamination of water wells in Bainbridge Township, Ohio. By contrast, fluid movement through a fracture network, then through the intervening rock, and finally into a drinking water resource may take a longer time and deliver a comparatively lower volume. Even in this case, however, the impacts could still be severe if the fluid movement was to go undetected and unaddressed.

10.1.4 Wastewater Disposal and Reuse

The last stage of the hydraulic fracturing water cycle is wastewater disposal and reuse. Produced water from hydraulically fractured oil or gas production wells is managed predominantly through disposal in underground Class II wells. Secondarily, it is disposed of via other practices, such as discharge to surface waters or disposal in pits or evaporation ponds, or reused in other hydraulic fracturing operations. Activities in the wastewater disposal and reuse stage of the hydraulic fracturing water cycle can impact drinking water resources in some instances. Two such activities are: the discharge of inadequately treated wastewater to surface water, and the storage or disposal of wastewater in unlined pits or impoundments leading to contamination of surface water or groundwater. In this section, we address factors increasing or decreasing the frequency or severity of impacts from these activities. As in the water acquisition section, we combine our discussion of frequency and severity here.

10.1.4.1 Frequency and Severity

Discharge of inadequately treated wastewater has impacted surface water. The quality of the wastewater discharged is a factor affecting the frequency and severity of impacts. This factor is a function of the chemical characteristics of the wastewater prior to treatment (i.e., the composition and concentration of chemicals in the wastewater) and the efficacy of the treatment process. The pre-2011 treatment of Marcellus wastewater in Pennsylvania illustrates this combination. In

Pennsylvania before 2011, wastewater from shale gas operations was treated at centralized waste treatment facilities (CWTs) and publicly owned treatment works (POTWs). The POTWs and some CWTs at the time were not equipped to adequately treat high TDS wastewater. This resulted in wastewater discharges containing elevated levels of TDS, including bromide and iodide, to surface waters.

The elevated levels of TDS raised concerns about the formation of disinfection byproducts (DBPs) after treatment at downstream drinking water facilities. Disinfection byproducts are formed when organic material comes in contact with disinfectants (e.g., chlorine, chloramine, chlorine dioxide or ozone). Many DBPs have long-term health effects including an increased risk of cancer, anemia, liver and kidney effects, and central nervous system effects. Of particular concern are DBPs formed in the presence of bromide or iodide, which are considered particularly toxic. Management of DBPs places a burden on downstream drinking water utilities. Concerns regarding elevated TDS (in particular high bromide) and the potential for formation of DBPs led the PA DEP to take steps in 2010 and 2011 to route Marcellus Shale wastewater away from POTWs and CWTs (that could not treat for TDS) to alternate options such as disposal via injection wells, on-site reuse, or reuse after limited treatment at CWTs. By 2014, only a small percentage (approximately less than 1%) of Marcellus wastewater went to CWTs permitted to discharge to surface waters (Figure 10-1). Additionally, the new EPA pretreatment standards prohibit oil and gas operators from sending unconventional oil and gas wastewater directly to POTWs (U.S. EPA, 2016d).

The combination of wastewater composition and inadequate treatment have also resulted in the discharge of other constituents such as barium, strontium, and radium into surface waters in Pennsylvania. Marcellus Shale wastewater contains radium, naturally occurring in the subsurface formation. Radium has been found in stream sediments at discharge points for POTWs and CWT facilities that have accepted Marcellus Shale wastewater. The ratio of radium isotopes (radium-228 to radium-226) in these sediments is consistent with ratios in Marcellus Shale wastewater (Warner et al., 2013a). Radium-226, with a half-life of approximately 1,600 years, causes long-term contamination. The practice of management of wastewaters via POTWs and CWTs without TDS removal has declined, yet it remains uncertain whether the discharge of radionuclides to surface waters from the oil and gas industry in Pennsylvania has ceased entirely (PA DEP, 2015b).

The storage or disposal of wastewater in pits or impoundments can also lead to contamination of surface water or groundwater resources. This can occur via surface spills or overflows. It can also occur via infiltration into the soil and percolation to groundwater through the pit itself. Whether the pit or impoundment is lined is an important factor affecting the frequency and severity of impacts on groundwater due to subsurface leaching. Historically, unlined pits have been used to dispose of wastewater via percolation (or evaporation). While this practice has been banned in most states, it is allowed in certain locations or instances (e.g., storage of wastewater, but not disposal) as of July 2016. Even where prohibited, unpermitted unlined disposal or storage pits exist. For example, approximately 1,000 unlined storage or disposal pits of oil and gas wastewater are located in the Central Valley Region of California (California State Water Resources Control Board, 2016; Esser et al., 2015). Of these, approximately 60% were still active as of July 2016, and roughly 20% of those pits lacked permits (CA Water Board, 2016).

Unlined pits have been shown to cause contamination of drinking water resources. The presence of BTEX (benzene, toluene, ethylbenzene, and xylenes) and other organics in groundwater are linked to pits in California and New Mexico (California Regional Water Quality Control Board Central Valley Region, 2015; Sumi, 2004; Eiceman, 1986). Groundwater impacts downgradient of an unlined pit in Oklahoma included high salinity (3500-25,600 mg/L) and the presence of volatile organic compounds (Kharaka et al., 2002). Impacts can also occur in the case of disposal of relatively low TDS wastewater (Healy et al., 2011; Healy et al., 2008). For example, a CBM wastewater impoundment in the Powder River Basin of Wyoming resulted in high concentrations of TDS, chloride, nitrate, and selenium in the groundwater (Healy et al., 2011; Healy et al., 2008). Total dissolved solids exceeded 100,000 mg/L in one groundwater sample, despite the much lower concentrations (2,300 mg/L) in the wastewater being discharged (Healy et al., 2008). Most of the solutes found in the groundwater did not originate with the CBM wastewater, but rather resulted from dissolution of previously existing salts and minerals in the subsurface. Lining pits or using closed-loop systems (i.e., tanks) can decrease the frequency of such impacts.

10.1.5 Summary

In the above section, we synthesized the information in this assessment by discussing factors increasing or decreasing the frequency or severity of impacts from activities in the hydraulic fracturing water cycle. We focused particularly on factors that could be managed, changed, or used to identify locations for additional monitoring or alteration of practices. Based on the information reviewed, we conclude the following combinations of activities and factors are more likely than others to result in more frequent or more severe impacts:

- Water withdrawals for hydraulic fracturing in times or areas of low water availability, particularly in areas with limited or declining groundwater resources;
- Spills during the management of hydraulic fracturing fluids and chemicals or produced water that result in large volumes or high concentrations of chemicals reaching groundwater resources;
- Injection of hydraulic fracturing fluids into wells with inadequate mechanical integrity, allowing gases or liquids to move to groundwater resources;
- Injection of hydraulic fracturing fluids directly into groundwater resources;
- Discharge of inadequately treated hydraulic fracturing wastewater to surface water resources; and
- Disposal or storage of hydraulic fracturing wastewater in unlined pits, resulting in contamination of groundwater resources.

Conversely, the scientific literature and data provide evidence that certain factors can reduce the frequency or severity of impacts. Based on the information reviewed in this assessment, we conclude the following factors are likely to reduce the frequency or severity of impacts:

- Passby flows, or low-flow criteria, for surface water withdrawals, and the use of brackish groundwater or reused wastewater as substitutes for fresh water withdrawals;

- Implementation of spill prevention and response measures;
- Design and placement of well casing and cement able to withstand the stresses imposed by hydraulic fracturing (including identifying the depth of the drinking water resource at the point of drilling, and setting and cementing casings through the entire drinking water resource);
- Confirming mechanical integrity of oil and gas wells prior to, during, and after hydraulic fracturing, and correcting deficiencies if necessary;
- Identification of active or abandoned wells near hydraulic fracturing operations and, if necessary, adjustment of the operations to minimize well-to-well communication and/or plugging improperly abandoned wells;
- The use of treatment technologies to remove TDS, and other constituents, such as radium, when present prior to discharge; and
- Storage of wastewater in lined pits or the use of closed-loop systems instead of pits.

The above factors are not the only factors that can reduce the frequency or severity of impacts, yet are the ones most emphasized by the information reviewed for this assessment. It should be noted that the above factors reduce, but do not completely eliminate, the possibility of an impact occurring. In the case of hydraulic fracturing directly into a drinking water resource or disposal of wastewater via unlined pits, we did not identify factors which could reduce the frequency or severity of impacts, besides restricting the activity itself.

10.2 Uncertainties and Data Gaps

In this assessment, we identified impacts on drinking water resources in all stages of the hydraulic fracturing water cycle and described the factors affecting the frequency or severity of impacts. The major conclusions presented above (in Section 10.2.5) are the strongest conclusions based on data and information synthesized for the assessment.

There were also many areas within the assessment for which strong conclusions could not be reached. This was because of the lack of publicly available data and large uncertainties in available sources of information. Below, we provide perspective on what data gaps and uncertainties prevented us from drawing additional strong conclusions about the potential for impacts and/or the factors affecting the frequency or severity of impacts.

We encountered uncertainties associated with, and gaps in, aggregated, publicly accessible information about both activities in the hydraulic fracturing water cycle and groundwater data. In general, comprehensive information on the location of activities in the hydraulic fracturing water cycle is lacking, either because it is not collected, not publicly-available, or prohibitively difficult to aggregate. Thus, we lacked complete information on the geographic locations of well sites (both new and existing) where the chemical mixing, well injection, and produced water handling stages take place; the depth(s) of zones that have been hydraulically fractured in these wells; where water is being acquired (i.e., the source water) for hydraulic fracturing; and where hydraulic fracturing wastewater is treated and/or disposed. FracFocus provided data on well locations, and water and other chemicals used at those locations. However, reporting to FracFocus at the time period studied was not always required, making it difficult to determine the completeness or representativeness of the information.

In addition, there are uncertainties about where groundwater resources are located. This includes the thickness of the resource, from its top to its lowest depth, and its relation to the shallowest depth where hydraulic fracturing occurred. If comprehensive data about the locations of both drinking water resources and activities in the hydraulic fracturing water cycle were available, it would have been possible to more completely identify areas in the United States where hydraulic fracturing-related activities and drinking water resources overlap.

There are also uncertainties and data gaps related to chemicals used in hydraulic fracturing fluid and those detected in produced water. Some chemicals and chemical mixtures remain undisclosed because of confidential business information (CBI) claims. Well operators claimed at least one chemical as CBI at more than 70% of disclosures reported to FracFocus between 2011 and early 2013. Data suggests this practice is increasing. Konschnik and Dayalu (2016) reported that 92% of FracFocus disclosures submitted between approximately March 2011 and April 2015 included at least one chemical claimed as confidential. When chemicals are claimed as CBI, there is no public means of accessing information on these chemicals. Furthermore, many of the chemicals and chemical mixtures disclosed, or those detected in produced water, lack information on properties affecting their movement, persistence, and toxicity in the environment should they be spilled. Better information on these chemicals would allow for a more robust evaluation of potential human health hazards posed, and thus a better understanding about the severity of impacts should the chemicals reach drinking water resources.

In places where we know hydraulic fracturing water cycle activities have occurred, data to assess impacts are often either not collected or are not publicly available in accessible forms. Specifically, local water quality monitoring and well mechanical integrity integrity data are not consistently collected or readily available. In particular, sufficient baseline data on local water quality are needed to quantify any changes post-hydraulic fracturing. There are exceptions to this, for example, the state of California recently implemented a plan to make water quality monitoring information public (Text Box 10-1). In general, however, the limited amount of data collected before, during, and after hydraulic fracturing activities and made public, reduces the ability to determine whether hydraulic fracturing affected drinking water resources.

Text Box 10-1. Hydraulic Fracturing and Groundwater Quality Monitoring in California.

In July 2015, the California Water Resources Control Board adopted Senate Bill 4 (SB4), *Model Criteria for Groundwater Monitoring in Areas of Oil and Gas Well Stimulation*. This resolution directed the establishment of a "comprehensive regulatory groundwater monitoring and oversight program...in order to assess the potential effects of well stimulation treatment activities on the state's groundwater resources" (California State Water Resources Control Board, 2015). The adoption of SB4 concluded a multi-year process, which incorporated stakeholder engagement, review by the public, and consultation with an expert scientific panel.

(Text Box 10-1 is continued on the following page.)

Text Box 10-1 (continued). Hydraulic Fracturing and Groundwater Quality Monitoring in California.

The recommendations of the expert panel informed the creation and implementation of SB4 with respect to criteria "to be used for assessment, sampling, analytical testing, and reporting of water quality associated with oil and gas well stimulation activities" (Esser et al., 2015).

The resolution requires two different scales of groundwater monitoring for different purposes. First, it requires well-by-well (also called "area-specific") groundwater monitoring by well operators. This includes groundwater monitoring conducted for all hydraulic fracturing projects initiated after July 2015. Each oil or gas production well operator must submit a design and timeline for monitoring groundwater resources in proximity to its proposed well. The State Water Resources Control Board approves the monitoring plan before hydraulic fracturing can proceed. The groundwater monitoring plan must include:

- The installation of monitoring wells within 0.5 miles of the wellhead. At least one monitoring well must be upgradient of the production well and two monitoring wells must be downgradient. Should the production well penetrate more than one protected groundwater resource (as defined by the resolution), monitoring wells must facilitate sampling of at least one that is shallow and one that is deep.
- A monitoring timeline that includes sampling prior to production well construction and hydraulic fracturing, as well as semi-annual sampling after completion.
- A list of water quality parameters and constituents to be monitored, including TDS, specific metals, and specific organic compounds.

The area-specific monitoring requirements also include submission of information by well operators about geologic and human-made features in the subsurface that could serve as pathways for impacts to groundwater, aspects of production well construction, and hydraulic fracturing fluid composition.

Second, a regional groundwater monitoring program will document trends in baseline water quality and locate protected groundwater state-wide. In addition to monitoring for trends in groundwater quality related to activities at well sites, it will also be designed to detect trends related to impacts from wastewater disposal practices.

All data from the monitoring programs will be publicly accessible in a state-maintained database. The database is intended to support public health, scientific, and academic needs, as well as future "investigation, assessment, and research relevant to oil and gas development impacts on groundwater quality" (Esser et al., 2015).

Together, the data and information collected and made publicly available as part of the area-specific and regional groundwater monitoring in California will help fill data gaps identified in this section of the assessment by locating groundwater resources, monitoring drinking water resources at spatial and temporal scales relevant for detecting impacts from activities in the hydraulic fracturing water cycle, and distinguishing impacts from hydraulic fracturing activities from the impacts of other potential sources.

In the cases where effects are suspected, it is often difficult to separate the potential effects of hydraulic fracturing activities from effects of broader oil and gas industry activities and other industries or causes. The use of long-lasting, mobile tracer chemicals added to hydraulic fracturing fluids to monitor for impacts has been proposed (Kurose, 2014), but has received relatively little attention in the scientific literature as of mid-2016. Instead, measured changes in water quality parameters can be associated with, but not necessarily diagnostic of, impacts from hydraulic fracturing activities. For instance, measurable changes in methane levels, TDS, ratios of geochemical constituents, and isotopic ratios might suggest impacts from hydraulic fracturing but could also be from other sources, either natural or anthropogenic. To try to assign a cause, these measurements often have to be followed with further collection of evidence supporting or refuting hydraulic fracturing activities as the cause of the changes. (See Text Box 10-2 for discussion of causal assessments.)

Text Box 10-2. Causal Assessment and Hydraulic Fracturing Water Cycle Activities.

A number of recent studies have conducted regional-scale assessments of trends in water quality in areas with hydraulic fracturing activity, showing either no trend or trends linked temporally or spatially with hydraulic fracturing (Burton et al., 2016; Hildenbrand et al., 2016; Hildenbrand et al., 2015; Siegel et al., 2015; Darrah et al., 2014; Fontenot et al., 2013; Warner et al., 2013b) Regional assessments can be important for integrating information over broader scales, and for posing hypotheses about how hydraulic fracturing water cycle activities may impact drinking water resources. Oftentimes, however, activities in the hydraulic fracturing water cycle are merely one of several possible causes of an observed change in water quality or quantity at a specific site. In this case, more thorough, site-specific investigations are often necessary. Causal assessment (also called causal analysis) involves collecting multiple kinds of evidence to determine which of several possible causes of contamination is most likely.

Causal assessment requires several steps. First, the spatial and temporal scope of the issue is defined, including a description of all the possible causes of an observed impact, in this case the change in quality or quantity of a drinking water resource. Once this is done, evidence is collected and assembled to support or refute the potential causes. Evidence indicating how a potential cause and an observed effect are related in time can help support or refute potential causes. Other kinds of evidence can also be useful in identifying a cause, including: determining whether the composition and volume of a leaked, spilled, or treated and discharged fluid are capable of causing observed impacts on water quality; and determining whether a physical pathway between a well or well site exists by measuring the mechanical integrity of hydraulically fractured wells and/or establishing the presence/absence of a contaminant plume.

Ideally, the evidence helps exclude possible causes of the reported contamination, narrowing down the list of potential causes to a single cause. Causal assessments can take a long time to complete and can require a lot of resources and expertise. In some situations, available data and resources are simply not sufficient to definitively identify the cause. Nevertheless, causal assessments conducted in a consistent and transparent way can help enable the identification of the likely cause(s) of contamination of drinking water resources.

The retrospective case studies conducted by the EPA under the Study Plan are examples of scientific investigations using a multiple lines of evidence approach consistent with the principles of causal assessment (U.S. EPA, 2015i, j, l, 2014f, g). These case studies were cited throughout this report. For instance, as noted previously, the Killdeer, North Dakota case study found that an inner string of casing burst during hydraulic fracturing of an oil well, resulting in a release of hydraulic fracturing fluids and formation fluids that impacted a groundwater resource (U.S. EPA, 2015i). Following an analysis of potential sources, the only potential source consistent with the conditions observed was the ruptured well (U.S. EPA, 2015i).

Regardless of whether a single cause can be determined, actions can still be taken to mitigate one or more potential causes of contamination. Information gained once the suspected activity has been halted or at least reduced could elucidate whether hydraulic fracturing operations are more or less likely to have been the source of the contamination.

Many members of the public are interested in understanding the national frequency of impacts to drinking water resources from activities across the entire hydraulic fracturing water cycle. Because of the significant data gaps and uncertainties in the available data, it was not possible to estimate the national frequency of impacts to drinking water resources from activities in the hydraulic fracturing water cycle collectively. We were, however, able to estimate impact frequencies in some, limited cases within the larger hydraulic fracturing water cycle (i.e., spills of hydraulic fracturing fluids or produced water, and mechanical integrity failures). These more specific estimates had a high degree of uncertainty, but were the best estimates that could be provided with the data and literature currently available.

Finally, it should be recognized that this assessment is a snapshot in time. Our understanding of the factors affecting the frequency or severity of impacts may change in the future as industry practices evolve and new information becomes available.

10.3 Use of this Assessment

This assessment contributes to the understanding of the potential impacts to drinking water resources by activities in the hydraulic fracturing water cycle and the factors influencing those impacts. The scientific information presented can be used by federal, tribal, state, and local officials; industry; and the public to better understand and address vulnerabilities of drinking water resources to activities in the hydraulic fracturing water cycle.

The uncertainties and data gaps identified throughout this assessment could be used to identify future data collection efforts. Data collection efforts could include, for example, surface water and groundwater monitoring programs in areas with hydraulically fractured oil and gas production wells; collection and the public dissemination of data on the condition of hydraulically fractured wells; or targeted research programs to better characterize the environmental fate and transport and human health hazards associated with chemicals in the hydraulic fracturing water cycle. Data collected and analyzed through new data collection efforts may identify new factors increasing or decreasing the frequency or severity of impacts.

In the near term, decision-makers could focus their attention on the combinations of activities and factors that we conclude are more likely than others to result in more frequent or more severe impacts (Section 10.2.5). By focusing attention on the above combinations, impacts to drinking water resources from activities in the hydraulic fracturing water cycle can be prevented or reduced.

Overall, the practice of hydraulic fracturing is expanding and continues to change. Oil and gas production associated with hydraulic fracturing was insignificant in 2000, but by 2015 it accounted for an estimated 51% of U.S. oil production and 67% of U.S. gas production (EIA, 2016c, d). The number of wells drilled and hydraulically fractured is likely to continue to increase in the coming decades (EIA, 2014a). The work of evaluating potential impacts from combinations of activities and factors in the hydraulic fracturing water cycle will need to keep pace with this industry and as new scientific studies are produced. This assessment provides a foundation for those efforts, while offering information to support the reduction of current vulnerabilities of drinking water resources.

Executive Summary

> A USDW is defined as an aquifer or a portion of an aquifer that:
> A. 1. *Supplies any public water system; or*
> 2. *Contains sufficient quantity of groundwater to supply a public water system; and*
> i. *currently supplies drinking water for human consumption; or*
> ii. *contains fewer than 10,000 milligrams per liter (mg/L) total dissolved solids (TDS); and*
> B. *Is not an exempted aquifer.*
>
> ***NOTE***: Although aquifers with greater than 500 mg/L TDS are rarely used for drinking water supplies without treatment, the Agency believes that protecting waters with less than 10,000 mg/L TDS will ensure an adequate supply for present and future generations.

The U.S. Environmental Protection Agency (EPA, or the Agency) conducted a study that assesses the potential for contamination of underground sources of drinking water (USDWs) from the injection of hydraulic fracturing fluids into coalbed methane (CBM) wells. To increase the effectiveness and efficiency of the study, EPA has taken a phased approach. Apart from using real world observations and gathering empirical data, EPA also evaluated the theoretical potential for hydraulic fracturing to affect USDWs. Based on the information collected and reviewed, EPA has concluded that the injection of hydraulic fracturing fluids into CBM wells poses little or no threat to USDWs and does not justify additional study at this time. EPA's decision is consistent with the process outlined in the April, 2001 Final Study Design, which is described in Chapter 2 of this report.

The first phase of the study, documented in this report, is a fact-finding effort based primarily on existing literature to identify and assess the potential threat to USDWs posed by the injection of hydraulic fracturing fluids into CBM wells. EPA evaluated that potential based on two possible mechanisms. The first mechanism was the direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system). The second mechanism was the creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

EPA also reviewed incidents of drinking water well contamination believed to be associated with hydraulic fracturing and found no confirmed cases that are linked to fracturing fluid injection into CBM wells or subsequent underground movement of fracturing fluids. Although thousands of CBM wells are fractured annually, EPA did not find confirmed evidence that drinking water wells have been contaminated by hydraulic fracturing fluid injection into CBM wells.

EPA has determined that in some cases, constituents of potential concern (section ES-6) are injected directly into USDWs during the course of normal fracturing operations. The use of diesel fuel in fracturing fluids introduces benzene, toluene, ethylbenzene, and xylenes (BTEX) into USDWs. BTEX compounds are regulated under the Safe Drinking Water Act (SDWA).

Given the concerns associated with the use of diesel fuel and the introduction of BTEX constituents into USDWs, EPA recently entered into a Memorandum of Agreement (MOA) with three major service companies to voluntarily eliminate diesel fuel from hydraulic fracturing fluids that are injected directly into USDWs for CBM production (USEPA, 2003). Industry representatives estimate that these three companies perform approximately 95 percent of the hydraulic fracturing projects in the United States. These companies signed the MOA on December 15, 2003 and have indicated to EPA that they no longer use diesel fuel as a hydraulic fracturing fluid additive when injecting into USDWs.

ES-1 How Does CBM Play a Role in the Nation's Energy Demands?

CBM production began as a safety measure in underground coalmines to reduce the explosion hazard posed by methane gas (Elder and Deul, 1974). In 1980, the U.S. Congress enacted a tax credit for non-conventional fuels production, including CBM production, as part of the Crude Oil Windfall Profit Act. In 1984, there were very few CBM wells in the U.S.; by 1990, there were almost 8,000 CBM wells (Pashin and Hinkle, 1997). In 1996, CBM production in 12 states totaled about 1,252 billion cubic feet, accounting for approximately 7 percent of U.S. gas production (U.S. Department of Energy, 1999). At the end of 2000, CBM production from 13 states totaled 1.353 trillion cubic feet, an increase of 156 percent from 1992. During 2000, a total of 13,973 CBM wells were in production (GTI, 2001; EPA Regional Offices, 2001). According to the U.S. Department of Energy, natural gas demand is expected to increase at least 45 percent in the next 20 years (U.S. Department of Energy, 1999). The rate of CBM production is expected to increase in response to the growing demand.

In evaluating CBM production and hydraulic fracturing activities, EPA reviewed the geology of 11 major coal basins throughout the United States (Figure ES-1). The basins shown in red have the highest CBM production volumes. They are the Powder River Basin in Wyoming and Montana, the San Juan Basin in Colorado and New Mexico, and the Black Warrior Basin in Alabama. Hydraulic fracturing is or has been used to stimulate CBM wells in all basins, but it has not frequently been used in the Powder River, Sand Wash, or Pacific Coal Basins. Table ES-1 provides production statistics for 2000 and information on hydraulic fracturing activity for each of the 11 basins in 2000.

Figure ES-1. Major United States Coal Basins

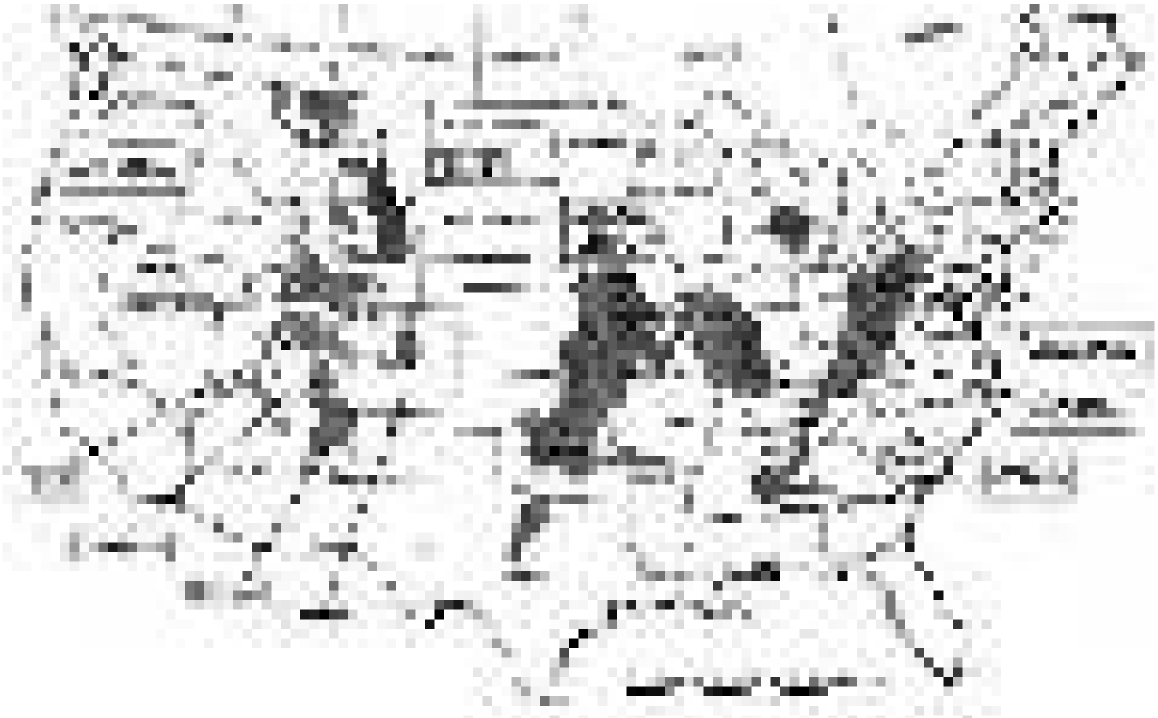

Table ES-1. Coal Basins Production Statistics and Activity Information in the U.S.

Basin	Number of CBM Producing Wells (Year 2000)*	Production of CBM in Billions of Cubic Feet (Year 2000)*	Does Hydraulic Fracturing Occur?
Powder River	4,200	147	Yes (but infrequently)
Black Warrior	3,086	112	Yes
San Juan	3,051	925	Yes
Central Appalachian	1,924	52.9	Yes
Raton Basin	614	30.8	Yes
Uinta	494	75.7	Yes
Western Interior	420	6.5	Yes
Northern Appalachian	134	1.41	Yes
Piceance	50	1.2	Yes
Pacific Coal	0	0	Yes (but infrequently)
Sand Wash	0	0	Yes (but infrequently)

* Data provided by the Gas Technology Institute and EPA Regional Offices. Production figures include CBM extracted using hydraulic fracturing and other processes.

ES-2 What Is Hydraulic Fracturing?

CBM gas is not structurally trapped in the natural fractures in coalbeds. Rather, most of the methane is adsorbed to the coal (Koenig, 1989; Winston, 1990; Close, 1993). To extract the CBM, a production well is drilled through the rock layers to intersect the coal seam that contains the CBM. Next, fractures are created or existing fractures are enlarged in the coal seam through which the CBM can be drawn to the well and pumped to the surface.

Figure ES-2 illustrates what occurs in the subsurface during a typical hydraulic fracturing event. This diagram shows the initial fracture creation, fracture propagation, proppant placement, and the subsequent fracturing fluid recovery/groundwater extraction stage of the CBM production process. The actual extraction of CBM generally begins after a period of fluid recovery/groundwater extraction. The hydraulically created fracture acts as a conduit in the rock or coal formation, allowing the CBM to flow more freely from the coal seams, through the fracture system, and to the production well where the gas is pumped to the surface.

To create or enlarge fractures, a thick fluid, typically water-based, is pumped into the coal seam at a gradually increasing rate and pressure. Eventually the coal seam is unable to accommodate the fracturing fluid as quickly as it is injected. When this occurs, the pressure is high enough that the coal fractures along existing weaknesses within the coal (steps 1 and 2 of Figure ES-1). Along with the fracturing fluids, sand (or some other propping agent or "proppant") is pumped into the fracture so that the fracture remains "propped" open even after the high fracturing pressures have been released. The resulting proppant-containing fracture serves as a conduit through which fracturing fluids and groundwater can more easily be pumped from the coal seam (step 3 of Fig. ES-1).

To initiate CBM production, groundwater and some of the injected fracturing fluids are pumped out (or "produced" in the industry terminology) from the fracture system in the coal seam (step 4 of Figure ES-1). As pumping continues, the pressure eventually decreases enough so that methane desorbs from the coal, flows toward, and is extracted through the production well (step 5 of Figure ES-1). In contrast to conventional gas production, the amount of water extracted declines proportionally with increasing CBM production. In some basins, huge volumes of groundwater are extracted from the production well to facilitate the production of CBM.

Figure ES-2. A Graphical Representation of the Hydraulic Fracturing Process in Coalbed Methane Wells (Continued)

ES-3 Why Did EPA Evaluate Hydraulic Fracturing?

SDWA requires EPA and EPA-authorized states to have effective programs to prevent underground injection of fluids from endangering USDWs (42 U.S.C. 300h et seq.). Underground injection is the subsurface emplacement of fluids through a well bore (42 U.S.C. 300h(d)(1)). Underground injection endangers drinking water sources if it may result in the presence of any contaminant in underground water which supplies or can reasonably be expected to supply any public water system, and if the presence of such a contaminant may result in such system's noncompliance with any national primary drinking water regulation (i.e., maximum contaminant levels (MCLs)) or may otherwise adversely affect the health of persons (42 U.S.C. 300h(d)(2)). SDWA's regulatory authority covers underground injection practices, but the Act does not grant authority for EPA to regulate oil and gas production.

In 1997, the Eleventh Circuit Court ruled, in *LEAF v. EPA* [LEAF v. EPA, 118F.3d 1467 (11th Circuit Court of Appeals, 1997)], that because hydraulic fracturing of coalbeds to produce methane is a form of underground injection, Alabama's EPA-approved Underground Injection Control (UIC) Program must effectively regulate this practice. In the wake of the Eleventh Circuit's decision, EPA decided to assess the potential for hydraulic fracturing of CBM wells to contaminate USDWs. EPA's decision to conduct this study was also based on concerns voiced by individuals who may be affected by CBM development, Congressional interest, and the need for additional information before EPA could make any further regulatory or policy decisions regarding hydraulic fracturing.

The Phase I study is tightly focused to address hydraulic fracturing of CBM wells and does not include other hydraulic fracturing practices (e.g., those for petroleum-based oil and gas production) because: (1) CBM wells tend to be shallower and closer to USDWs than conventional oil and gas production wells; (2) EPA has not heard concerns from citizens regarding any other type of hydraulic fracturing; and (3) the Eleventh Circuit litigation concerned hydraulic fracturing in connection with CBM production. The study also does not address potential impacts of non-injection related CBM production activities, such as impacts from groundwater removal or production water discharge. EPA did identify, as part of the fact-finding process, citizen concerns regarding groundwater removal and production water.

ES-4 What Was EPA's Project Approach?

Based on public input, EPA decided to carry out this study in discrete phases to better define its scope and to determine if additional study is needed after assessing the results of the preliminary phase(s). EPA designed the study to have three possible phases, narrowing the focus from general to more specific as findings warrant. This report describes the findings from Phase I of the study. The goal of EPA's hydraulic fracturing Phase I study was to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into CBM wells and to determine based on these findings, whether further study is warranted.

Phase I is a fact-finding effort based primarily on existing literature. EPA reviewed water quality incidents potentially associated with CBM hydraulic fracturing, and evaluated the theoretical potential for CBM hydraulic fracturing to affect USDWs. EPA researched over 200 peer-reviewed publications, interviewed approximately 50 employees from industry and state or local government agencies, and communicated with approximately 40 citizens and groups who are concerned that CBM production affected their drinking water wells.

For the purposes of this study, EPA assessed USDW impacts by the presence or absence of documented drinking water well contamination cases caused by CBM hydraulic fracturing, clear and immediate contamination threats to drinking water wells from CBM hydraulic fracturing, and the potential for CBM hydraulic fracturing to result in USDW contamination based on two possible mechanisms as follows:

1. The direct injection of fracturing fluids into a USDW in which the coal is located (Figure ES-3), or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. The creation of a hydraulic connection between the coalbed formation and an adjacent USDW (Figure ES-4).

Figure ES-3. Hypothetical Mechanisms - Direct Fluid Injection into a USDW (Where Coal Lies Within a USDW or USDWs)

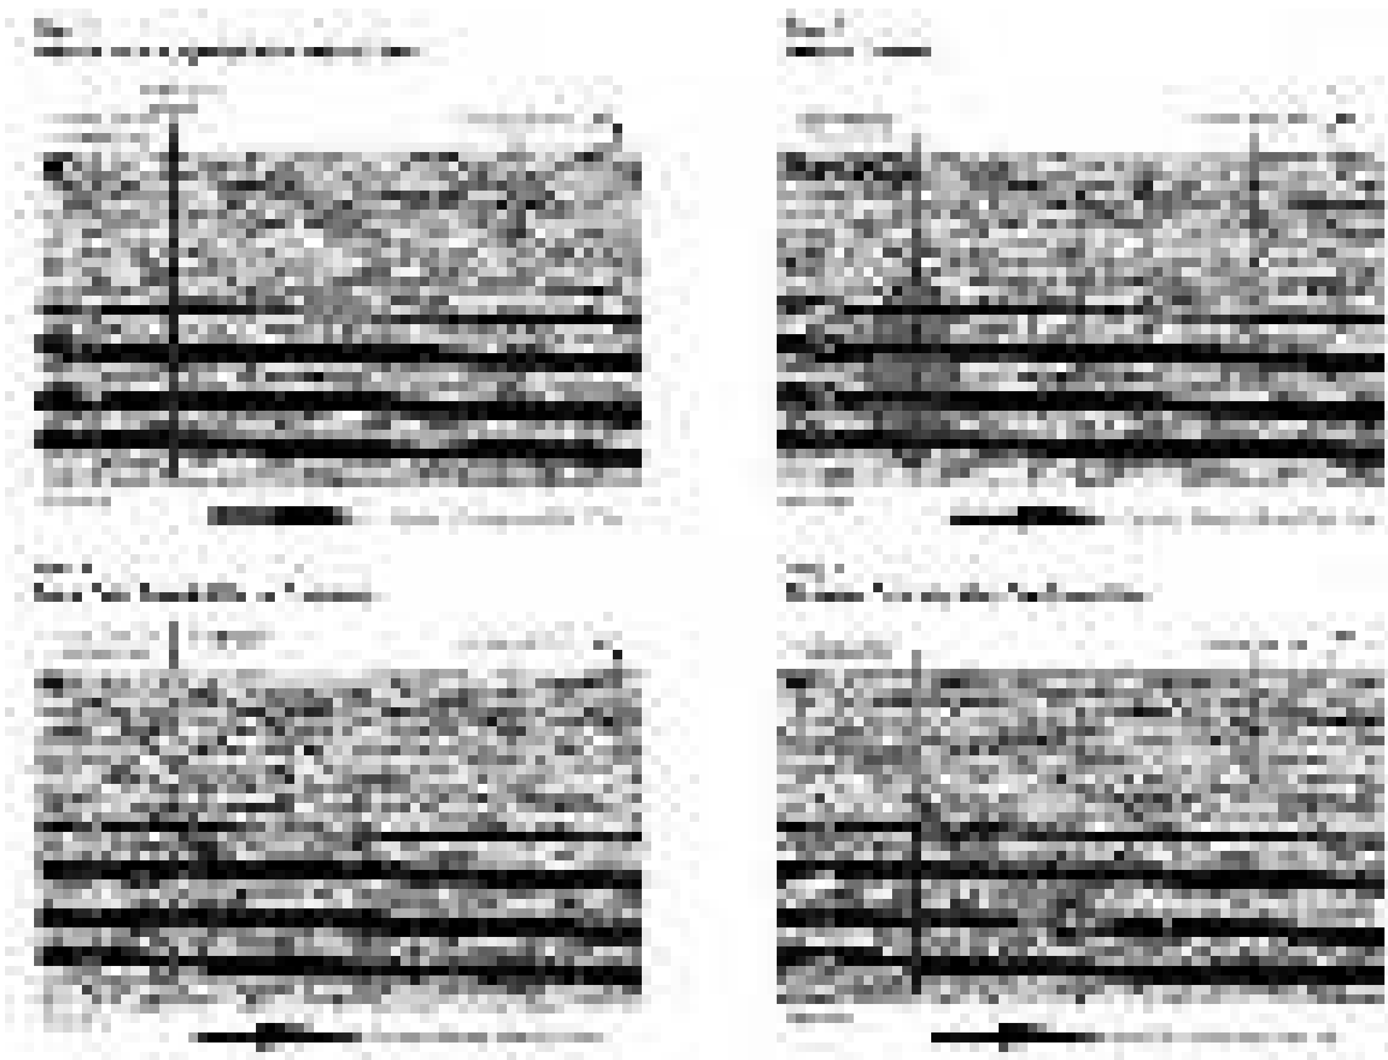

Figure ES-4. Hypothetical Mechanisms - Fracture Creates Connection to USDW

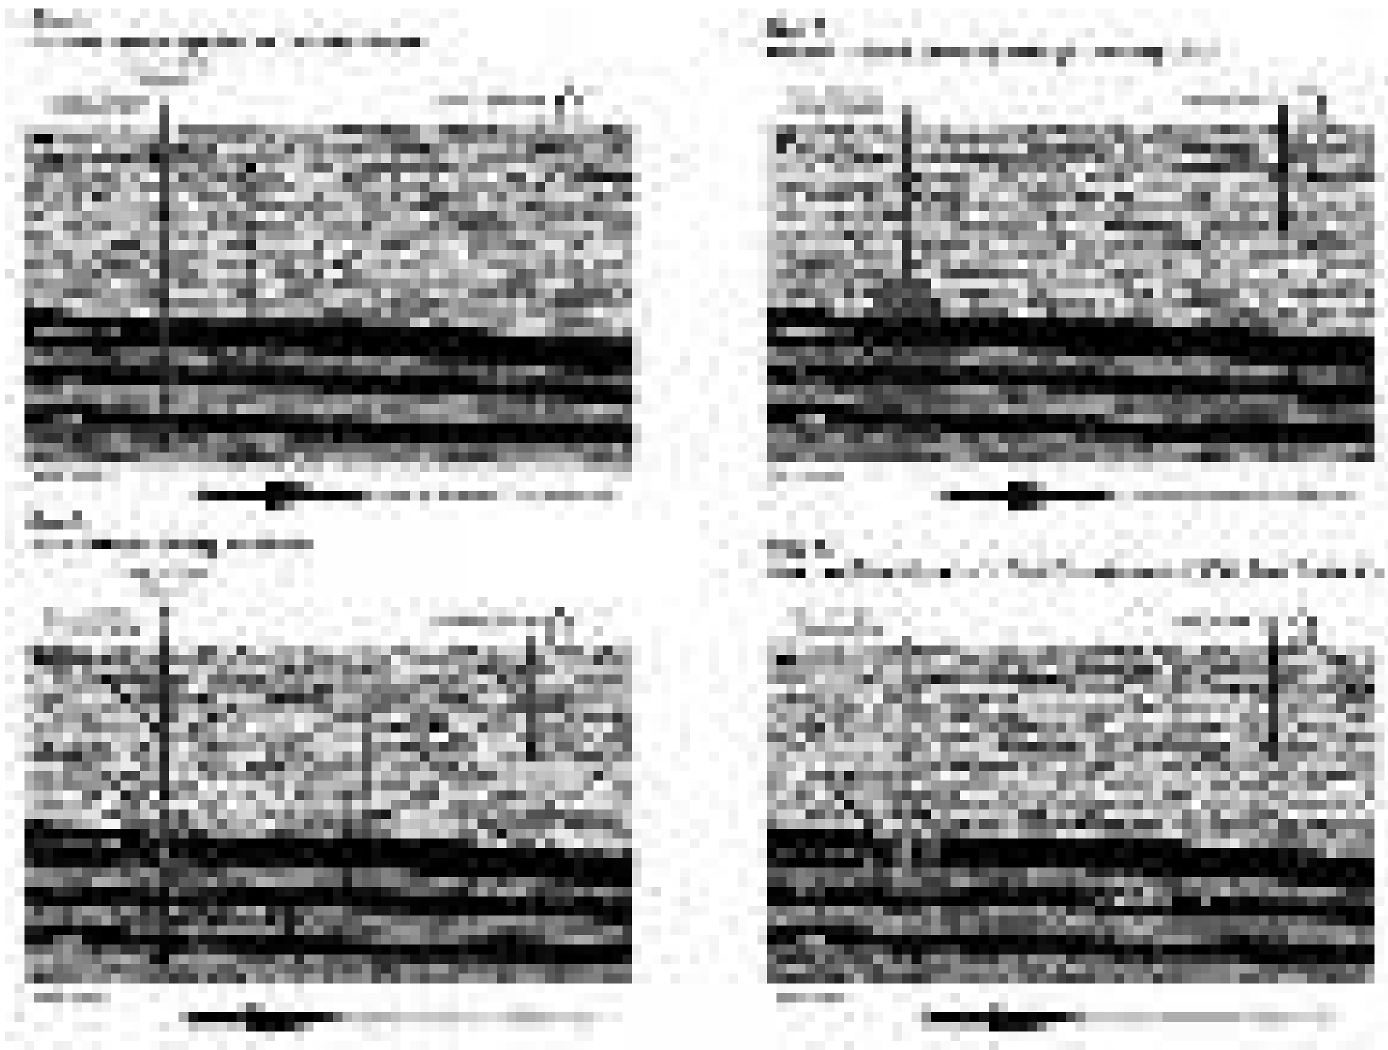

ES-5 How Do Fractures Grow?

In many CBM-producing regions, the target coalbeds occur within USDWs, and the fracturing process injects “stimulation” fluids directly into the USDWs. In other production regions, target coalbeds are adjacent to the USDWs (i.e., either higher or lower in the geologic section). Because shorter fractures are less likely to extend into a USDW or connect with natural fracture systems that may transport fluids to a USDW, the extent to which fractures propagate vertically influences whether hydraulic fracturing fluids could potentially affect USDWs.

The extent of the fractures is difficult to predict because it is controlled by the characteristics of the geologic formation (including the presence of natural fractures), the fracturing fluid used, the pumping pressure, and the depth at which the fracturing is being performed. Fracture behavior through coals, shales, and other geologic strata commonly present in coal zones depends on site-specific factors such as the relative thickness and in-situ stress differences between the target coal seam(s) and the surrounding geologic strata, as well as the presence of pre-existing natural fractures. Often, a high stress contrast between adjacent geologic strata results in a barrier to fracture propagation. An example of this would be where there is a geologic contact between a coalbed and an overlying, thick, higher-stress shale.

Another factor controlling fracture height can be the highly cleated nature of some coalbeds. In some cases, highly cleated coal seams will prevent fractures from growing vertically. When the fracturing fluid enters the coal seam, it is contained within the coal seam's dense system of cleats and the growth of the hydraulic fracture will be limited to the coal seam (see Appendix A).

Deep vertical fractures can propagate vertically to shallower depths and develop a horizontal component (Nielsen and Hansen, 1987, as cited in Appendix A: DOE, Hydraulic Fracturing). In the formation of these "T-fractures," the fracture tip may fill with coal fines or intercept a zone of stress contrast, causing the fracture to turn and develop horizontally, sometimes at the contact of the coalbed and an overlying formation. (Jones et al., 1987; Morales et al., 1990). For cases where hydraulically induced fractures penetrate into, or sometimes through, formations overlying coalbeds, they are most often attributed to the existence of pre-existing natural fractures or thinly inter-bedded layering.

ES-6 What Is in Hydraulic Fracturing Fluids?

Fracturing fluids consist primarily of water or inert foam of nitrogen or carbon dioxide. Other constituents can be added to fluids to improve their performance in optimizing fracture growth. Components of fracturing fluids are stored and mixed on-site. Figures ES-5 and ES-6 show fluids stored in tanks at CBM well locations.

During a hydraulic fracturing job, water and any other additives are pumped from the storage tanks to a manifold system placed on the production wells where they are mixed and then injected under high pressure into the coal formation (Figure ES-6). The hydraulic fracturing in CBM wells may require from 50,000 to 350,000 gallons of fracturing fluids, and from 75,000 to 320,000 pounds of sand as proppant (Holditch et al., 1988 and 1989; Jeu et al., 1988; Hinkel et al., 1991; Holditch, 1993; Palmer et al., 1991, 1993a, and 1993b). More typical injection volumes, based on average injection volume data provided by Halliburton for six basins, indicate a maximum average injection volume of 150,000 gallons of fracturing fluids per well, with a median average injection volume of 57,500 gallons per well (Halliburton, Inc., 2003).

Figure ES-5. Water used for the fracturing fluid is stored on-site in large, upright storage tanks and in truck-mounted tanks.

EPA reviewed material safety data sheets to determine the types of additives that may be present in fracturing fluids. Water or nitrogen foam frequently constitutes the solute in fracturing fluids used for CBM stimulation. Other components of fracturing fluids contain benign ingredients, but in some cases, there are additives with constituents of potential concern. Because much more gel can be dissolved in diesel fuel as compared to water, the use of diesel fuel increases the efficiency in transporting proppant in the fracturing fluids. Diesel fuel is the additive of greatest concern because it introduces BTEX compounds, which are regulated by SDWA.

A thorough discussion of fracturing fluid components and fluid movement is presented in Chapter 4.

Figure ES-6. The fracturing fluids, additives, and proppant are pumped from the storage tanks to a manifold system placed on the wellhead where they are mixed just prior to injection.

ES-7 Are Coalbeds Located within USDWs?

EPA reviewed information on 11 major coal basins to determine if coalbeds are co-located with USDWs and to understand the CBM activity in the area. If coalbeds are located within USDWs, then any fracturing fluids injected into coalbeds have the potential to contaminate the USDW. As described previously, a USDW is not necessarily currently used for drinking water and may contain groundwater unsuitable for drinking without treatment. EPA found that 10 of the 11 basins may lie, at least in part, within USDWs. Table ES-2 identifies coalbed basin locations in relation to USDWs and summarizes evidence used as the basis for the conclusions.

ES-8 Did EPA Find Any Cases of Contaminated Drinking Water Wells Caused by Hydraulic Fracturing in CBM Wells?

EPA did not find confirmed evidence that drinking water wells have been contaminated by hydraulic fracturing fluid injection into CBM wells. EPA reviewed studies and follow-up investigations conducted by state agencies in response to citizen reports that CBM production resulted in water quality and quantity incidents. In addition, EPA received reports from concerned citizens in each area with significant CBM development. These complaints pertained to the following basins:

- San Juan Basin (Colorado and New Mexico);
- Powder River Basin (Wyoming and Montana);
- Black Warrior Basin (Alabama); and
- Central Appalachian Basin (Virginia and West Virginia).

Examples of concerns and claims raised by citizens include:

- Drinking water with strong, unpleasant taste and odor.
- Impacts on fish, and surrounding vegetation and wildlife.
- Loss of water in wells and aquifers, and discharged water creating artificial ponds and swamps not indigenous to region.

Water quantity complaints were the most predominant cause for complaint by private well owners. After reviewing data and incident reports provided by states, EPA sees no conclusive evidence that water quality degradation in USDWs is a direct result of injection of hydraulic fracturing fluids into CBM wells and subsequent underground movement of these fluids. Several other factors may contribute to groundwater problems, such as various aspects of resource development, naturally occurring conditions, population growth, and historical well-completion or abandonment practices. Many of the incidents that were reported (such as water loss and impacts on nearby flora and fauna from discharge of produced water) are beyond the authorities of EPA under SDWA and the scope of Phase I of this study.

ES-9 What Are EPA's Conclusions?

Based on the information collected and reviewed, EPA has determined that the injection of hydraulic fracturing fluids into CBM wells poses little or no threat to USDWs. Continued investigation under a Phase II study is not warranted at this time.

As proposed in the Final Study Design (April 2001), Phase I of the study was a limited–scope assessment in which EPA would:

- Gather existing information to review hydraulic fracturing processes, practices, and settings;

- Request public comment to identify incidents that have not been reported to EPA;

- Review reported incidents of groundwater contamination and any follow-up actions or investigations by other parties (state or local agencies, industry, academia, etc.); and,

- Make a determination regarding whether further investigation is needed, based on the analysis of information gathered through the Phase I effort.

EPA's approach for evaluating the potential threat to USDWs was an extensive information collection and review of empirical and theoretical data. EPA reviewed incidents of drinking water well contamination believed to be associated with hydraulic fracturing and found no confirmed cases that are linked to fracturing fluid injection into CBM wells or subsequent underground movement of fracturing fluids. Although thousands of CBM wells are fractured annually, EPA did not find confirmed evidence that drinking water wells have been contaminated by hydraulic fracturing fluid injection into CBM wells.

EPA also evaluated the theoretical potential for hydraulic fracturing to affect USDWs through one of two mechanisms:

1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

Regarding the question of injection of fracturing fluids directly into USDWs, EPA considered the nature of fracturing fluids and whether or not coal seams are co-located with USDWs. Potentially hazardous chemicals may be introduced into USDWs when fracturing fluids are used in operations targeting coal seams that lie within USDWs. In particular, diesel fuel contains BTEX compounds, which are regulated under SDWA. However, the threat posed to USDWs by the introduction of some fracturing fluid constituents is reduced significantly by the removal of large quantities of groundwater (and injected fracturing fluids) soon after a well has been hydraulically fractured. In fact, CBM production is dependent on the removal of large quantities of groundwater. EPA believes that this groundwater production, combined with the mitigating effects of dilution and dispersion, adsorption, and potentially biodegradation, minimize the possibility that chemicals included in the fracturing fluids would adversely affect USDWs.

Because of the potential for diesel fuel to be introduced into USDWs, EPA requested, and the three major service companies agreed to, the elimination of diesel fuel from hydraulic fracturing fluids that are injected directly into USDWs for CBM production (USEPA, 2003). Industry representatives estimate that these three companies perform approximately 95 percent of the hydraulic fracturing projects in the United States.

In evaluating the second mechanism, EPA considered the possibility that hydraulic fracturing could cause the creation of a hydraulic connection to an adjacent USDW. The low permeability of relatively unfractured shale may help to protect USDWs from being affected by hydraulic fracturing fluids in some basins. If sufficiently thick and relatively unfractured shale is present, it may act as a barrier not only to fracture height growth, but also to fluid movement. Shale's ability to act as a barrier to fracture height growth is primarily due to the stress contrast between the coalbed and the shale. Another factor controlling fracture height can be the highly cleated nature of some coalbeds. In some cases, when the fracturing fluid enters the coal seam, it is contained within the coal seam's dense system of cleats and the growth of the hydraulic fracture will be limited to the coal seam (see Appendix A).

Some studies that allow direct observation of fractures (i.e., mined-through studies) indicate many fractures that penetrate into, or sometimes through, one or more formations overlying coalbeds can be attributed to the existence of pre-existing natural fractures. However, given the concentrations and flowback of injected fluids, and the mitigating effects of dilution and dispersion, adsorption, and potentially biodegradation, EPA does not believe that possible hydraulic connections under these circumstances represent a significant potential threat to USDWs.

It is important to note that states with primary enforcement authority (primacy) for their UIC Programs implement and enforce their regulations, and have the authority under SDWA to place additional controls on any injection activities that may threaten USDWs. States may also have additional authorities by which they can regulate hydraulic fracturing. With the expected increase in CBM production, the Agency is committed to working with states to monitor this issue.

Glossary

Adsorption	*Adhesion of gas molecules, ions or molecules in solution to the surface of solid bodies with which they are in contact.*
Alluvial aquifer	*A water-bearing deposit of unconsolidated material (e.g., sand and gravel) left behind by a river or other flowing water.*
Amphoteric	*Having both basic and acidic properties.*
Anaerobic Bacteria	*Bacteria that thrive in oxygen-poor environments.*
Anisotropic	*Having some physical property that varies with direction from a given location.*
Annulus	*The space between the casing (the material that is used to keep the well stable; typically this material is steel) in a well and the wall of the hole, or between two concentric strings of casing, or between casing and tubing.*
Anticline	*A fold of layered, sedimentary rocks whose core contains stratigraphically older rocks, the shape of the fold is generally convex upward.*
Aureole	*A ring surrounding a volcanic intrusion where the surrounding rock has been altered.*
Azimuth	*The direction of a horizontal line as measured on an imaginary horizontal circle.*
Bedrock aquifer	*An aquifer located in the solid rock underlying unconsolidated surface materials (i.e., sediment). Solid rock can bear water when it is fractured.*
Billion cubic feet	*A unit typically used to define gas production volumes in the coalbed methane industry; 1 Bcf is roughly equivalent to the volume of gas required to heat approximately 12,000 households for one year (based on the Department of Energy's average household energy consumption statistic, 2001).*
Biogenic	*A direct product of the physiological activities of organisms.*
Bituminous	*From the base word bitumen, referring to a general term for various solid and semi-solid hydrocarbons that are able to join together and are soluble in carbon bisulfide (e.g., asphalts).*
Breaker	*A fracturing fluid additive that is added to break down the viscosity of the fluid.*
Breccia	*A coarse-grained clastic rock composed of angular broken rock fragments held together by a mineral cement or a fine-grained matrix.*
Brecciated	*Consisting of angular fragments cemented together.*
Btu	*British thermal unit; a unit of measure used to define energy.*
Butt Cleat	*The coal cleat set that abuts into face cleats.*
Capture Zone	*The portion of an aquifer that contributes water to a particular pumping well.*

Cavitation Cycling	*Also known as cavity completion, an alternative completion technique to hydraulic fracturing, in which a cavity is generated by alternately pumping in nitrogen and blowing down pressure.*
Cleats	*Natural fractures in coal that often occur in systematic sets, through which gas and water can flow.*
CMHPG	*Carboxymethyl hydroxypropylguar; a form of guar gel.*
Craton	*A part of the earth's crust that has attained stability and has been relatively undeformed for a long time; the term is restricted to continents, and includes both shield and platform.*
Crosslinker	*An additive that when added to a linear gel, will create a complex, high viscosity, pseduoplastic fracturing fluid.*
Crosslinked Gel	*A gel to which a crosslinker has been added (see crosslinker).*
Darcy	*A measure of the permeability of rock or sediment.*
Desorption	*Liberation of tightly held methane gas molecules previously bound to the solid surface of the coal.*
Epiclastic	*Formed from the fragments or particles broken away (by weathering and erosion) from pre-existing rocks to form an altogether new rock in a new place.*
Evapotranspiration	*The portion of precipitation returned to the air through evaporation and transpiration.*
Face Cleat	*A coal cleat set that is through-going and continuous.*
Flowback	*The process of causing fluid to flow back to the well out of a fracture after a hydraulic fracturing event is completed.*
Fracture Conductivity	*The capability of the fracture to conduct fluids under a given hydraulic head difference.*
Geophone	*A seismic detector, placed on or in the ground, that responds to ground motion at its point of location.*
Graben	*An elongate, down-dropped block that is bounded by nearly parallel faults on both sides.*
Guar	*Organic powder thickener, typically used to make viscous fracturing fluids, completely soluble in hot and cold water, insoluble in oils, grease and hydrocarbons.*
HCl	*Molecular formula for hydrochloric acid; can be used in diluted form in the hydraulic fracturing process to fracture limestone formations and to clean up perforations in coalbed methane fracturing treatments.*
HEC	*Hydroxyethylcellulose; a form of guar gel.*
Hydraulic Conductivity	*(see permeability)*
Injectate	*In relation to the coalbed methane industry, this is the fracturing fluid injected into a coalbed methane well.*
Isopach	*A line drawn on a map through points of equal true thickness of a designated stratigraphic unit or group of stratigraphic units.*

Isotopic *Rocks formed in the same environment, i.e. in the same sedimentary basin or geologic province.*

Isotropic *A medium, such as unconsolidated sediments or a rock formation, whose properties are the same in all directions.*

KCl *Molecular formula for potassium chloride.*

Lacustrine *Pertaining to, produced by, or formed in a lake or lakes.*

Laminar Flow *Water flow in which the stream lines remain distinct and the flow direction at every point remains unchanged with time; non-turbulent flow.*

Leakoff *The magnitude of pressure exerted on a formation that causes fluid to be forced into the formation. In common usage, leakoff is often considered the movement of fluid out of primary fractures and into a geologic formation, either through small existing permeable paths (connected pores and natural fracture networks) or through small pathways created or enlarged in the rock through the fracturing process.*

Lenticular *Pertaining to a discontinuous, lens-shaped (saucer-shaped) stratigraphic body.*

Linear Gel *A simple guar-based fracturing fluid usually formulated using guar and water with additives or guar with diesel fuel.*

Lithology *The description of rocks based on mineralogic composition and texture.*

Millidarcy *The customary unit of measurement of fluid permeability; equivalent to 0.001 Darcy.*

Mcf *Million cubic feet; a unit typically used to define gas production volumes in the coalbed methane industry; 1 Mcf is roughly equivalent to the volume of gas required to heat approximately 12 households for one year (based on the Department of Energy's average household energy consumption statistic, 2001); Mcf can sometimes represent 1,000 cubic feet.*

mg/L *Milligrams per liter; typically used to define concentrations of a dissolved compound in a fluid.*

Mined-through studies *Mined-through studies are projects in which coalbeds have been actually mined through (i.e., the coal has been removed) so that remaining coal and surrounding rock can be inspected, after the coalbeds have been hydraulically fractured. These studies provide unique subsurface access to investigate coalbeds and surrounding rock after hydraulic fracturing.*

Moduli *Plural of modulus (often referred to as bulk modulus), the ratio of stress to strain, abbreviated as "k". The bulk modulus is an elastic constant equal to the applied stress divided by the ratio of the change in volume to the original volume of a body.*

Overthrust *A low-angle thrust fault of large scale, with total displacement (lateral or vertical) generally measured in kilometers.*

Pad *An initial volume of fluid that is used to initiate and propagate a fracture before a proppant is placed.*

Paleochannels *Old or ancient river channels preserved in the subsurface as lenticular sandstones.*

Permeability	*The capacity of a porous rock, sediment, or soil to transmit a fluid; it is a measure of the relative ease of fluid flow under equal pressure and from equal elevations.*
Physiographic	*A region of which all parts are similar in geologic structure and climate and which has had a unified geomorphic history; its relief features differ significantly from those of adjacent regions.*
Play	*A productive coalbed methane formation, or a productive oil or gas deposit.*
Potentiometric	*The total head of ground water, defined by the level to which water will rise in a well.*
ppm	*Parts per million; typically used to define concentrations of a dissolved compound in a fluid; equivalent to 1 mg/L.*
Primacy	*The right to self-establish, self-enforce and self-regulate environmental standards; this enforcement responsibility is granted by EPA to States and Indian Tribes.*
Primary porosity	*The porosity preserved from some time between sediment deposition and the final rock-forming process; (e.g., the spaces between grains of sediment).*
Proppant	*Granules of sand, ceramic or other minerals that are wedged within the fracture and act to "prop" it open after the fluid pressure from fracture injection has dissipated.*
psi	*Pounds per square inch; a unit of pressure.*
Rank	*The degree of metamorphism in coal; the basis of coal classification into a natural series from lignite to anthracite.*
Screen-out	*Term used to describe a fracturing job where proppant placement has failed.*
Secondary porosity	*The porosity created through alteration of rock, commonly by processes such as, dissolution and fracturing.*
Semianthracite	*Term used to identify coal rank; specifically representing coal that possesses a fixed-carbon content of 86% to 92%.*
Stratigraphy	*The study of rock strata; concerning all characteristics and attributes of rocks and their interpretation in terms of mode of origin and geologic history.*
Subbituminous	*A black coal, intermediate in rank between lignite and bituminous.*
Subgraywacke	*A sedimentary rock (sandstone) that contains less feldspar, and more and better-rounded quartz grains than graywacke; intermediate in composition between graywacke and orthoquartzite; it is lighter-colored and better-sorted, and has less matrix than greywacke.*
Surficial	*Pertaining to or lying in or on a surface; specific to the surface of the earth.*
Syncline	*A fold of layered, sedimentary rocks whose core contains stratigraphically younger rocks; shape of fold is generally concave upward.*
Tcf	*Trillion cubic feet; a unit typically used to define gas production volumes in the coalbed methane industry; 1 Tcf is roughly equivalent to the volume of gas required to heat approximately 12 million households for one year (based on the Department of Energy's average household energy consumption statistic, 2001).*

Thermogenic *A direct product of high temperatures, (e.g. Thermogenic methane).*

Toughness *The point at which enough stress intensity has been applied to a rock formation, so that a fracture initiates and propagates.*

Transmissivity *A measure of the amount of water that can be transmitted horizontally through a unit width by the full saturated thickness of the aquifer under a hydraulic gradient of one.*

Up-warp *The uplift of a region; usually a result of the release of isostatic pressure, e.g. the melting of an ice sheet.*

Viscosity *The property of a substance to offer internal resistance to flow; internal friction.*

Volcaniclastic *Composed of fragments or particles, and related to volcanic processes either by forming as the result of explosive processes or due to the weathering and erosion of volcanic rocks.*

Chapter 1
Introduction

Section 1421 of SDWA tasks EPA with protecting USDWs for all current and future drinking water supplies across the country (see section 1.3 for the complete definition of a USDW). EPA's UIC Program is responsible for ensuring that fluids injected into the ground (for purposes including waste disposal, oil field brine disposal, enhanced recovery of oil and gas, mining, and emplacement of other fluids) do not endanger USDWs.

EPA, through its UIC Program, conducted a fact-finding effort based primarily on existing literature. The goal of this study was to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into coalbed methane wells and to determine, based on these findings, whether further study is warranted. For the purposes of this study, EPA assessed USDW impacts by the presence or absence of documented drinking water well contamination cases caused by coalbed methane hydraulic fracturing, clear and immediate contamination threats to drinking water wells from coalbed methane hydraulic fracturing, and the potential for coalbed methane hydraulic fracturing to result in USDW contamination based on two possible mechanisms as follows:

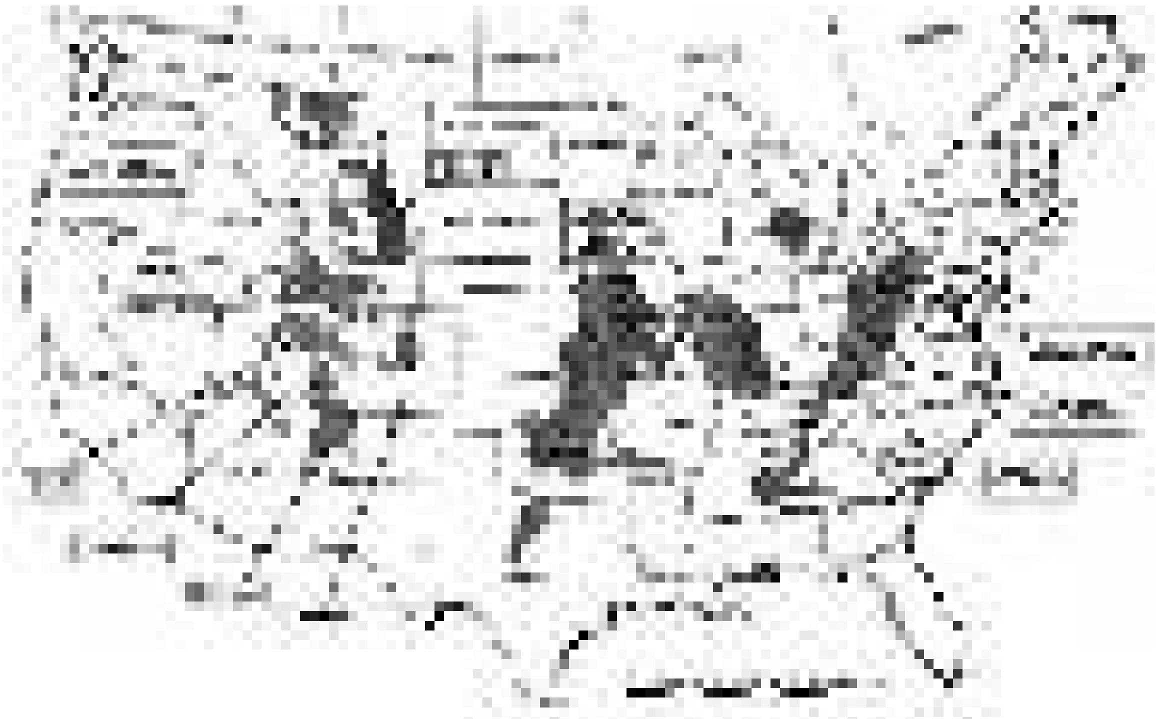
1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

EPA obtained information for this study from literature searches, field visits, a review of reported groundwater contamination incidents in areas where coalbed methane is produced, and solicitation of information from the public on any impacts to groundwater believed to be associated with hydraulic fracturing.

EPA also reviewed 11 major coal basins throughout the United States to determine if coalbeds are co-located with USDWs and to understand the coalbed methane activity in the area (Figure 1-1). The basins shown in red have the highest coalbed methane production volumes. They are the Powder River Basin in Wyoming and Montana, the San Juan Basin in Colorado and New Mexico, and the Black Warrior Basin in Alabama. Hydraulic fracturing is or has been used to stimulate coalbed methane wells in all basins, although it has not frequently been used in the Powder River, Sand Wash, or Pacific Coal Basins.

Figure 1-1. Locus Map of Major United States Coal Basins



1.1 EPA's Rationale for Conducting This Study

Although coalbed methane has many environmental advantages over traditional energy sources, concerns have been raised regarding the environmental impacts of coalbed methane production. Coalbed methane production in certain areas has led to groundwater depletion and production water discharge issues (i.e., issues that are not associated with the quality of USDWs). Citizens, state agencies, producers, and the regional EPA offices in those areas are working in concert to better understand and mitigate these potential problems.

This study examines the potential for hydraulic fracturing fluid injection into coalbed methane wells to contaminate USDWs. EPA conducted this study in response to allegations that hydraulic fracturing of coalbed methane wells has affected the quality of groundwater (i.e., issues that are associated with the mandates of the UIC Program). State oil and gas agencies receiving such complaints have indicated that, based on their investigations, hydraulic fracturing of coalbed methane wells has not contributed to water quality degradation in USDWs.

In response to an Eleventh Circuit Court of Appeals (hereafter, "the Court") decision [*LEAF v. EPA*, 118F.3d 1467 (11th Cir, 1997)], the State of Alabama recently supplemented its rules governing the hydraulic fracturing of wells to include additional requirements to protect USDWs during the hydraulic fracturing of coalbeds for methane production. Prior to the Court's decision, EPA had not considered hydraulic fracturing as an underground injection activity, because the Agency did not consider production well stimulation as an activity subject to UIC regulations. Nevertheless, the Court held that the injection of fluids for the purpose of hydraulic fracturing constitutes underground injection as defined under SDWA, that all underground injection must be regulated, and that hydraulic fracturing of coalbed methane wells in Alabama must be regulated under Alabama's UIC program.

In the wake of the Eleventh Circuit Court decision, EPA decided to assess the potential for hydraulic fracturing fluid injection into coalbed methane wells to contaminate USDWs. EPA's decision to conduct this study was also based on concerns voiced by individuals who may be affected by coalbed methane development, Congressional interest, and the need for additional information before EPA could make any further regulatory or policy decisions regarding hydraulic fracturing.

1.2 Overview of Hydraulic Fracturing

Hydraulic fracturing is a technique used by the oil and gas industry to improve the production efficiency of oil and coalbed methane wells. The hydraulic fracturing process uses high hydraulic pressures to initiate a fracture. A hydraulically induced fracture acts as a conduit in the rock or coal formation that allows the oil or coalbed methane to travel more freely from the rock pores to the production well that can bring it to the surface.

In the case of coalbed methane gas production, the gas is not structurally "trapped" under pressure. Rather, most of the coalbed methane is adsorbed within small pores in the "micro-porous matrix" of the coal (Koenig, 1989; Winston, 1990; Close, 1993). When coalbed methane production begins, water is first pumped out (or "produced" in the industry terminology) from the fractures, joints, and cleats (i.e., tiny, disconnected clusters of fractures) in the coal until the pressure declines to the point that methane begins to desorb from the coal matrix itself (Gray, 1987).

To extract the coalbed methane, a production well is drilled through rock layers to intersect the coal seam that contains the coalbed methane. Next, a fracture is created or enlarged in the coal seam to connect the well bore to the coalbed joint/cleat system. To create such a fracture, a thick, water-based fluid is pumped into the coal seam at a gradually increasing rate. At a certain point, the coal seam will not be able to accommodate the fracturing fluid as quickly as it is being injected. When this occurs, the pressure is high enough that the coal gives way, and a fracture is created or an existing fracture is enlarged. To hold the fracture open, a propping agent, usually sand (commonly known as "proppant"), is pumped into the fracture so that when the pumping pressure is released, the fracture does not close completely because the proppant is "propping" it open. The resulting fracture filled with proppant becomes a conduit through which water can flow to the production well, thus depressurizing the coal matrix, allowing for the desorption of methane and its flow towards the production well.

The extent of the fracture in a coalbed is controlled by the characteristics of the geologic formation (including the presence of natural fractures), the fracturing fluid used, the pumping pressure, and the depth at which the fracturing is performed. Whether the fracture grows taller or longer is determined by the properties of the surrounding rock. A hydraulically created fracture will always take the path of least resistance through the coal seam and surrounding formations.

A more comprehensive discussion of the fracturing process and the fracturing fluids/additives used in hydraulic fracturing of coalbed methane wells is presented in Chapters 3 and 4, respectively.

1.3 EPA's Authority to Protect Underground Sources of Drinking Water

SDWA requires EPA and EPA-authorized states to have effective programs to prevent underground injection of fluids from endangering USDWs (42 U.S.C. 300h et seq.). Underground injection is the subsurface emplacement of fluids through a well bore (42 U.S.C. 300h(d)(1)). Underground injection endangers drinking water sources if it may result in the presence of any contaminant in underground water which supplies or can reasonably be expected to supply any public water system, and if the presence of such contaminant may result in such system's noncompliance with any national primary drinking water regulation (i.e., maximum contaminant levels) or may otherwise adversely affect the health of persons (42 U.S.C. 300h(d)(2)). SDWA's regulatory authority extends to underground injection practices; SDWA does not provide a general grant of authority for EPA to regulate oil and gas production.

A USDW is defined in the UIC regulations at 40 CFR 144.3 as an aquifer or a portion of an aquifer that:

"A. 1. Supplies any public water system; or
2. Contains sufficient quantity of groundwater to supply a public water system; and
   i. currently supplies drinking water for human consumption; or
   ii. contains fewer than 10,000 milligrams per liter (mg/L) total dissolved solids (TDS); and
B. Is not an exempted aquifer."

The water quality standard for USDWs is more stringent than EPA's National Secondary Drinking Water Standards for potable water, which cover aesthetic concerns such as taste and odor. These secondary standards recommend a TDS limit of 500 mg/L (40 CFR 143.3).

An accurate understanding of the definition of USDW requires understanding of two other terms: public water system and aquifer exemption.

A public water system is defined at 40 CFR 141.2 as:

> "A system for the provision to the public of water for human consumption through pipes or, after August 5, 1998, other constructed conveyances, if such a system has at least 15 service connections or regularly serves an average of at least twenty-five individuals daily at least 60 days out of the year."

To better quantify the definition of USDW, EPA determined that any aquifer yielding more than 1 gallon per minute can be expected to provide sufficient quantity of water to serve a public water system and therefore falls under the definition of a USDW (U.S. EPA Memorandum, 1993). EPA also assumes that all aquifers contain sufficient quantity of groundwater to supply a public water system, unless proven otherwise through empirical data.

An aquifer exemption may be granted under certain circumstances. According to 40 CFR 144.3, an exempted aquifer meets the definition of a USDW, but has been exempted according to the procedures in 40 CFR 144.7. An aquifer, or portion thereof, can be designated as an exempted aquifer, if it meets the following criteria (40 CFR 146.4):

1. It does not currently serve as a source of drinking water; and,

2. It cannot now and will not in the future serve as a source of drinking water because it is:

   - Mineral, hydrocarbon, or geothermal energy producing, or can be demonstrated to be commercially producible; or
   - Situated at a depth or location which makes recovery of water for drinking water purposes economically or technologically impractical; or
   - So contaminated that it would be economically or technologically impractical to render that water fit for human consumption; or
   - Located over a Class III well mining area subject to subsidence or catastrophic collapse; or,

3. The TDS content of the groundwater is more than 3,000 and less than 10,000 mg/L and, it is not reasonably expected to supply a public water system.

All requests for aquifer exemptions must be approved by the EPA Administrator or an authorized representative. A list of exempted aquifers, for states where such exemptions exist, is maintained by the state agency managing the UIC program or the regional EPA office. A comprehensive list or map identifying all USDWs in every state does not exist. Identification of USDWs is an ongoing effort, as is EPA's consideration of aquifer exemptions. For example, coalbed methane production wells using hydraulic fracturing to stimulate production may be located in areas that coincide with existing aquifer exemptions.

Currently, injection associated with hydraulic fracturing of coalbed methane production wells is regulated only in Alabama under the state UIC program, and that injection activity falls under the category of Class II wells (Alabama Oil and Gas Board, Administrative Code, Oil and Gas Report 1, 400-3). Class II wells include the injection of brines and other fluids that are associated with oil and gas production.

1.4 Potential Effects of Hydraulic Fracturing of Coalbed Methane Wells on USDWs

EPA identified two possible mechanisms by which hydraulic fracturing fluid injection into coalbed methane wells might affect the quality of USDWs:

1. The direct injection of fracturing fluids into a USDW in which the coal is located (Figure 1-2), or injection of fracturing fluids into a coal seam which is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. The creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

Fracturing fluids can be directly or indirectly injected into a USDW, depending on the location of the coalbed relative to a USDW. In many coalbed methane-producing regions, the target coalbeds occur *within* USDWs, and the fracturing process injects stimulation fluids directly into the USDWs (Figure 1-2 at the end of the chapter). In other production regions, target coalbeds are adjacent to the USDWs, which are either higher or lower in the geologic section. EPA investigated the potential for fractures to extend through stratigraphic layers that separate coalbeds and USDWs and the potential for stimulation fluids to indirectly enter a USDW during the fracturing process (Figure 1-3 at the end of the chapter).

Local geologic conditions may interfere with the complete recovery of fracturing fluids injected into a formation. As a result, some of the fracturing fluids may be "stranded" in the USDW (Figures 1-2 and 1-3). Any hazardous constituents in the stimulation fluids could potentially contaminate groundwater in a USDW and any drinking water supplies that rely on the USDW.

1.5 Study Approach

Given the enormous variation in geology among and within coalbed basins in the United States, any initial evaluation of potential impacts by hydraulic fracturing of coalbeds on USDWs at a national level would necessarily be broadly focused. Based on public input, EPA decided to carry out this study in discrete phases to better define its scope and to determine if additional study is needed after assessing the results of the preliminary phase(s). EPA designed the study to have three possible phases, changing the focus from general to more specific as findings warrant.

Phase I of the study is a fact-finding effort based primarily on existing literature to identify and assess the potential threat to USDWs posed by hydraulic fracturing fluid injection into coalbed methane wells. It is designed to determine if site-specific detailed studies, including collection of new data, are needed. An overview of the methodology used for Phase I is provided below; a detailed discussion of this methodology is provided in Chapter 2.

In Phase I, EPA:

- Conducted a literature review for information on hydraulic fracturing processes, hydraulic fracturing fluids and additives, the geologic settings of and the hydraulic fracturing practices used in the 11 major coal basins (Figure 1-1), and the identification of coal seams that are co-located with USDWs.

- Published a request in the *Federal Register* (66 FR 39396 (U.S. EPA, 2001)) for information from the public, as well as governmental and regulatory agencies, regarding incidents of groundwater contamination believed to be associated with hydraulic fracturing of coalbed methane wells.

- Reviewed reported incidents of groundwater contamination and any follow-up actions or investigations by other parties such as state or local agencies, industry, and academia.

- Conducted field visits in three states.

In addition, EPA collaborated with the Department of Energy (DOE) to produce a document that details the technical aspects of hydraulic fracturing in the oil and gas industry. This document is included as Appendix A to this report.

EPA also provided support for a site-specific study, which was conducted by the Geological Survey of Alabama (GSA). This study attempts to address a concern that is central to USDW contamination and drawdown issues: the degree to which flow is confined within coalbeds in coalbed methane fields. Information on the GSA study is available at http://www.gsa.state.al.us/gsa/3DFracpage/3Dfracstudy.htm.

1.6 Stakeholder Involvement

EPA took several steps to fully involve the public and all stakeholders during the study. These steps included:

- Publishing *Federal Register* notices:
    - requesting comments on the study plan (65 FR 45774 (USEPA, 2000));
    - requesting information from the public on any impacts to groundwater believed to be associated with hydraulic fracturing of coalbed methane wells (66 FR 39396 (USEPA, 2001));
    - Requesting comments on the August 2002 draft of the study (67 FR 55249 (USEPA, 2002)).
- Holding a public meeting to obtain additional stakeholder input on the proposed study plan published in the July 2000 *Federal Register* notice (65 FR 45774 (USEPA, 2000))
- Providing periodic updates for stakeholders in the form of written communication.
- Maintaining a Web site where stakeholders can view the project documents and provide information to EPA.

EPA also received and reviewed comments from 105 commenters submitted in response to the August 2002 *Federal Register* notice (67 FR 55249 (USEPA, 2002)), which announced the availability of the August 2002 version of this Phase I study report. EPA incorporated many of these comments into this final Phase I report. A summary of the public comments and EPA's responses is provided in, "Public Comment and Response Summary for the Study on the Potential Impacts of Hydraulic Fracturing of Coalbed Methane Wells on Underground Sources of Drinking Water" (EPA 816-R-04-004), available on EPA's electronic docket.

1.7 Information Contained within This Report

This Phase I report is composed of an executive summary, 7 chapters, 11 attachments, and 2 appendices. The main chapters address the following topics:

- Chapter 2, Study Methodology, discusses in detail EPA's method for collecting information under Phase I of the study.

- Chapter 3, Characteristics of Coalbed Methane Production and Associated Hydraulic Fracturing Practices, discusses the hydraulic fracturing process as it applies to coalbed methane production.

- Chapter 4, Hydraulic Fracturing Fluids, describes the use and nature of hydraulic fracturing fluids and their additives. It also discusses EPA's evaluation of the fate and transport of fracturing fluids that are injected into targeted coal layers during the hydraulic fracturing process.

- Chapter 5, Summary of Coalbed Methane Basin Descriptions, briefly describes each of the 11 major coal basins in the United States and discusses the potential for impacts to USDWs in these basins.

- Chapter 6, Water Quality Incidents, in response to stakeholders' recommendations, summarizes water quality and quantity complaints received from citizens pertaining to hydraulic fracturing, coalbed methane production, and well stimulation.

- Chapter 7, Summary of Findings, summarizes the major findings presented in Chapters 3 through 6.

In addition, Chapters 3 through 6 contain numerous figures and tables to help readers visualize the hydraulic fracturing process and to help summarize some of the key information in the report.

The attachments to the report are a collection of in-depth hydrologic investigations of the 11 coal basins, focusing primarily on the coalbed methane production activities and the relationship between coalbed and USDW locations within these 11 basins. The attachments expand the discussions of Chapter 5 with greater details on the specific geology and gas production activities for the 11 basins.

Appendix A, Hydraulic Fracturing, contains DOE's technical report on hydraulic fracturing. Appendix B, Quality Assurance Protocol, explains the quality assurance and quality control measures EPA used to conduct this study.

Figure 1-2. Hypothetical Mechanism - Direct Fluid Injection Into a USDW (Coal within USDW)

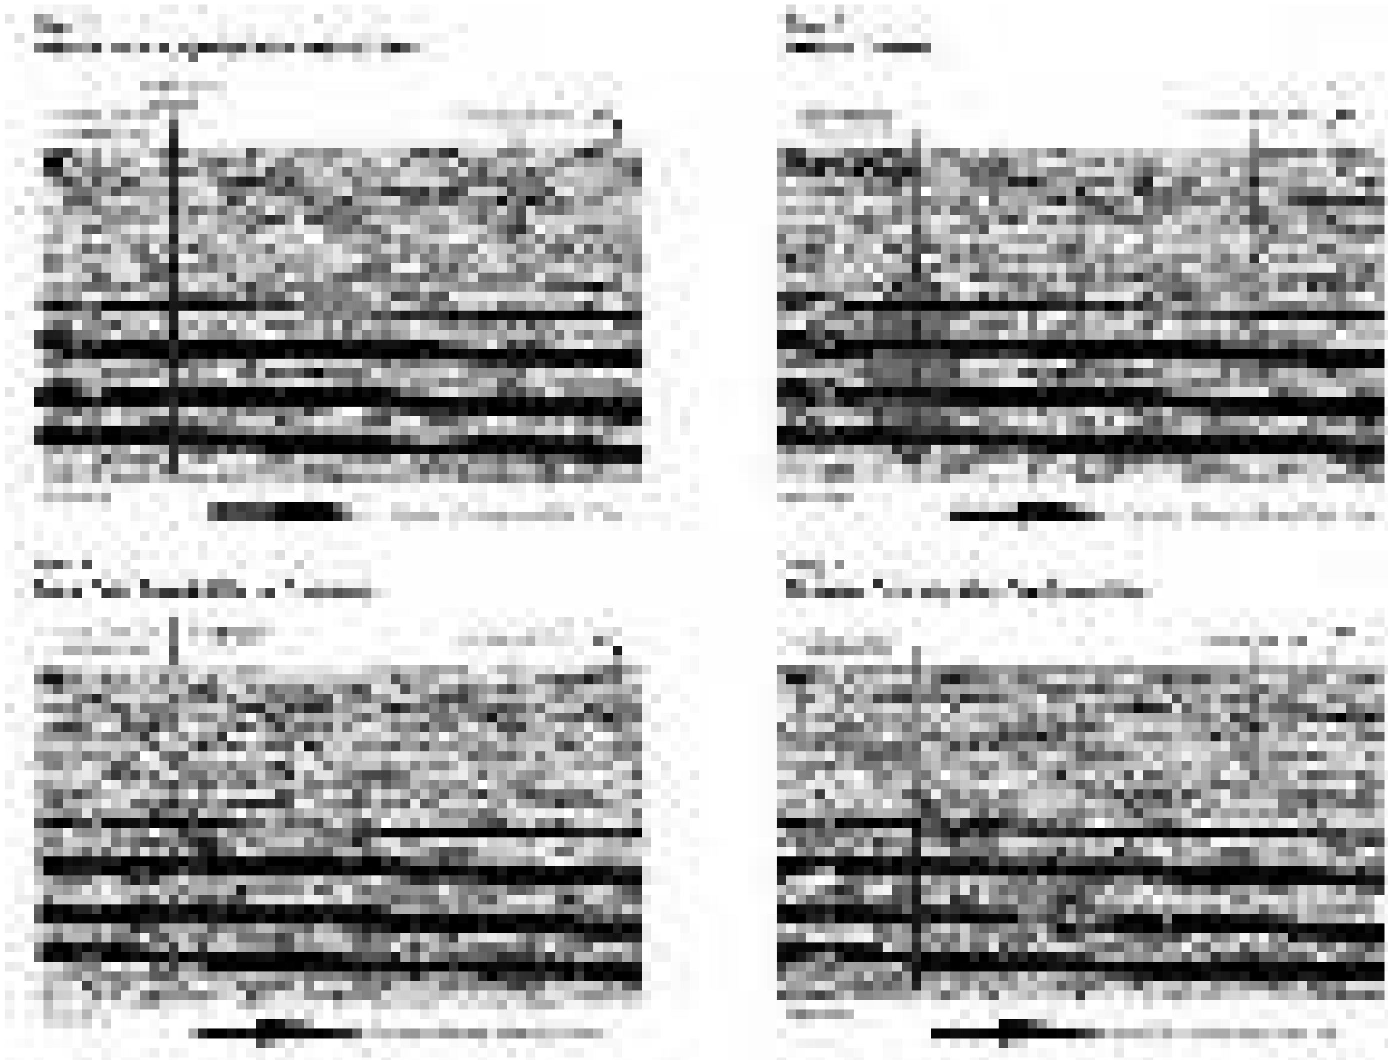


Figure 1-3. Hypothetical Mechanism - Fracture Creates Connection to USDW

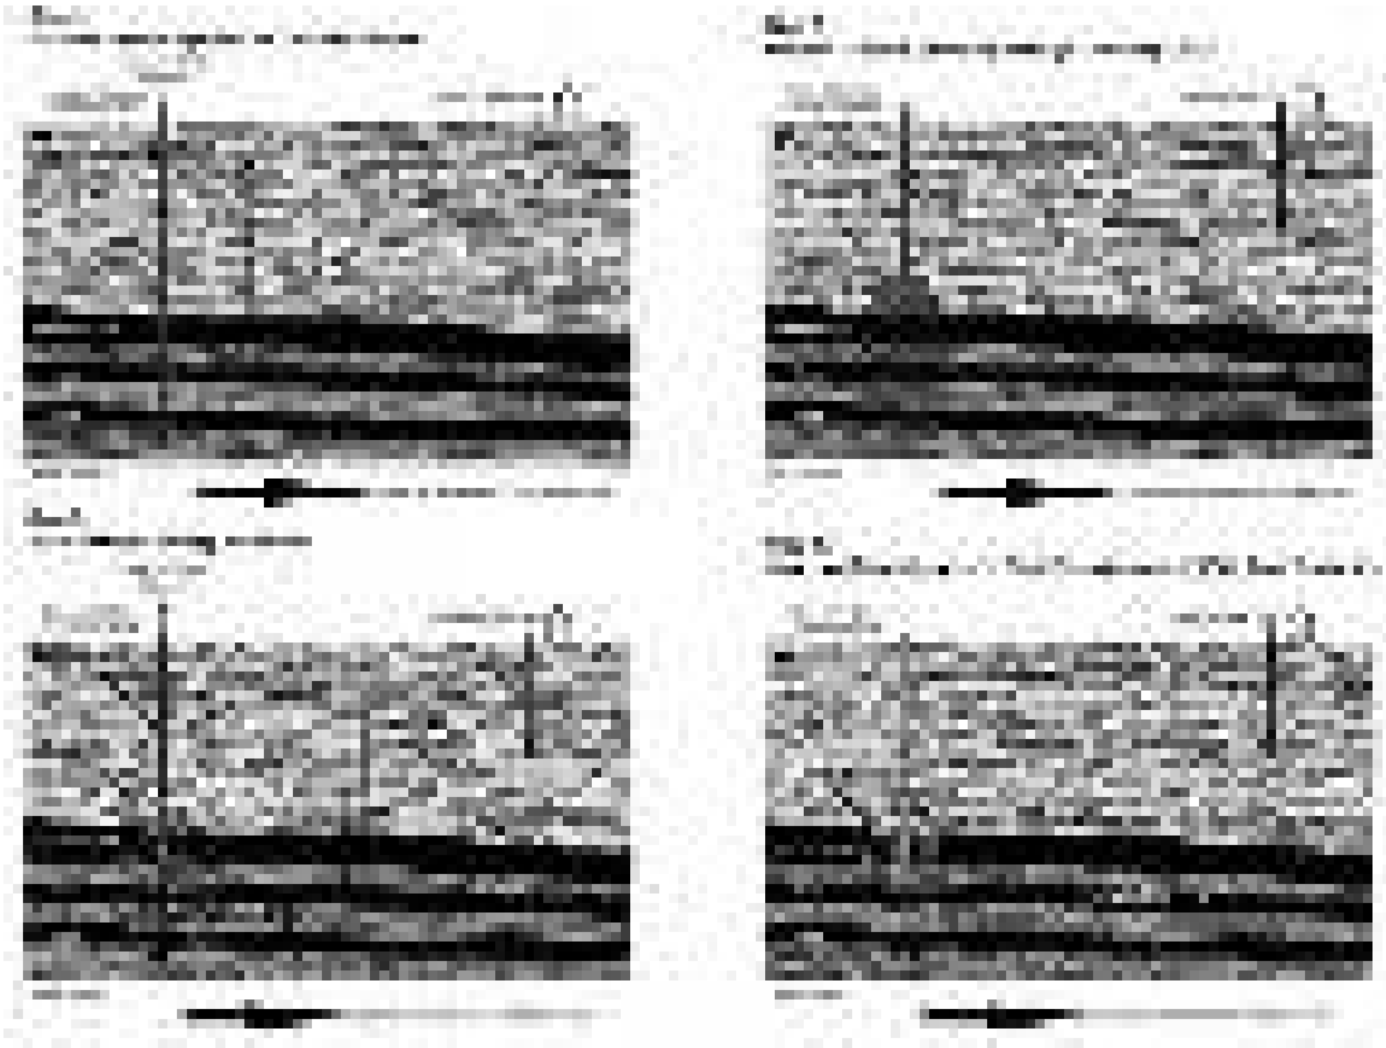


Chapter 2
Study Methodology

This chapter outlines EPA's approach for completing Phase I of the study. This chapter describes the development of the study, the information collection and review process that EPA used, and the internal and external review process for the report.

2.1 Overview of the Study Methods

EPA developed the Phase I study methodology to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into coalbed methane wells, and to determine, based on these findings, whether further study is warranted.

On July 25, 2000, EPA published a *Federal Register* notice (65 FR 45774 (USEPA, 2000)) requesting comment on a conceptual study design in order to receive stakeholder input on how an EPA study should be structured. On August 24, 2000, EPA held a public meeting to obtain additional stakeholder input on the proposed study design. EPA received more than 80 sets of comments from industry, state oil and gas agencies, environmental groups, and individual citizens in response to the *Federal Register* notice and public meeting. A summary of these comments can be viewed on EPA's Web site at www.epa.gov/safewater/uic/cbmstudy.

EPA revised its study approach in response to the comments it received on the conceptual study design. The final study design, "Study Design for Evaluating the Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reservoirs", was released in April 2001 and is available on the website referenced above. One significant change in the final study design was EPA's decision to complete the study in a phased approach to efficiently address the stated project objectives. This phased approach, similar in design to that used in other complex studies, would allow EPA to use information gained in one phase to focus on the need for, and direction of, subsequent phases.

Phase I of the study was intended as a limited-scope assessment that would enable the Agency to determine if hydraulic fracturing of coalbed methane wells clearly poses little or no threat to USDWs, or if the practice may pose a threat. In Phase I, EPA:

- Gathered existing information to review hydraulic fracturing processes, practices and settings;
- Requested public comment to identify incidents that had not been reported to EPA; and
- Reviewed reported incidents of groundwater contamination and any follow-up

actions or investigations by other parties (state or local agencies, industry, academia, etc.).

In addition, as recommended by commenters, EPA decided to compile accounts of personal experiences with coalbed methane impacts on drinking water wells. These experiences are summarized in Chapter 6.

In its final study design, EPA indicated that the Agency would make a determination regarding whether further investigation was needed after analyzing the Phase I information. Specifically, EPA determined that it would not continue into Phase II of the study if the investigation found that no hazardous constituents were used in fracturing fluids, hydraulic fracturing did not increase the hydraulic connection between previously isolated formations, *and* reported incidents of water quality degradation could be attributed to other, more plausible causes.

EPA identified two possible mechanisms by which hydraulic fracturing fluid injection into coalbed methane wells could potentially affect the quality of USDWs:

1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

To determine if contamination might occur through either mechanism, EPA collected information on:

1. Hydraulic fracturing practices.

2. Hydraulic fracturing fluids and additives to determine whether these substances contain hazardous constituents.

3. The hydrogeology of the coalbed methane basins, including the identification of coal seams that are located in USDWs.

4. Water quality incidents potentially associated with hydraulic fracturing.

EPA anticipated that sufficient information would be available to evaluate the impacts of direct injection into USDWs because the main considerations are the location of the coal formations relative to USDWs and the chemical constituents in hydraulic fracturing fluids. The Agency further anticipated that documenting USDW impacts via the creation of a hydraulic connection between the coalbed formation and adjacent USDW(s) would be more difficult. This is because more detailed, site-specific, geological information or data for specific fracturing events needed to definitively document such a hydraulic communication are not readily available. Site-specific data include:

- Water quantity and quality conditions in a USDW (or a well) both before and after a fracturing event;
- Location, dimensions, and conductivity of fractures created during the coalbed stimulation event;
- Measured changes in groundwater flow between the USDW and coalbeds or other aquifers; and
- Impacts of other, unrelated, hydrologic and water quality processes that could also be affecting the USDW.

2.2 Information Sources

EPA obtained available literature and information through:

- Literature reviews.
- Coordination with DOE.
- Interviews with companies that perform hydraulic fracturing and interviews with citizens, local and state authorities, the Bureau of Land Management and EPA Region 8 personnel.
- Field visits.
- Responses to EPA's *Federal Register* request (66 FR 39396 (U.S. EPA, 2001)) for information on incidents of groundwater contamination believed to be associated with hydraulic fracturing of coalbed methane wells.

EPA researched more than 200 peer-reviewed publications, interviewed approximately 50 employees from industry and state or local government agencies, and communicated with approximately 40 citizens and groups who are concerned that CBM production affected their drinking water wells.

The procedure that EPA used to obtain information from each of these sources is discussed in more detail below. A copy of the quality assurance protocol that EPA employed to verify all the sources of data used to write this report is provided as Appendix B.

2.2.1 Literature Reviews

EPA conducted a review of existing literature and information on hydraulic fracturing for coalbed methane production. The focus of the literature review was to obtain information on topics 1 through 3 listed in Section 2.1, above.

The degree to which information was available for each of the 11 coalbed basins in the report was variable. The amount of information available depended on the extent of exploration and production in each basin.

EPA conducted an extensive literature search, using the Engineering Index and GeoRef on-line reference databases, for abstracts from technical articles, books, and proceedings. EPA also conducted Internet-based searches to locate additional information using relevant Web sites located using various search engines, including Google™, Yahoo®, and Alta Vista®. EPA used specialized search engines, such as those provided on state geological survey Web sites and by the Gas Technology Institute (GTI) for specific queries. All relevant Web sites were logged in project books and referenced in this report when cited.

EPA conducted these literature searches by subject topics and using the following key words, either separately or in combination: coal basin, coalbed methane, cross-linked gel, fracturing fluid additives, fracturing fluid technology, fracturing fluid performance, fracturing fluids, ground water, hydraulic fracturing, hydraulic fracture dimension, hydraulic fracture growth, hydrology, linear gel, methane gas production, nitrogen foam, underground sources of drinking water, and USDWs. EPA printed, catalogued, and surveyed all results of searches for pertinent journal articles, books, and conference proceedings containing information that might meet the specific data needs of this report.

EPA acquired most of the pertinent articles, which were identified from the Engineering Index and GeoRef on-line reference databases, from the University of Texas Library in Austin because this library's holdings include an extensive collection of publications related to oil and gas production. EPA researched references from the University of Texas documents and acquired those documents that were relevant to the study. Only a small fraction of the pertinent articles, specifically proprietary articles and articles published for overseas conferences were unavailable. EPA also acquired articles from GTI. EPA has archived, by topic, all papers collected for the study.

To verify key information extracted from the literature, EPA contacted by phone relevant organizations such as state regulatory agencies, state geological surveys, natural gas companies, GTI, and service companies. The Agency used telephone logs to document all communications. Personal conversations with the employees of the various organizations yielded additional information in the form of reports, figures, and maps, as well as statements based on best professional judgment and experience. These were collected, documented, and referenced in conjunction with the literature identified in the literature searches. The majority of the literature pertaining to coalbed methane basins and hydraulic fracturing was written in the early to mid 1990s. According to the Texas Bureau of Economic Geology (TBEG) (personal communication, TBEG Staff, 2000), this period of intense activity was a result of the emphasis placed on gas exploration by the Section 29 Tax Credit of the Crude Oil Windfall Profit Tax Act of 1980 and research grants to industry, academia, and government agencies. The Section 29 credit does not, however, apply to coal gas wells drilled after December 31, 1992.

2.2.2 Department of Energy

EPA reviewed information from DOE's "White Paper" on hydraulic fracturing practices. This paper addresses the following topics:

- Objectives of hydraulic fracturing.
- How candidate wells are selected for hydraulic fracturing.
- How fracture treatments are designed.
- Field operation considerations.
- Physics of fracture formation in coalbeds.
- Fracturing fluids.
- Stimulation techniques used for developing coalbeds.
- Instrumentation/methods for tracking fractures.

The complete DOE paper is included as Appendix A, and excerpts from this paper are included in Chapter 3, Characteristics of Coalbed Methane Production and Associated Hydraulic Fracturing Practices.

2.2.3 Interviews

EPA contacted hydraulic fracturing service companies including BJ Services Company, Halliburton Energy Services, Inc., and Schlumberger Technology Corporation, as well as a fracturing fluids producer, Hercules, Inc., to obtain information regarding the content of hydraulic fracturing fluids and additives they use or manufacture. Two companies, Halliburton and Schlumberger, provided EPA with material safety data sheets (MSDSs) for several hydraulic fracturing fluids and additives. The MSDSs were reviewed to determine the nature of the constituents in fracturing fluids used to stimulate coalbed methane production. These topics are discussed in Chapter 4, Hydraulic Fracturing Fluids.

EPA also evaluated reports from individuals and organizations that are concerned that their drinking water supplies were affected by hydraulic fracturing. These reported personal experiences came from Colorado, New Mexico, Wyoming, Alabama, and Virginia. In response to these reports, EPA conducted telephone interviews with citizens, local and state authorities, the Bureau of Land Management and EPA Region 8 personnel. EPA also evaluated state agency responses to any complaints received by EPA or state agencies. The Agency also evaluated the available data to determine whether there is sufficient information to reveal the source of the alleged water quality contamination.

2.2.4 Field Visits

EPA conducted field visits in Colorado, Kansas, and Virginia to better understand how local coalbed methane production activities may vary from basin to basin. In addition, during the field visits, EPA was able to meet with concerned local citizens and state agencies to discuss coalbed methane production issues. A summary of these field visits is outlined below.

In August 2000, EPA met with a group of concerned citizens, officials from the Colorado Oil and Gas Conservation Commission, and representatives of the La Plata County government. EPA witnessed a fracturing event, reviewed records including temperature logs of past fracturing events conducted on coalbed methane wells, and performed a reconnaissance of the area allegedly affected by coalbed methane production.

In August 2001, EPA met with the Virginia Department of Mines, Minerals and Energy, the agency that regulates the coalbed methane production industry in Virginia. The Department provided information about the state's investigation of water quality incidents potentially associated with coalbed methane production in the Central Appalachian Valley. The Department also submitted water quality incident reports for review by EPA. During this visit, EPA met with concerned citizens in Virginia. Citizens groups from Buchannan and surrounding counties were invited to meet with EPA and DOE staff to discuss water quality issues believed to be related to local hydraulic fracturing of coalbed methane wells. Notes from the meeting are referenced in Chapter 6.

EPA also organized a field visit with Consol Energy, Inc. and Halliburton to witness a hydraulic fracturing event. Halliburton performed a hydraulic fracture job on a coalbed methane well in western Virginia using equipment, fracturing fluids, and techniques, which are typical of those described in the literature. EPA was able to observe the fracturing process and collect information, including MSDSs from the service company and gas company engineers. The information from this field visit was used to supplement the data on hydraulic fracturing fluids in Chapter 4.

In November 2001, EPA witnessed a fracturing event in Wilson County, Kansas, to gain a better understanding of the regional geology and hydraulic fracturing practices in the area. In attendance were Colt Energy (the well operator); Consolidated Industrial Services, Inc. (the service company conducting the fracture job); and two state agencies, the Kansas Corporation Commission, and the Missouri Department of Natural Resources. MSDSs for fracturing fluids typically used in the area were also provided to EPA by the Kansas Corporation Commission.

2.2.5 Federal Register Notice to Identify Reported Incidents

EPA provided an opportunity for the public to submit information on any impacts to groundwater believed to be associated with hydraulic fracturing through a request for public comment (66 FR 39396 (USEPA, 2001)). EPA also sent copies of the *Federal Register* notice with a cover letter to county-level public health and/or environmental officials in counties that may be producing coalbed methane. In addition, letters were sent to stakeholders informing them that the *Federal Register* notice had been published. Responses to the *Federal Register* notice are available at EPA's water docket (docket number W-01-09; Water Docket (MC 4101); Rm EB 57; U.S. Environmental Protection Agency; 1200 Pennsylvania Avenue, NW; Washington, DC 20460; phone number: (202) 566-2426). A summary of the comments is provided in Chapter 6.

2.3 Review Process

This report has benefited from a series of internal and external technical reviews. EPA verified information through telephone interviews with state and local officials, as well as through the Agency's internal quality assurance process. EPA conducted a quality assurance review of the data collection procedures as well as a review of the individual literature sources cited in the report. In addition, more than nine EPA offices reviewed and commented on the draft report. Other federal agencies that reviewed the draft report included DOE and the U.S. Geological Survey (USGS).

In 2001, EPA also submitted the draft report to a scientific peer-review panel consisting of experts from industry, academia, and government agencies. The panel's task was to review the draft report and provide comments on the descriptions and conclusions developed by EPA. The panel also provided information about additional data sources to supplement those used in the report. Following receipt of comments on the draft report, EPA made the appropriate changes to the document prior to its publication and release.

EPA made the report available for public comment by an announcement in the *Federal Register* on August 28, 2002 (67 FR 55249 (USEPA, 2002)). The 60-day public comment period officially ended on October 28, 2002. The Agency received and reviewed comments from 105 commenters and incorporated many of these comments into this final Phase I report. A summary of the public comments and EPA's responses is provided in, "Public Comment and Response Summary for the Study on the Potential Impacts of Hydraulic Fracturing of Coalbed Methane Wells on Underground Sources of Drinking Water" (EPA 816-R-04-004), available on EPA's electronic docket.

Chapter 3
Characteristics of Coalbed Methane Production and Associated Hydraulic Fracturing Practices

Understanding the practice of hydraulic fracturing as it pertains to coalbed methane production is an important first step in evaluating its potential impacts on the quality of USDWs. This chapter presents the following: an overview of the geologic processes leading to coal formation, an overview of coalbed methane production practices, a discussion of fracture behavior, a review of the literature on the use and recovery of fracturing fluids, a discussion of mechanisms affecting fluid recovery, and a summary of the methods used for measuring and predicting fracture dimensions and fracturing fluid movement. In addition, several diagrams have been included at the end of this chapter to help illustrate many of these topics. Specifically, Figures 3-1 through 3-8 show the location of the coal basins, the geography of a peat-forming system, the geometry of natural cleats and hydraulically induced fractures, an overview of the hydraulic fracturing process, the relationship between water and gas production rates, and side and plan views of vertical hydraulic fractures.

3.1 Introduction

Coalbed methane is a gas formed as part of the geological process of coal generation, and is contained in varying quantities within all coal. Coalbed methane is exceptionally pure compared to conventional natural gas, containing only very small proportions of "wet" compounds (e.g., heavier hydrocarbons such as ethane and butane) and other gases (e.g., hydrogen sulfide and carbon dioxide). Coalbed gas is over 90 percent methane, and is suitable for introduction into a commercial pipeline with little or no treatment (Rice, 1993; Levine, 1993).

From the earliest days of coal mining, the flammable and explosive gas in coalbeds has been one of mining's paramount safety problems. Over the centuries, miners have developed several methods to extract the coalbed methane from coal and mine workings. Coalbed methane well production began in 1971 and was originally intended as a safety measure in underground coalmines to reduce the explosion hazard posed by methane (Elder and Deul, 1974).

In 1980, the United States Congress enacted a tax credit for "Non-conventional energy production." In 1984, there were only several hundred coalbed methane wells in the United States and most were used for mine de-methanization. By 1990, the anticipated expiration of the tax credit contributed to a dramatic increase in the number of coalbed methane wells nationwide. In addition, DOE and GTI supported extensive research into coalbed exploration and production methods. Federal tax credits and State Severance Tax exemptions served to subsidize the development of coalbed methane resources (Soot, 1991; Pashin and Hinkle, 1997). The federal tax credits and incentives expired at the end of 1992, but coalbed methane exploration, development, and reserves have remained stable or increased (Stevens et al., 1996). At the end of 2000, coalbed methane production from 13 states totaled 1.353 trillion cubic feet, an increase of 156 percent from 1992. During 2000, a total of 13,973 coalbed methane wells were in production (GTI; EPA Regional Offices, 2001). By the end of 2000, coalbed methane production accounted for about 7 percent of the total United States dry gas production and 9 percent of proven dry gas reserves (EIA, 2001).

Coal is defined as a rock that contains at least 50 percent organic matter by weight. The precursor of coal is peat, plant matter deposited over time in fresh-water swamps associated with coastal deltaic rivers. The coal resources from which coalbed methane is derived have similar geologic origins. In the United States, they are usually found in geologic formations that are approximately 65-325 million years old. Coal formation occurred during a time of moderate climate and broad inland oceans. Sea level rose and fell in conjunction with tectonic forces (i.e., subsidence and uplift of land masses) and melting/freezing cycles of decreases and increases in the polar ice masses. As a result, coastal environments such as coastal deltas and peat swamps migrated landward when sea levels rose and moved seaward when sea levels fell, marked by cycles of submergence and emergence. With these cycles of rising and falling sea levels, what was a peat swamp at one time would later be under 100 feet of water. The cycle of sea level rising and falling is marked in the geologic record as cycles of inter-layered deep and shallow water sediments.

The type of sediments deposited at a given location varied with the depth of submergence (Figure 3-2). Generally, carbon-rich organic plant matter was deposited in shallow peat swamps, sand was deposited along beaches and other near-shore, shallow marine environments, and silts and clays and calcium-rich muds were deposited further off-shore in deeper marine environments. Subjected to high pressure over considerable time (due to burial under subsequent sediments), the peats were transformed into coal, the sand into sandstone, the silts and clays into shales, siltstones, and mudstones, and the calcium-rich muds were transformed into limestones. These coal-bearing inter-layered sedimentary sequences are sometimes referred to as “coal cycles.” The idealized coal cycle consists of repeated sequences of very fine-grained sediments (shales and limestones) overlain by coarser sediments (siltstones and sandstones), and then capped by coal. The sequence repeats with shales and limestones over the coal, followed by siltstones and sandstones, then more coal, and so on. Sometimes certain formations are missing from the sequences, so coal is often, though not always, overlain by shales and limestones.

The sedimentation patterns in these fluctuating coastal environments over geologic time scale determined the presence, thickness, and geometry of present-day coalbeds. The number of coal cycles determines the number of resulting coalbeds. For example, the Black Warrior Basin of Alabama includes up to 10 cycles, whereas the San Juan Basin (New Mexico and Colorado) contains as few as 3. The short, rising and falling sea level cycles reflected in the Black Warrior Basin geology produced many thin coalbeds, ranging from less than 1 inch to as much as 4 feet thick (Carrol et al., 1993; Pashin, 1994a and 1994b), whereas the stable, long-term cycles of the San Juan Basin produced fewer, but thicker coalbeds, with single coalbeds up to 70 feet thick (Kaiser and Ayers, 1994).

Peat is transformed into coal when it is buried by accumulating sediment and heated in the subsurface over geologic time. The "rank" of coal describes the amount of energy (measured in British thermal units or Btus) it contains, and is a function of the proportion and type of organic matter, the length and temperature of burial, and the influences of subsequent hydrogeologic and tectonic processes (Carrol et al., 1993; Levine, 1993; Rice, 1993). Methane is generated as part of the process whereby peat is transformed into coal. The origin of methane in coal of low rank, such as bituminous coal, is primarily biogenic (i.e., the result of bacterial action on organic matter) (Levine 1993, as cited by the Alabama Oil and Gas Board, 2002). Low rank coals tend to have lower gas content than high rank coals such as anthracite. Anthracite can have extremely high gas content, but the gas tends to desorb so slowly that anthracite is an insignificant source of coalbed methane (Levine, 1993, as cited by the Alabama Oil and Gas Board, 2002). Commercial coalbed methane production takes place in coals of mid-rank, usually low- to high-volatile bituminous coals (Levine, 1993; Rice, 1993).

A network of fractures, joints, and a sub-network of small joints called cleats commonly characterize the physical structure of coalbeds. Joints are larger, systematic, near-vertical fractures within the coal, generally spaced from several feet to several dozen feet apart (Close, 1993; Levine, 1993). There are two types of cleats: the primary, more continuous cleats are called *face cleats*, while the abutting cleats are called *butt cleats* (Laubach and Tremain 1991; Close, 1993; Levine, 1993) (Figure 3-3). The butt cleats appear as the rungs on a ladder that are bounded on each side by the face cleats. The spacing between cleats is often roughly proportional to the thickness of coal cut by the cleats; thin coals have more closely spaced cleats and thick coals more widely spaced cleats (Laubach et al., 1998, as cited by Olson, 2001).

The primary (or natural) permeability of coal is very low, typically ranging from 0.1 to 30 millidarcies (md) (McKee et al., 1989). According to Warpinski (2001), because coal is a very weak (low modulus) material and cannot take much stress without fracturing, coal is almost always highly fractured and cleated. The resulting network of fractures commonly gives coalbeds a high secondary permeability (despite coal's typically low primary permeability). Groundwater, hydraulic fracturing fluids, and methane gas can more easily flow through the network of fractures. Because hydraulic fracturing generally enlarges pre-existing fractures and rarely creates new fractures (Steidl, 1993; Diamond, 1987a and b; Diamond and Oyler, 1987), this network of natural fractures is very important to the extraction of methane from the coal.

3.2 Hydraulic Fracturing

This section provides an overview of the hydraulic fracturing process, and the factors that affect fracture behavior and fracture orientation. Figure 3-4 provides a simplified graphical representation of a hypothetical hydraulic fracturing event in a coalbed methane well. This diagram shows the fracture initiation and propagation stages, as well as the proppant placement and fracturing fluid recovery stages. Only horizontal fractures are shown in this diagram, although hydraulically induced fractures are often vertically oriented.

3.2.1 The Hydraulic Fracturing Process

Hydraulic fracturing is a technique used by the oil and gas industry to improve the production efficiency of oil and coalbed methane wells. The extraction of coalbed methane is enhanced by hydraulically enlarging and/or creating fractures in the coal zones. The resulting fracture system facilitates pumping of groundwater from the coal zone, thereby reducing pressure and enabling the methane to be released from the coal and more easily pumped through the fracture system back to the well (and then through the well to the surface). To initiate the process, a production well is drilled into the targeted coalbeds. Fracturing fluids containing proppants are then injected under high pressure into the well and specifically into the targeted coalbeds in the subsurface.

The fracturing fluids are injected into the subsurface at a rate and pressure that are too high for the targeted coal zone to accept. As the resistance to the injected fluids increases, the pressure in the injecting well increases to a level that exceeds the breakdown pressure of the rocks in the targeted coal zone, and the rocks "breakdown" (Olson, 2001). In this way, the hydraulic fracturing process "fractures" the coalbeds (and sometimes other geologic strata within or around the targeted coal zones). This process sometimes can create new fractures, but most often opportunistically enlarges existing fractures, increasing the connections of the natural fracture networks in and around the coalbeds (Steidl 1993; Diamond 1987a and b; Diamond and Oyler, 1987). The pressure-induced fracturing serves to connect the network of fractures in the coalbeds to the hydraulic fracturing well (which subsequently will serve as the methane extraction or production well). The fracturing fluids pumped into the subsurface under high pressure also deliver and emplace the "proppant." The most common proppant is fine sand; under pressure, the sand is forced into the natural and/or enlarged fractures and acts to "prop" open the fractures even after the fracturing pressure is reduced. The increased permeability due to fracturing and proppant emplacement facilitates the flow and extraction of methane from coalbeds.

Methane within coalbeds is not structurally "trapped" by overlying geologic strata, as in the geologic environments typical of conventional gas deposits. Only about 5 to 9 percent of the coalbed methane is present as "free" gas within the joints and cleats of coalbeds. Most of the coalbed methane is contained within the coal itself (adsorbed to the sides of the small pores in the coal) (Koenig, 1989; Winston, 1990; Close, 1993).

Before coalbed methane production begins, groundwater and injected fracturing fluids are first pumped out (or "produced" in industry terminology) from the network of fractures in and around the coal zone. The fluids are pumped until the pressure declines to the point that methane begins to desorb from the coal (Gray, 1987).

Coalbed methane production initially requires pumping and removing significant amounts of water to sufficiently reduce the hydrostatic pressure in the subsurface so that methane can desorb from the coal before methane extraction can begin. Coalbed methane is produced at close to atmospheric pressure (Ely et al., 1990; Schraufnagel, 1993). The proportion of water to methane pumped is initially high and declines with increasing coalbed methane production (Figure 3-5). In contrast, in the production of conventional petroleum-based gas, the production of gas is initially high, and as gas production continues over time and the gas resources are progressively depleted, gas production decreases and the amount of water pumped increases.

Almost every coalbed targeted for methane production must be hydraulically fractured to connect the production well bore to the coalbed fracture network (Holditch et al., 1988). Although the general hydraulic fracturing process (described above) is generally similar across the country, the details of the process can differ significantly from location to location depending on the site-specific geologic conditions. For example, although most hydraulic fracturing wells are completely cased except for openings at the targeted coal zone, many wells in the San Juan Basin are fractured by creating a cavity in the open-hole section. Also, in contrast to the typical fracturing job, many wells in the Black Warrior Basin are stimulated more than once. Here, when wells are open to multiple coal seams, the hydraulic fracturing process may involve several or multiple fracturing events, using from 2 to 5 hydraulic fracture treatments per well (depending on number of seams and spacing between seams). Many coalbed methane wells are re-fractured at some time after the initial treatment in an effort to re-connect the wellbore to the production zones to overcome plugging or other well problems (Holditch, 1990; Saulsberry et al., 1990; Palmer et al., 1991a and 1991b; Holditch, 1993). Also, in response to site-specific coal geology and the economics of coalbed methane production where coal seams are thin and vertically separated by up to hundreds of feet of intervening rock) operators might design fracture treatments to enhance the vertical dimension and perform several fracture treatments within a single well to produce methane in an economically viable fashion, (Ely, et al., 1990; Holditch, 1990; Saulsberry et al., 1990; Spafford, 1991; Holditch, 1993).

3.2.2 Factors Affecting Fracture Behavior

Fracture behavior is of interest because it contributes to an understanding of the potential impact of fracturing fluid injection on USDWs; the opportunities for fracture connections within or into a USDW are affected by the extent to which a hydraulically induced fracture grows. Specifically, when hydraulic fracturing fluids are injected into formations that are not themselves USDWs, the following scenarios are of potential concern:

- The hydraulically induced fracture may extend from the target formation into a USDW.

- The hydraulically induced fracture may connect with natural (existing) fracture systems and/or porous and permeable formations, which may facilitate the movement of fracturing fluids into a USDW.

Fracture behavior through coal and other geologic formations commonly present above and below coalbeds depends on site-specific factors such as the following:

1. Physical properties, types, thicknesses, and depths of the targeted coalbeds as well as those of the surrounding geologic formations.

2. Presence of existing natural fracture systems and their orientation in the coalbeds and surrounding formations.

3. Amount and distribution of stress (i.e., in-situ stress), and the stress contrasts between the targeted coalbeds and surrounding formations.

4. Hydraulic fracture stimulation design including volume of fracturing fluid injected into the subsurface as well as the fluid injection rate and fluid viscosity.

Many of these factors are interrelated and together will influence whether and how far hydraulic fractures will propagate into or beyond coalbeds targeted for fracturing. These factors are discussed below.

Properties of Coalbeds and Surrounding Formations

Coalbed depth and rock types in the coal zone have important fundamental influences on fracture dimensions and orientations. According to Nielsen and Hansen (1987, as cited in Appendix A: DOE, Hydraulic Fracturing), generally, at depths of less than 1,000 feet, the direction of least principal stress tends to be vertical and, therefore, at these relatively shallow depths fractures typically have more of a horizontal than a vertical component. Here, horizontal fractures tend to be created because the hydraulically induced pressure forces the walls of the fracture to open in the direction of least stress (which is vertical), creating a horizontal fracture. At these shallower depths, the horizontal fractures result from the low vertical stress due to the relatively low weight of overlying geologic material (due to the shallow depth). Shallow vertical fractures are most likely due to the presence of natural (existing) vertical fractures, from which hydraulically induced vertical fractures can initiate. Generally, in locations deeper than 1,000 feet, the least principal stress tends to be horizontal so vertical fractures tend to form. Vertical fractures created in these greater depths can propagate vertically to shallower depths and develop a horizontal component (Nielsen and Hansen, 1987 as cited in Appendix A: DOE, Hydraulic Fracturing). In the formation of these "T-fractures," the fracture tip may fill with coal fines or intercept a zone of stress contrast, causing the fracture to turn and develop horizontally, sometimes at the contact of the coalbed and an overlying formation.

In many coalbed methane basins, the depths, lithologic properties, and stress fields of the coal zones result in hydraulic fractures that are higher than they are long ("length" refers to horizontal distance from the well bore) (Diamond, 1987a; Morales et al., 1990; Zuber et al., 1990; Holditch et al., 1989; Palmer and Sparks, 1990; Jones and Schraufnagel, 1991; Steidl, 1991; Wright, 1992; Palmer et al., 1991a and 1993a). Almost all of the sites studied by Diamond (1987a and b) had vertical fractures, and about half had horizontal fractures.

Naceur and Touboul (1990) state that the primary mechanisms controlling fracture height are contrasts in the physical properties of the rock strata within and surrounding the coal zone being fractured. Contrasts in strata stresses, moduli, leakoff, and toughness affect fracture growth, with stress contrasts being the most important mechanism controlling fracture height (Naceur and Touboul 1990). (Stress is discussed in more detail later in this section.) Moduli are the ratios of stress to strain in various formations. Leakoff is the magnitude of pressure exerted on a formation that causes fluid to be forced into the formation. The fluid may be flowing into the pore spaces of the rock or into cracks opened and propagated into the formation by the fluid pressure. Toughness can be defined as the point at which enough stress intensity has been applied to a rock formation, so that a fracture initiates and propagates. Coal is generally very weak (with low modulus) and easily fractures. Siltstones, sandstones, and mudstones (other rock types commonly occurring in coal zones) tend to have higher moduli, greater toughness and fracture less easily (Warpinski, 2001). Thick shales, which commonly overlie coalbeds, often act as a barrier to fracture growth (see Appendix A).

Another factor controlling fracture height can be the highly cleated nature of some coalbeds. In some cases, highly cleated coal seams will prevent fractures from growing vertically. When the fracturing fluid enters the coal seam, it is contained within the coal seam's dense system of cleats and the growth of the hydraulic fracture will be limited to the coal seam (see Appendix A).

The low permeability of relatively unfractured shale may help to protect USDWs from being affected by hydraulic fracturing fluids in some basins. If sufficiently thick and relatively unfractured shales are present, they may act as a barrier not only to fracture height growth, but also to fluid movement. The degree to which any formation overlying targeted coalbeds will act as a hydraulic barrier will depend on site-specific factors.

The lithology of coalbeds and surrounding formations is variable in the basins where coalbed methane is produced. Although common, the idealized coal cycle (with shales overlying coalbeds) is not always present in all coal basins or necessarily in all parts of any basin. Although Holditch (1993) states that fracture heights can grow where the coal seam is bounded above or below by sandstone, Warpinski (2001) states that highly layered formations or very permeable strata, such as some sandstones, can act to inhibit fracture growth. Some of the coal seams of the San Juan Basin are bounded below by sandstone. In some locations in each of the other basins, coalbeds are underlain by, overlain by, or interbedded with sandstones. Additional detail on the stratigraphy within each basin is provided in the attachments to this study.

Differences in fracture behavior may also be due in part to very small (but influential) layers or irregularities that exist in the rocks as part of the sedimentation process that created them. Therefore, a valid measurement of rock properties relevant to fracture behavior at one location may not adequately represent the properties of similar rock at another location (Hanson et al., 1987; Jones et al., 1987a and 1987b; Palmer et al., 1989; Morales et al., 1990; Naceur and Touboul, 1990; Jones and Schraufnagel, 1991; Palmer et al., 1993b; Elbel, 1994). For example, the presence of a shallow clay layer as thin as 10 millimeters at the upper contact of a coal seam can cause a vertically propagating, shallow hydraulic fracture to "turn" horizontal and fail to penetrate the next overlying coal seam (Jones et al., 1987a; Palmer et al., 1989; Morales et al., 1990; Palmer et al., 1991b and 1993b). In other cases, hydraulic fractures may penetrate into or even, as shown in the case of some thin shales, completely through overlying shale layers (Diamond, 1987a and b; Diamond and Oyler, 1987). Warpinski et al. (1982) found that even microscopically-thin ash beds can influence hydraulic fracture propagation. In other words, the site-specific geology can play a key role in influencing fracture behavior. In addition to the effects of the rock type and sometimes even thin layers within strata, natural fractures also play a role in fracture behavior and fracture propagation.

Natural Fracture Systems

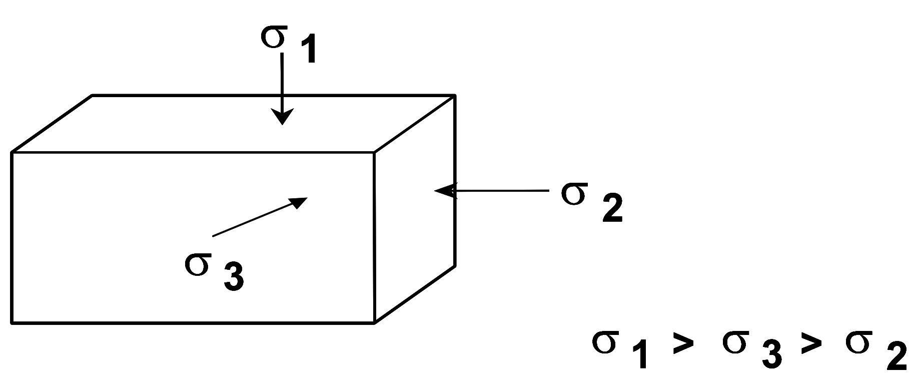
Steidl (1993), based on his "mined-through" studies, concluded that high coalbed methane production depends greatly on the presence of pre-existing natural fracture systems. Hydraulic fracturing tends to widen naturally occurring planes of weakness and rarely creates new fractures, as based on observations by Diamond (1987a and b) and Diamond and Oyler (1987) in their mined-through studies. ("Mined-through" studies provide unique subsurface access to investigate coalbeds and surrounding rock after hydraulic fracturing. Mined-through studies are reviewed in more detail in section 3.4.1.) Diamond and Oyler (1987) also noted that this opportunistic enlarging of preexisting fractures appears to account for those cases where hydraulic fractures propagate from the targeted coalbeds into overlying rock, and their studies found penetration into overlying layers in nearly half of the fractures intercepted by underground mines.

Importantly, in several locations in the Diamond (1987a and b) study sites, fluorescent paint was injected along with the hydraulic fracturing fluids and the paint was found in natural fractures from 200 to slightly more than 600 feet beyond the sand-filled ("propped") portions of hydraulically induced or enlarged fractures. This suggests that the induced/enlarged fractures link into the existing fracture network system and that hydraulic fracturing fluids can move beyond, and sometimes significantly beyond, the propped, sand-filled portions of hydraulically induced fractures (Steidl 1993; Diamond 1987a and b; Diamond and Oyler, 1987). The mined-through studies did not conduct systematic assessments of the extent of the fractures into or through the roof rock shales that were immediately above the mined coal (the rock strata immediately above a mined coal layer is referred to as the "roof rock").

In-Situ Stress and Stress Contrasts

In-situ stress and the relative stress of neighboring geologic strata are important influences on fracture behavior. A discussion of in-situ stress is provided in DOE's paper "Hydraulic Fracturing" (provided as Appendix A). In-situ stress is described as:

> "Underground formations are confined and under stress… [The graphic below] illustrates the local stress state at depth for an element of formation. The stresses can be divided into 3 principal stresses… [In the graphic below,] σ_1 is the vertical stress, σ_2 is the maximum horizontal stress, while σ_3 is the minimum horizontal stress, where $\sigma_1>\sigma_2>\sigma_3$. This is a typical configuration for coalbed methane reservoirs. However, depending on geologic conditions, the vertical stress could also be the intermediate (σ_2) or minimum stress (σ_3). These stresses are normally compressive and vary in magnitude throughout the reservoir, particularly in the vertical direction (from layer to layer). The magnitude and direction of the principal stresses are important because they control the pressure required to create and propagate a fracture, the shape and vertical extent of the fracture, the direction of the fracture, and the stresses trying to crush and/or embed the propping agent during production."



Local in-situ stress at depth.

According to (Naceur and Touboul 1990), the contrast in stress between adjacent rock strata within and surrounding the targeted coal zone is the most important mechanism controlling fracture height. Stress contrast is important in determining whether a fracture will continue to propagate in the same direction when it hits a geologic contact between two different rock types. Often, a high stress contrast results in a barrier to fracture propagation. An example of this would be where there is a geologic contact between a coalbed and an overlying, thick, higher-stress shale.

Hydraulic Fracture Stimulation Design

The procedures and fracturing fluids used to stimulate coalbed methane wells can differ from operator to operator in a single basin due to local characteristics of geology and depth and to perceived advantages of cost, effectiveness, production characteristics, or other factors. On a larger scale, although fracture stimulations in coalbed methane projects in different basins may share common rock types and characteristics, fracture behavior can differ significantly. Discussions on hydraulic fracturing practices in 11 individual coal basins are included in Chapter 5 and in Attachments 1 through 11.

Aspects of fracture behavior, such as fracture dimensions (height, length, and width), are affected by the different fracturing approaches taken by the operator during a hydraulic fracturing event. Generally, the larger the volume of fracturing fluids injected, the larger the potential fracture dimensions. Fluid injection rates and viscosity can also affect fracture dimensions (Olson, 2001; Diamond and Oyler, 1987). Large injection volumes also often result in extensive networks of induced fractures. Gelled water treatments may result in the widest and longest fractures, but this occurrence cannot be concluded with certainty from the mined-through studies (Diamond and Oyler, 1987; Diamond 1987a and b).

The effects of these operator-controlled actions interact with and are influenced by the physical properties, depths, and in-situ stress of the geologic formations being fractured (as listed above). For example, if a hydraulically induced fracture has a relatively constant height due to a geologic layer acting as a barrier to fracture propagation, and the fracture is forced to grow and increase in volume (through an increased volume of fracturing fluid), the fracture will mainly grow in length. Also, increasing fluid viscosity can increase the pressure due to injection, resulting in greater fracture width, and thus often shorter fractures (Olson, 2001).

3.3 Fracturing Fluids

The fluids used for fracture development are pumped at high pressure into the well. They may be “clear” (most commonly water, but may include acid, oil, or water with friction-reducer additives) or “gelled” (viscosity-modified water, using guar or other gelling agents). Some literature indicates that coalbed fracture treatments use from 50,000 to 350,000 gallons of various stimulation and fracturing fluids, and from 75,000 to 320,000 pounds of sand as proppant (Holditch et al., 1988 and 1989; Jeu et al., 1988; Hinkel et al., 1991; Holditch, 1993; Palmer et al., 1991b, 1993a, and 1993b). More typical injection volumes, based on average injection volume data provided by Halliburton for six coalbed methane locations, indicate a maximum average injection volume of 150,000 gal/well and a median average injection volume of 57,500 gal/well (Halliburton, Inc., 2003).

Depending on the basin and treatment design, the composition of these fluids varies significantly, from simple water and sand to complex polymeric substances with a multitude of additives. Types of fracturing fluids are discussed in greater detail in Chapter 4.

3.3.1 Quantifying Fluid Recovery

Several studies have evaluated the recovery rates of hydraulic fracturing treatment fluids in coal and non-coal formations as discussed in more detail below. Non-coal formations were evaluated to augment the available flowback data.

Coal Formation

Palmer et al. (1991a) measured flowback rates in 13 hydraulic fracturing wells to compare the gas production resulting from the use of water versus gel-based fracturing fluids. This study was conducted in a coal seam with permeabilities from 5 to 20 md. Ten samples collected over a 19-day flowback period indicated a recovery rate of 61 percent. Palmer et al. (1991a) predicted total recovery to be from 68 percent to as much as 82 percent.

Non-Coal Formations

Willberg et al. (1997) conducted a flowback analysis in 10 wells in a heterogeneous sandstone and shale environment that was highly impermeable (i.e., with a permeability of 0.01 md). The fluids used in this study were recovered at an average efficiency of 35 percent during the 4 to 5 day flowback period. Three wells were then sampled every 4 to 8 hours during the subsequent gas production phase to assess long-term polymer recovery, which was found to be minimal (3 percent). Sampling of injected fluid and chloride concentrations indicated that as the flowback and gas production periods progressed, decreasing proportions of the extracted water consisted of the injected fluid, while increasing proportions were natural formation water. In other words, natural formation water was able to bypass viscous gel trapped in the formation and flow into the production wells.

The authors further cited laboratory studies indicating that water may flow past the gel in sand such as that used as proppant in these studies (Willberg et al., 1997). Because the gel is more viscous than water, it is easier for water to respond to pumping and flow through the formation towards the production well. As Willberg et al. (1997) writes, "Production of formation water effectively competes and eventually supersedes residual fracturing fluid recovery, thereby limiting the overall cleanup efficiency." Given that the environments in which coalbed methane is produced are also generally saturated with water, and similar sands are used as proppants, it is possible that gel recovery is impeded in much the same way in coalbed methane stimulations.

Willberg et al. (1998) conducted another flowback analysis and described the effect of flowback rate on cleanup efficiency in an initially dry, very low permeability (0.001 md) shale. Some wells in this study were pumped at low flowback rates (less than 3 barrels per minute (bbl/min). Other wells were pumped more aggressively at greater than 3 bbl/min. Thirty-one percent of the injected fluids were recovered when low flowback rates were applied over a 5-day period. Forty-six percent of the fluids were recovered when aggressive flowback rates were applied in other wells over a 2-day period. Additional fluid recovery (10 percent to 13 percent) was achieved during the subsequent gas production phase, resulting in a total recovery rate of 41 percent to 59 percent. Willberg speculated that the lower recovery rate in the 1997 study was due to the pumping of large amounts of formation water during the recovery process, compared to the 1998 study that was conducted in a relatively dry environment.

3.3.2 Mechanisms Affecting Fluid Recovery

A variety of site-specific factors will influence the recovery efficiency of fracturing fluids. These factors are summarized as follows:

- Fluids can "leakoff" (flow away) from the primary hydraulically induced fracture into smaller secondary fractures. The fluids then become trapped in the secondary fractures and/or pores of porous rock.

- Fluids can become entrapped due to the "check-valve effect," wherein fractures narrow again after the injection of fracturing fluid ceases, formation pressure decreases, and extraction of methane and groundwater begins.

- Some fluid constituents can become adsorbed to coal or react chemically with the formation.

- Some volume of the fluids, moving along the hydraulically induced fracture, may move beyond the capture zone of the pumping well, and thus cannot be recovered during fluid recovery. The capture zone of the production well is that portion of the aquifer that contributes water to the well.

- Some fluid constituents may not completely mix with groundwater and therefore would be difficult to recover during production pumping.

Each of these mechanisms is discussed in greater detail in this section.

Fluid Leakoff

Fluids can be "lost" (i.e., remain in the subsurface unrecovered) due to "leakoff" into connected fractures and the pores of porous rocks (Figure 3-7). Fracturing fluids injected into the primary hydraulically induced fracture can intersect and flow (leakoff) into preexisting smaller natural fractures. Some of the fluids lost in this way may occur very close to the well bore after traveling minimal distances in the hydraulically induced fracture before being diverted into other fractures and pores. The volume of fracturing fluids that may be lost in this way depends on the permeability of the rocks and the surface area of the fracture(s).

The high injection pressures of hydraulic fracturing can force the fracturing fluids to be transported deep into secondary fractures. The cleats in coal are presumed to play an important role in leakoff (Olson, 2001). Movement into smaller fractures and cleats can be to a point where flowback efforts will not recover them. The pressure reduction caused by pumping during subsequent production is not sufficient to recapture all the fluid that has leaked off into the formation. The loss of fluids due to leakoff into small fractures and pores is minimized by the use of cross-linked gels, discussed in more detail in Chapter 4.

Check-Valve Effect

A check-valve effect occurs when natural or propagating fractures open and allow fluids to flow through when fracturing pressure is high, but subsequently prevent the fluids from flowing back towards the production well as they close after fracturing pressure decreases (Warpinski et al., 1988; Palmer et al., 1991a). A long fracture can be pinched off at some distance from the well. This reduces the effective fracture length available to transport methane from various locations within the coalbed to the production well. Fluids trapped beyond the "pinch point" are unlikely to be recovered during flowback.

In most cases, when the fracturing pressure is released, the fracture closes in response to natural subsurface compressive stresses. Because the primary purpose of hydraulic fracturing is to increase the effective permeability of the target formation and connect new or widened fractures to the well, a closed fracture is of little use. Therefore, a component of coalbed methane production well development is to "prop" the fracture open, so that the enhanced permeability from the pressure-induced fracturing persists even after fracturing pressure is terminated. To this end, operators use a system of fluids and "proppants" to create and preserve a high-permeability fracture-channel from the well into the formation.

The check-valve effect takes place in locations beyond the zone where proppants have been emplaced (or in smaller secondary fractures that have not received any proppant). Because of the heterogeneous, stratified, and fractured nature of coal deposits, it is likely that some volume of stimulation fluid cannot be recovered due to its movement into zones that were not completely "propped."

Adsorption and Chemical Reactions

Adsorption and chemical reactions can prevent the fluid from being recovered. Adsorption is the process by which fluid constituents adhere to a solid surface (i.e., the coal, in this case) and are thereby unavailable to flow with groundwater. Adsorption to coal is likely; however, adsorption to other surrounding geologic material (e.g., shale, sandstone) is likely to be minimal. Another possible reaction affecting the recovery of fracturing fluid constituents is the neutralization of acids (in the fracturing fluids) by carbonates in the subsurface.

Movement of Fluids Outside the Capture Zone

Fracturing fluids injected into the target coal zone flow into fractures under very high pressure. The hydraulic gradients driving fluid flow away from the well during injection are much greater than the hydraulic gradients pulling fluid flow back towards the production well during flowback and production pumping. Some portion of the coalbed methane fracturing fluids could be forced along the hydraulically induced fracture to a point beyond the capture zone of the production well. The size of the capture zone will be affected by the regional groundwater gradients, as well as by the drawdown caused by the well. If fracturing fluids have been injected to a point outside of the well's capture zone, they will not be recovered through production pumping and, if mobile, may be available to migrate through an aquifer. Site-specific geologic, hydrogeologic, injection pressure, and production pumping details would provide the information needed to estimate the dimension of the production well capture zone and the extent to which the fracturing fluids might travel, disperse, and dilute.

Incomplete Mixing of Fracturing Fluids with Water

Steidl (1993) documented the occurrence of a gelling agent that did not dissolve completely and formed clumps at 15 times the injected concentration in the fracture induced by one well. Steidl (1993) also directly observed, in his mined-through studies, gel hanging in stringy clumps in many other fractures induced by that one well. As Willberg et al. (1997) noted, laboratory studies indicate that fingered flow of water past residual gel may impede fluid recovery. Therefore, some fracturing fluid gels appear not to flow with groundwater during production pumping and remain in the subsurface unrecovered. Such gels are unlikely to flow with groundwater during production, but may present a source of gel constituents to flowing groundwater during and after production.

3.4 Measuring and Predicting the Extent of Fluid Movement

Because fractures can possibly connect with or even extend into USDWs, fracture height is relevant to the issue of whether hydraulic fracturing fluids can affect USDWs. Current methods of measuring or predicting fracture growth, including mathematical models, are described. The models are effective in setting parameters for a given hydraulic fracture operation. Coalbed methane well operators have a financial incentive to keep the hydraulically induced fracture generally within the target coal zone so that expenditures on hydraulic horsepower, fracturing fluids, and proppants are minimized for commercial extraction of methane from the coal. In addition, a detailed review is included on "mined-through" studies that were conducted primarily by the U.S. Bureau of Mines. These studies provide unique information on the direct measurement of the dimensions and other characteristics of fractures created in coal seams and surrounding strata by hydraulic fracturing. Paint, injected with the fracturing fluids, was used as a tracer in some of these studies, enabling one of the most direct measurements of the extent of fluid movement due to hydraulic fracturing.

The particular stratigraphy of a fracturing site will determine what fracture heights are significant with respect to USDWs. That is, a given fracture height may be considered small at a particular site in one basin, but may be more significant in another basin where there is a smaller vertical separation between hydraulically fractured coalbeds and a USDW. The extent of fracturing is controlled by the characteristics of the geologic formations (including the presence of shales or natural fractures), the volume and type of fracturing fluid used, the pumping pressure, and the depth at which the fracturing is performed. Several methods are available to operators to measure or predict the extent to which fracture stimulation fluid moves and the related values of maximum induced fracture extension and "propped" fracture height. Propped height (i.e., height in the fracture to which proppant has been distributed) was found to be 60 percent to 75 percent of total vertical fracture height (Mavor et al., 1991; Rahim and Holditch, 1992; Nolte and Smith, 1981; Nolte and Economides, 1991; Zuber et al., 1991). Furthermore, in cases where proppant "screens out" or emplacement partially fails, proppant may exist in 20 percent or less of fracture height.

Both the current and some older methods for estimating fracture dimensions are discussed below. In general, these methods fall into three areas: direct measurements; indirect measurements; and model estimates. Terminology in the literature regarding fracture dimensions is sometimes inconsistent; some articles describe "measured" fracture dimensions when referring to indirect measures or even model estimates.

3.4.1 Direct Measurements

Direct measures include mined-through (or mineback) studies (where mining of subsurface coal seams that were previously hydraulically fractured allows direct access to fractures for measurement); dye tracing conducted in conjunction with mined-through studies; downhole cameras (used to visually inspect fractures in the borehole), including borehole image logging and downhole video logging; surface and downhole tiltmeters; and microseismic monitoring (or imaging). Fracture geometry is most dependably measured by microseismic monitoring or downhole tiltmeters (Warpinski, 2001), or by tracers (Diamond and Oyler, 1987). Downhole cameras can be used only in open bore holes (uncased wells), so fracture measurements using cameras do not reflect conventional coalbed methane fracturing that typically occurs in cased wells. Both downhole cameras and mined-through approaches to fracture measurements are limited to areas exposed by the wellbore and mining activities, respectively. Nonetheless, the mined-through studies provide the most direct approach for estimating fracture dimensions.

Mined-Through Studies

Twenty-two coalbeds were hydraulically fractured, subsequently mined-through, and investigated several months to several years later in Pennsylvania, Alabama, West Virginia, Illinois, Virginia, and Utah (Diamond 1987a and b; Diamond and Oyler 1987). Similar studies have been conducted by Jeffrey et al. (1993) in Queensland, Australia, and Steidl (1991a; 1991b; 1993) in the Black Warrior Basin, Alabama. The Diamond studies were designed to evaluate the effect of the hydraulic fracturing treatment on mining safety. All the mined-through studies enabled direct observation of induced fractures and surrounding material and evaluation of the movement of sand proppant and fracturing fluids through both induced and natural fractures. Eight of the treatments included fluorescent paint in the injected fluid to aid in mapping fluid movement (Diamond 1987a and b).

Steidl (1993) found that fracture widths were typically 0.1 inch, but could be as wide as 4 inches. Measured sand-filled (propped) fractures were 2 to 526 feet in length (Steidl 1993, Jeffrey et al., 1993), although Steidl found a sand-free extension of a sand-filled fracture 870 feet from the borehole. Diamond (1987a and b) found treatment fluids beyond the sand-filled portions of the fractures using paint injected with the fracturing fluids. In most of the wells where paint was injected, the paint was found 200 to 300 feet beyond the sand-filled portions of fractures. However in one borehole, paint extended out from the well bore for 630 feet, although the sand-filled portion of the fracture was only 95 feet in extent (Diamond, 1987a and b). These paint-coated fractures were produced using typical hydraulic fracturing processes in fairly typical coalbed methane geologic conditions.

Fluorescent paint was observed in locations that indicated fluids did not travel in a direct linear path from the induced fracture. Fluids often followed a stair-step pathway through the coalbed (Diamond and Oyler, 1987). The fluorescent paint was also useful for identifying small fractures penetrated by treatment fluids but not by sand proppant. Multiple small, parallel fractures were penetrated by treatment fluids at many of the locations studied. Given that treatment fluids have been documented to travel more than six times farther than sand proppant, studies looking at the dimensions of sand-filled fractures alone are unlikely to capture the extent of fluid movement within and beyond coalbed methane reservoirs (Diamond, 1987a and b).

About half of the sites studied by Diamond (1987a and b) and Diamond and Oyler (1987) had fractures penetrating beyond the coalbeds into the roof rock (the rock overlying the coal in the mined areas). Jeffrey et al. (1993) found that most of the proppant in three of their four treatments was found in the roof rock. Thus, mined-through studies in Australia and in six states in the United States found that hydraulic fracturing fluids penetrated into, and, when shales were very thin, through strata surrounding coalbeds in 50 percent of stimulations in the United States and 75 percent of the stimulations in Australia. The mined-through studies, however, generally cannot provide measures of how far the fractures actually extend, since mining did not extend beyond the coal and into the roof rock.

Other Direct Measurements

A discussion of other fracture diagnostic methods is provided in DOE's paper "Hydraulic Fracturing" (provided as Appendix A).

> "Fracture diagnostics involves analyzing the data before, during and after a hydraulic fracture treatment to determine the shape and dimensions of both the created and propped fracture. Fracture diagnostic techniques have been divided into several groups (Cipolla and Wright, 2000).
>
> **Direct far field techniques**
>
> Direct far field methods are comprised of tiltmeter fracture mapping and microseismic fracture mapping techniques. These techniques require delicate instrumentation that has to be emplaced in boreholes surrounding and near the well to be fracture treated. When a hydraulic fracture is created, the expansion of the fracture will cause the earth around the fracture to deform. Tiltmeters can be used to measure the deformation and to compute the approximate direction and size of the created fracture. Surface tiltmeters are placed in shallow holes surrounding the well to be fracture treated and are best for determining fracture orientation and approximate size. Downhole tiltmeters are placed in vertical wells at depths near the location of the zone to be fracture treated. As with surface tiltmeters, downhole tiltmeter data can be analyzed to determine the orientation and dimensions of the created fracture, but are most useful for determining fracture height. Tiltmeters have been used on an

experimental basis to map hydraulic fractures in coal seams (Nielson and Hanson, 1987).

Microseismic fracture mapping relies on using a downhole receiver array of accelerometers or geophones to locate microseisms or micro-earthquakes that are triggered by shear slippage in natural fractures surrounding the hydraulic fracture. … In essence, noise is created in a zone surrounding the hydraulic fracture. Using sensitive arrays of instruments, the noise can be monitored, recorded, analyzed and mapped.

…Microseismic monitoring has traditionally been too expensive to be used on anything but research wells, but its cost has dropped dramatically in the past few years, so although still expensive (on the order of $50,000 to $100,000), it is being used more commonly throughout the industry. … If the technology is used at the beginning of the development of a field, however, the data and knowledge gained are often used on subsequent wells, effectively spreading out the costs.

Direct near-wellbore techniques

Direct near-wellbore techniques are run in the well that is being fracture treated to locate or image the portion of fracture that is very near (inches) the wellbore. Direct near-wellbore techniques…[include] borehole image logging [and] downhole video logging, and caliper logging. If a hydraulic fracture intersects the wellbore, these direct near-wellbore techniques can be of some benefit in locating the hydraulic fracture.

However, these near-wellbore techniques are not unique and cannot supply information on the size or shape of the fracture once the fracture is 2-3 wellbore diameters in distance from the wellbore. In coal seams, where multiple fractures are likely to exist, the reliability of these direct near-wellbore techniques are even more speculative. As such, very few of these direct near-wellbore techniques are used on a routine basis to look for a hydraulic fracture."

3.4.2 Indirect Measurements

Indirect measures of fracture dimensions include pressure analyses (sometimes referred to as net, treating, or bottom hole pressure analyses that are sometimes analyzed in conjunction with proppant volume assessments) and radioactive tracing. (Radioactive tracing can be conducted on either fracturing fluids or proppants. It is sometimes referred to as a "tagged" study, and is typically measured through gamma ray logging.) Pressure analyses generally monitor bottom hole pressures (BHPs) over time to infer fracture propagation. For example, declining net pressure during water/gel pumping stages indicates rapid fracture height growth (Saulsberry, et al., 1990). Proppant volumes and historical fracturing and methane production data are used to improve estimates based on pressure analyses. Fracture heights and lengths that are inferred by pressure analyses are commonly described in the literature as "measured." Radioactive tracers provide only approximate estimates of fracture dimensions because they are measured in near-wellbore environments.

3.4.3 Model Estimates

The other main category of indirect measures of fracture dimensions is hydraulic fracture modeling. The basic elements of fracture modeling were developed between 1955 and 1961 (Nolte and Economides, 1991). Many modeling studies were conducted to aid in the design of fracture stimulation treatments (i.e., to determine the volume and pump rate of fluids and proppants that are required to achieve a desired fracture geometry).

Model estimates of fracture heights and lengths are common, including estimates using three-dimensional (and quasi-three dimensional) models. Modeling capabilities have advanced considerably in the last several 15 years, and the newest P3D (pseudo 3 dimensional) models simultaneously predict height, width, and length based on treatment input data and reservoir parameters (Olson, 2001). A discussion of indirect fracture modeling techniques is provided by DOE in the "Hydraulic Fracturing" paper (provided as Appendix A). An excerpt from that paper is provided below.

> "The indirect fracture techniques consist of hydraulic fracture modeling of net pressures, pressure transient test analyses, and production data analyses. Because the fracture treatment data and the post-fracture production data are normally available on every well, the indirect fracture diagnostic techniques are the most widely used methods to estimate the shape and dimensions of both the created and the propped hydraulic fracture.
>
> The fracture treatment data can be analyzed with a P3D fracture propagation model to determine the shape and dimensions of the created fracture. The P3D model is used to history match the fracturing data, such as injection rates and injection pressures. Input data, such as the in-situ stress and permeability in key layers of rock can be varied (within reason) to achieve a history match of the field data.
>
> Post-fracture production and pressure data can be analyzed using a 3D reservoir simulator to estimate the shape and dimensions of the propped fracture. Values of formation permeability, fracture length and fracture conductivity can be varied in the reservoir model to achieve a history match of the field data.
>
> The main limitation of these indirect techniques is that the solutions are not unique and require as much fixed data as possible. For example, if the engineer has determined the formation permeability from a well test or production test prior to the fracture treatment, so that the value of formation permeability is

> known and can be fixed in the models, the solution concerning values of fracture length become more unique. Most of the information in the literature concerning post-fracture analyses of hydraulic fractures has been derived from these indirect fracture diagnostic techniques."

There are several caveats regarding the use and interpretation of model estimates. In-situ stress values of the target coal seams and surrounding strata are important model inputs. Actual in-situ stress measurements are very difficult to obtain and are rarely conducted (Warpinski, 2001). Therefore, almost all modeling is conducted using inferred stress values (as estimated, for example, from the mechanical and lithological properties of rocks from, or similar to those in, the target coal zone). Given the geologic variability and site-specific influences on fracture behavior described above, the reliability of fracture height and length estimates obtained from various models is obviously influenced by the quality of the inferred model inputs regarding geologic factors.

Models also necessarily rely on simplifying assumptions to simulate fracture propagation and behavior through sometimes complex geologic zones. As with all modeling, the reliance on inferred input variables and some assumptions introduces some subjectivity to the modeling process. Dependable modeling requires knowledge of and allowance for the detailed stratigraphy of the geologic strata throughout the coal zone. (It was noted in section 3.2.2 that thin clay layers or ash beds can influence fracture behavior.) Simplified geologic models might represent the subsurface as 2 to 3 distinct geologic layers, to reduce computing and data requirements, when a 30- or 50-layer model may be necessary to accurately predict fracture height (Rahim et al., 1998). Nevertheless, models are necessary simplifications of fracture behavior in the geologic subsurface, and significant research has been conducted in the last several decades so that model estimates of fracture behavior in methane-producing coalbeds are now an invaluable tool for industry.

3.4.4 Limitations of Fracture Diagnostic Techniques

Warpinski (1996) discussed many of these same fracture diagnostic techniques. In general, the best fracture diagnostics techniques are expensive and used only in research wells. Fracture diagnostic techniques can provide important data when entering a new production area or a new formation. However, for coalbed methane wells, where costs must be minimized to maintain profitability, the best fracture diagnostic techniques are rarely used and are often considered to be prohibitively expensive.

Warpinksi (2001) further provided other general conclusions regarding estimates of fracture dimensions:

- Fracture heights inferred from pressure data are almost always greater than the corresponding heights measured with the more dependable microseismic monitoring or tiltmeters.

- Actual fracture lengths may be greater or less than the lengths estimated from models or inferred from pressure analyses, depending on many site-specific geologic factors.

- Fracture geometry can be accurately measured using microseismic monitoring and measured somewhat using downhole tiltmeters. These technologies have been found to be invaluable for determining how fractures actually behave.

Table 3-1 lists certain diagnostic techniques and their limitations.

Table 3-1. Limitations of Fracture Diagnostic Techniques (Appendix A: DOE, Hydraulic Fracturing)

Parameter	Technique	Limitation
Fracture Height	Tracer logs	Shallow depth of investigation; shows height only near the wellbore
Fracture Height	Temperature logs	Difficult to interpret; shallow depth of investigation; shows height only near wellbore
Fracture Height	Stress profiling	Does not measure fracture directly; must be calibrated with *in-situ* stress tests
Fracture Height	P3D models	Does not measure fracture directly; estimates vary depending on which model is used
Fracture Height	Microseismic	Optimally requires nearby offset well; difficult to interpret; expensive
Fracture Height	Tiltmeters	Difficult to interpret; expensive and difficult to conduct in the field
Fracture Length	P3D models	Length inferred, not measured; estimates vary greatly depending on which model is used
Fracture Length	Well testing	Large uncertainties depending upon assumptions and lack of prefracture well test data
Fracture Length	Microseismic	Optimally requires nearby offset well; difficult to interpret; expensive
Fracture Length	Tiltmeters	Difficult to interpret; expensive and difficult to conduct in the field
Fracture Azimuth	Core techniques	Expensive to cut core and run tests; multiple tests must be run to assure accuracy
Fracture Azimuth	Log techniques	Requires open hole logs to be run; does not work if natural fractures are not present
Fracture Azimuth	Microseismic	Analysis intensive; expensive for determination of azimuth
Fracture Azimuth	Tiltmeters	Useful only to a depth of 5,000 feet; requires access to large area; expensive

3.5 Summary

Coalbed methane development began as a safety measure to extract methane, an explosion hazard, from coal prior to mining. Since 1980, coalbed methane production has grown rapidly, spurred by tax incentives to develop non-conventional energy production. At the end of 2000, coalbed methane production from 13 states totaled 1.353 trillion cubic feet, an increase of 156 percent from 1992. At year-end 2000, coalbed methane production accounted for about 7 percent of the total United States dry gas production and 9 percent of proven dry gas reserves (EIA, 2001).

Methane within coalbeds is not "trapped" under pressure as in conventional gas scenarios. Only about 5 to 9 percent of the methane is present as "free" gas within the natural fractures, joints, and cleats. Almost all coalbed methane is adsorbed within the micro-porous matrix of the coal (Koenig, 1989; Winston, 1990; Close, 1993).

Coalbed methane production starts with high-pressure injection of fracturing fluids and proppant into targeted coal zones. The resulting induced or enlarged fractures improve the connections of the production well to the fracture networks in and around the coal zone. When production begins, water is pumped from the fractures in the coal zone to reduce pressure in the formation. When pressures are adequately reduced, methane desorbs from the coal matrix, moves through the network of induced and natural fractures in the coal toward the production well, and is extracted through the well and to the surface.

Fractures that are created at shallow depths (less than approximately 1,000 feet) typically have more of a horizontal than a vertical component. Vertical fractures created at deeper depths can propagate vertically to shallower depths where they may develop a horizontal component. These "T-fractures" may involve the fracture "turning" and developing horizontally at a coalbed-mudstone interface.

Fracture behavior through coal, shale, and other geologic strata commonly present in coal zones depends on site-specific factors such as relative thicknesses and in-situ stress differences between the target coal seam(s) and the surrounding geologic strata, as well as the presence of pre-existing natural fractures. Often, a high stress contrast between adjacent geologic strata results in a barrier to fracture propagation. This occurs in coal zones where there is a geologic contact between a high-stress coal seam and an overlying, thick, relatively low-stress shale.

The fluids used for fracture development are injected at high pressure into the targeted coal zone in the subsurface. These fluids may be "clear" (primarily consisting of water, but may include acid, oil, or water with friction-reducer additives) or "gelled" (viscosity-modified water using guar or other gelling agents). Hydraulic fracturing in coalbed methane wells may require 50,000 to 350,000 gallons of fracturing fluids and 75,000 to 320,000 pounds of sand as proppant to prop or maintain the opening of fractures after the injection (fracturing) pressure is reduced (Holditch et al., 1988 and 1989; Jeu et al., 1988;

Hinkel et al., 1991; Holditch, 1993; Palmer et al., 1991b, 1993a, and 1993b). More typical injection volumes, based on average injection volume data provided by Halliburton for six coalbed methane locations, indicate a maximum average injection volume of 150,000 gal/well and a median average injection volume of 57,500 gal/well (Halliburton, Inc., 2003).

In any fracturing job, some fracturing fluids cannot be recovered and are said to be "lost" to the formation. Palmer (1991a) observed that for fracture stimulations in multi-layered coal formations, 61 percent of stimulation fluids were recovered during a 19-day production sampling of a coalbed methane well in the Black Warrior Basin. He further estimated that from 68 percent to possibly as much as 82 percent would eventually be recovered. A variety of site-specific factors, including leakoff into the coal seams and surrounding strata, the check-valve effect, adsorption and other geochemical processes, and flow through the hydraulic fracture beyond the well's capture zone will serve to reduce recovery of hydraulic fracturing fluids injected into subsurface coal zones to promote coalbed methane extraction.

The mined-through studies by the U.S. Bureau of Mines (see Diamond, 1987a and b) and others provide important directly-measured characteristics of hydraulic fracturing in coal seams and surrounding strata. Further, paint tracer studies conducted as part of Diamond's (1987a and b) mined-through studies can provide estimates on the extent of hydraulic fracturing fluid movement, which may be greater than the extent of sand-filled (propped) hydraulic fracture heights or lengths given fluid movement through natural fractures. These estimates of the extent of fluid movement are usually limited by the area exposed to mining.

A significant amount of diagnostic research has been conducted in the last decade enabling industry to develop a practical, applied understanding of general fracture behavior as it relates to methane production. Operators use a number of techniques to estimate fracture dimensions to design fracture stimulation treatments to minimize expenditures on hydraulic horsepower, fracturing fluids, and proppants. Modeling is increasingly more sophisticated, but still commonly depends on at least some inferred (and subjective) input data. Reliable fracture height and length can be measured accurately by microseismic monitoring and tiltmeters (Warpinksi, 2001).

Chapter 4
Hydraulic Fracturing Fluids

This chapter summarizes the information EPA collected on the types and volumes of fracturing fluids and additives that may be used for hydraulic fracturing of coalbed methane wells. This chapter also provides EPA's evaluation of the fate and transport of fracturing fluids that are injected into targeted coal layers during the hydraulic fracturing process. This evaluation was conducted to provide the Agency with information on whether a Phase II study is warranted. Captioned photographs in this chapter show the use of fracturing fluids at a coalbed methane well (Figures 4-1 through 4-11 at the end of this chapter).

4.1 Introduction

The types and use of fracturing fluids have evolved greatly over the past 60 years and continue to evolve. The U.S. oil and gas industry has used fluids for fracturing geologic formations since the early 1940s (Ely, 1985). *The Handbook of Stimulation Engineering* (Ely, 1985), a comprehensive history of the evolution of hydraulic fracturing fluids in the oil and gas industry, was used as a source of information for this chapter. In addition, EPA identified fluids and fluid additives commonly used in hydraulic fracturing through literature searches, reviews of relevant MSDSs provided by service companies, and discussions with field engineers, service company chemists, and state and federal employees.

Available scientific literature indicates that hydraulic fracturing fluid performance became a prevalent research topic in the late 1980s and the 1990s. Most of the literature pertaining to fracturing fluids relates to the fluids' operational efficiency rather than their potential environmental or human health impacts. There is very little documented research on the environmental impacts that result from the injection and migration of these fluids into subsurface formations, soils, and USDWs. Some of the existing literature does offer information regarding the basic chemical components present in most of these fluids. The composition of fracturing fluids and additives is discussed in detail in the next section.

The main goal of coalbed hydraulic fracturing is to create a highly conductive fracture system that will allow flow through the methane-bearing coal zone to the production well used to extract methane (and groundwater). Hydraulic fracturing fluids are used to initiate and/or expand fractures, as well as to transport proppant into fractures in coalbed formations. Proppants are sand or other granular substances injected into the formation to hold or "prop" open coal formation fractures created by hydraulic fracturing. The viscosity of fracturing fluids is considered when they are formulated, to provide for efficient transport and placement of proppant into a fracture. Most of the fracturing fluids injected into the formation are pumped back out of the well along with groundwater and methane gas (see section 3.3 in Chapter 3 for a more detailed discussion of fracturing fluid recovery).

4.2 Types of Fracturing Fluids and Additives

Service companies have developed a number of different oil- and water-based fluids and treatments to more efficiently induce and maintain permeable and productive fractures. The composition of these fluids varies significantly, from simple water and sand to complex polymeric substances with a multitude of additives. Each type of fracturing fluid has unique characteristics, and each possesses its own positive and negative performance traits. For ideal performance, fracturing fluids should possess the following four qualities (adapted from Powell et al., 1999):

- Be viscous enough to create a fracture of adequate width.
- Maximize fluid travel distance to extend fracture length.
- Be able to transport large amounts of proppant into the fracture.
- Require minimal gelling agent to allow for easier degradation or “breaking” and reduced cost.

Water-based fracturing fluids have become the predominant type of coalbed methane fracturing fluid (Appendix A: DOE, Hydraulic Fracturing). However, fracturing fluids can also be based on oil, methanol, or a combination of water and methanol. Methanol is used in lieu of, or in conjunction with, water to minimize fracturing fluid leakoff and enhance fluid recovery (Thompson et al., 1991). Polymer-based fracturing fluids made with methanol usually improve fracturing results, but require 50 to 100 times the amount of breaker (e.g., acids used to degrade the fracturing fluid viscosity, which helps to enhance post-fracturing fluid recovery) (Ely, 1985). In some cases, nitrogen or carbon dioxide gas is combined with the fracturing fluids to form foam as the base fluid. Foams require substantially lower volumes to transport an equivalent amount of proppant. Diesel fuel is another component of some fracturing fluids although it is not used as an additive in all hydraulic fracturing operations. A variety of other fluid additives (in addition to the proppants) may be included in the fracturing fluid mixture to perform essential tasks such as formation clean up, foam stabilization, leakoff inhibition, or surface tension reduction. These additives include biocides, fluid-loss agents, enzyme breakers, acid breakers, oxidizing breakers, friction reducers, and surfactants such as emulsifiers and non-emulsifiers. Several products may exist in each of these categories. On any one fracturing job, different fluids may be used in combination or alone at different stages in the fracturing process. Experienced service company engineers will devise the most effective fracturing scheme, based on formation characteristics, using the fracturing fluid combination they deem most effective.

The main fluid categories are:

- Gelled fluids, including linear or cross-linked gels.
- Foamed gels.
- Plain water and potassium chloride (KCl) water.
- Acids.
- Combination treatments (any combination of 2 or more of the aforementioned fluids).

Some of the fluids and fluid additives may contain constituents of potential concern. Table 4-1, at the end of section 4.2.6, lists examples of chemicals found in hydraulic fracturing fluids according to the MSDSs provided by service companies, and potential human health effects associated with the product. It is important to note that information presented in MSDSs is for pure product. Each of the products listed in Table 4-1 is significantly diluted prior to injection.

EPA also obtained two environmental impact statements that were prepared by the Bureau of Land Management (BLM). In these impact statements, BLM identified additional chemical compounds that may be in fracturing fluids including methyl tert butyl ether (MTBE) (U.S. Department of the Interior, CO State BLM, 1998). However, EPA was unable to find any indications in the literature, on MSDSs, or in interviews with service companies that MTBE is used in fracturing fluids to stimulate coalbed methane wells.

4.2.1 Gelled Fluids

Water alone is not always adequate for fracturing certain formations because its low viscosity limits its ability to transport proppant. In response to this problem, the industry developed linear and cross-linked fluids, which are higher viscosity fracturing fluids. Water gellants or thickeners are used to create these gelled fluids. Gellant selection is based on formation characteristics such as pressure, temperature, permeability, porosity, and zone thickness. These gelled fluids are described in more detail below.

Linear Gels

A substantial number of fracturing treatments are completed using thickened, water-based linear gels. The gelling agents used in these fracturing fluids are typically guar gum, guar derivatives such as hydroxypropylguar (HPG) and carboxymethylhydroxypropylguar (CMHPG), or cellulose derivatives such as carboxymethylguar or hydroxyethylcellulose (HEC). In general, these products are biodegradable. Guar is a polymeric substance derived from the seed of the guar plant

(Ely, 1985). Guar gum, on its own, is non-toxic and, in fact, is a food-grade product commonly used to increase the viscosity and elasticity of foods such as ice cream.

To formulate a viscous fracturing gel, guar powder or concentrate is dissolved in a carrier fluid such as water or diesel fuel. Increased viscosity improves the ability of the fracturing fluid to transport proppant and decreases the need for more turbulent flow. Concentrations of guar gelling agents within fracturing fluids have decreased over the past several years. It was determined that reduced concentrations provide better and more complete fractures (Powell et al., 1999).

Diesel fuel has been frequently used in lieu of water to dissolve the guar powder because its carrying capacity per unit volume is much higher (Halliburton, Inc., 2002). "Diesel is a common solvent additive, especially in liquid gel concentrates, used by many service companies for continuous delivery of gelling agents in fracturing treatments" (GRI, 1996). Diesel does not enhance the efficiency of the fracturing fluid; it is merely a component of the delivery system (Halliburton, Inc., 2002). Using diesel instead of water minimizes the number of transport vehicles needed to carry the liquid gel to the site (Halliburton, Inc., 2002).

The percentage of diesel fuel in the slurried thickener can range between 30 percent and almost 100 percent, based on the MSDSs summarized in Table 4-1. Diesel fuel is a petroleum distillate and may contain known carcinogens. One such component of diesel fuel is benzene, which, according to literature sources, can make up anywhere between 0.003 percent and 0.1 percent by weight of diesel fuel (Clark and Brown, 1977; R. Morrison & Associates, Inc., 2001). Slurried diesel and gel are diluted with water prior to injection into the subsurface. The dilution is approximately 4 to 10 gallons of concentrated liquid gel (guar slurried in diesel) per 1,000 gallons of make-up water to produce an adequate polymer slurry (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001; Consolidated Industrial Services, Inc., Virginia Site Visit, 2001; BJ Services, 2001).

Cross-linked Gels

One major advance in fracturing fluid technology was the development of cross-linked gels. The first cross-linked gels were developed in 1968 (Ely, 1985). When cross-linking agents are added to linear gels, the result is a complex, high-viscosity fracturing fluid that provides higher proppant transport performance than do linear gels (Messina, Inc. Web site, 2001; Ely, 1985; Halliburton Inc., Virginia Site Visit, 2001). Cross-linking reduces the need for fluid thickener and extends the viscous life of the fluid indefinitely. The fracturing fluid remains viscous until a breaking agent is introduced to break the cross-linker and, eventually, the polymer. Although cross-linkers make the fluid more expensive, they can considerably improve hydraulic fracturing performance, hence increasing coalbed methane well production rates.

Cross-linked gels are typically metal ion-cross-linked guar (Ely, 1985). Service companies have used metal ions such as chromium, aluminum, titanium, and other metal ions to achieve cross-linking (Ely, 1985). In 1973, low-residue (cleaner) forms of cross-linked gels, such as cross-linked hydroxypropylguar, were developed (Ely, 1985).

According to MSDSs summarized in Table 4-1, cross-linked gels may contain boric acid, sodium tetraborate decahydrate, ethylene glycol, and monoethylamine. These constituents are hazardous in their undiluted form and can cause kidney, liver, heart, blood, and brain damage through prolonged or repeated exposure. According to a BLM environmental impact statement, cross-linkers may contain hazardous constituents such as ammonium chloride, potassium hydroxide, zirconium nitrate, and zirconium sulfate (U.S. Department of the Interior, CO State BLM, 1998). Concentrations of these compounds in the fracturing fluids were not reported in the impact statement. The final concentration of cross-linkers is typically 1 to 2 gallons of cross-linker per 1,000 gallons of gel (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001).

4.2.2 Foamed Gels

Foam fracturing technology uses foam bubbles to transport and place proppant into fractures. The most widely used foam fracturing fluids employ nitrogen or carbon dioxide as their base gas. Incorporating inert gases with foaming agents and water reduces the amount of fracturing liquid required. Foamed gels use fracturing fluids with higher proppant concentrations to achieve highly effective fracturing. The gas bubbles in the foam fill voids that would otherwise be filled by fracturing fluid. The high concentrations of proppant allow for an approximately 75-percent reduction in the overall amount of fluid that would be necessary using a conventional linear or cross-linked gel (Ely, 1985; Halliburton, Inc., Virginia Site Visit, 2001). Foaming agents can be used in conjunction with gelled fluids to achieve an extremely effective fracturing fluid (Halliburton, Inc., Virginia Site Visit, 2001).

Foam emulsions experience high leakoff; therefore, typical protocol involves the addition of fluid-loss agents, such as fine sands (Ely, 1985; Halliburton, Virginia Site Visit, 2001). Foaming agents suspend air, nitrogen, or carbon dioxide within the aqueous phase of a fracturing treatment. The gas/liquid ratio determines if a fluid will be true foam or simply a gas-energized liquid (Ely, 1985). Carbon dioxide can be injected as a liquid, whereas nitrogen must be injected as a gas to prevent freezing (Halliburton, Inc., Virginia Site Visit, 2001).

According to the MSDSs summarized in Table 4-1, foaming agents can contain diethanolamine and alcohols such as isopropanol, ethanol, and 2-butoxyethanol. They can also contain hazardous substances including glycol ethers (U.S. Department of the Interior, CO State BLM, 1998). One of the foaming agent products listed in Table 4-1 can cause negative liver and kidney effects, although the actual component causing these effects is not specified on the MSDS. The final concentration is typically 3 gallons of foamer per 1,000 gallons of gel (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001).

4.2.3 Water & Potassium Chloride Water Treatments

Many service companies use groundwater pumped directly from the formation or treated water for their fracturing jobs. In some coalbed methane well stimulations, proppants are not needed to prop fractures open, so simple water or slightly thickened water can be a cost-effective substitute for an expensive polymer or foam-based fracturing fluid with proppant (Ely, 1985). Hydraulic fracturing performance is not exceptional with plain water, but, in some cases, the production rates achieved are adequate. Plain water has a lower viscosity than gelled water, which reduces proppant transport capacity.

Similar to plain water, another fracturing fluid uses water with potassium chloride (KCl) in addition to small quantities of gelling agents, polymers, and/or surfactants (Ely, 1985). Potassium chloride is harmless if ingested at low concentrations.

4.2.4 Acids

Acids are used in limestone formations that overlay or are interbedded within coals to dissolve the rock and create a conduit through which formation water and coalbed methane can travel (Ely, 1985). Typically, the acidic stimulation fluid is hydrochloric acid or a combination of hydrochloric and acetic or formic acid. For acid fracturing to be successful, thousands of gallons of acid must be pumped far into the formation to etch the face of the fracture (Ely, 1985). Some of the cellulose derivatives used as gelling agents in water and water/methanol fluids can be used in acidic fluids to increase treatment distance (Ely, 1985). As discussed in section 4.2.5, acids may also be used as a component of breaker fluids.

In addition, acid can be used to clean up perforations of the cement surrounding the well casing prior to fracturing fluid injection (Halliburton, Inc., Virginia Site Visit, 2001; Halliburton, Inc., 2002). The cement is perforated at the desired zone of injection to ease fracturing fluid flow into the formation (Halliburton, Inc., Virginia Site Visit, 2001; Halliburton, Inc., 2002).

Table 4-1 provides information on formic and hydrochloric acids. Acids are corrosive, and can be extremely hazardous in concentrated form. Acids are substantially diluted with water-based or water-and-gas-based fluids prior to injection into the subsurface. The injected concentration is typically 1,000 times weaker than the concentrated versions presented in the product MSDSs (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001).

4.2.5 Fluid Additives

Several fluid additives have been developed to enhance the efficiency and increase the success of fracturing fluid treatments. The major categories of these additives are defined and briefly described in the following sections.

Breakers

Breaker fluids are used to degrade the fracturing fluid viscosity, which helps to enhance post-fracturing fluid recovery, or flowback. Breakers can be mixed with the fracturing fluid during pumping, or they can be introduced later as an independent fluid. There are a variety of breaker types including time-release and temperature-dependent types. Most breakers are typically acids, oxidizers, or enzymes (Messina, Inc. Web site, 2001). According to a BLM environmental impact statement, breakers may contain hazardous constituents, including ammonium persulfate, ammonium sulphate, copper compounds, ethylene glycol, and glycol ethers (U.S. Department of the Interior, CO State BLM, 1998). Concentrations of these compounds in the fracturing fluids were not presented in the environmental impact statement.

Biocides

One hydraulic fracturing design problem that arises when using organic polymers in fracturing fluids is the incidence of bacterial growth within the fluids. Due to the presence of organic constituents, the fracturing fluids provide a medium for bacterial growth. As the bacteria grow, they secrete enzymes that break down the gelling agent, which reduces the viscosity of the fracturing fluid. Reduced viscosity translates into poor proppant placement and poor fracturing performance. To alleviate this degradation in performance, biocides, bactericides, or microbicides are added to the mixing tanks with the polymeric gelling agents to kill any existing microorganisms (e.g., sulfate-reducing bacteria, slime-forming bacteria, algae), and to inhibit bacterial growth and deleterious enzyme production. Bactericides are typically hazardous by nature (Messina, Inc. Web site, 2001). They may contain hazardous constituents, including polycyclic organic matter (POM) and polynuclear aromatic hydrocarbons (PAHs) (U.S. Department of the Interior, CO State BLM, 1998).

Information from MSDSs for a biocide and a microbicide is summarized in Table 4-1. These concentrated products are substantially diluted prior to injection into the subsurface. Typical dilution in the make-up water is 0.1 to 0.2 gallons of microbicide in 1,000 gallons of water (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001).

Fluid-Loss Additives

Fluid-loss additives restrict leakoff of the fracturing fluid into the exposed rock at the fracture face. Because the additives prevent excessive leakoff, fracturing fluid effectiveness and integrity are maintained. Fluid-loss additives of the past and present include bridging materials such as 100 mesh sand, 100 mesh soluble resin, and silica flour, or plastering materials such as starch blends, talc silica flour, and clay (Ely, 1985).

Friction Reducers

To optimize the fracturing process, water-based fluids must be pumped at maximum rates and fluids must be injected at maximum pressures. Increasing flow velocities and pressures in this manner can lead to undesirable levels of friction within the injection well and the fracture itself. In order to minimize friction, friction reducers are added to water-based fracturing fluids. The friction reducers are typically latex polymers or copolymers of acrylamides. They are added to slick water treatments (water with solvent) at concentrations of 0.25 to 2.0 pounds per 1,000 gallons (Ely, 1985). Some examples of friction reducers are oil-soluble anionic liquid, cationic polyacrilate liquid, and cationic friction reducer (Messina, Inc. Web site, 2001).

Acid Corrosion Inhibitors

Corrosion inhibitors are required in acid fluid mixtures because acids will corrode steel tubing, well casings, tools, and tanks. The solvent acetone is a common additive in corrosion inhibitors (GRI, 1996). Information from MSDSs for acid inhibitors is summarized in Table 4-1. These products can affect the liver, kidney, heart, central nervous system, and lungs. They are quite hazardous in their undiluted form. These products are diluted to a concentration of 1 gallon per 1,000 gallons of make-up water and acid mixture (Halliburton, Inc., Virginia Site Visit, 2001; Schlumberger, Ltd., 2001). Acids and acid corrosion inhibitors are used in very small quantities in coalbed methane fracturing operations (500 to 2,000 gallons per treatment).

4.2.6 Proppants

The purpose of a proppant is to prop open a hydraulic fracture. An ideal proppant should produce maximum permeability in a fracture. Fracture permeability is a function of proppant grain roundness, proppant purity, and crush strength. Larger proppant volumes allow for wider fractures, which facilitate more rapid flowback to the production well. Over a period of 30 minutes, 4,500 to 15,000 gallons of fracturing fluid will typically transport and place approximately 11,000 to 25,000 pounds of proppant into the fracture (Powell et al., 1999).

4.3 The Fate and Transport of Stimulation Fluids Injected into Coal and Surrounding Rock During Hydraulic Fracturing of Coalbed Methane Reservoirs (with a Special Focus on Diesel Fuel)

Diesel fuel is sometimes a component of gelled fluids. Diesel fuel contains constituents of potential concern regulated under SDWA – benzene, toluene, ethylbenzene, and xylenes (i.e., BTEX compounds). The use of diesel fuel in fracturing fluids poses the greatest threat to USDWs because BTEX compounds in diesel fuel exceed the MCL at the point-of-injection (i.e. the subsurface location where fracturing fluids are initially injected).

The remainder of this section presents EPA's qualitative evaluation of the fate and transport of fracturing fluids injected into targeted coal layers in the subsurface during hydraulic fracturing. Although EPA's MOA with the three major service companies has largely eliminated diesel fuel from fracturing fluids injected directly into any USDWs, there may still be rare instances in which diesel fuel is used by other service companies or operators (USEPA, 2003). Therefore an evaluation of the use of diesel fuel in fracturing fluid, which also provides follow-up on the draft of this report published in August, 2002, is included in this chapter.

EPA revised its procedure for assessing the potential effects of fracturing fluid constituents on USDWs from the procedure presented in the August 2002 draft of this report as follows:

- EPA has revised the fraction of BTEX compounds in diesel used to estimate the point-of-injection concentrations from a single value to a documented broader range of values for the fraction of BTEX in diesel fuel. For example, the fraction of benzene in diesel was revised from 0.00006$g_{benzene}/g_{diesel}$ to a range with a minimum value of 0.000026 $g_{benzene}/g_{diesel}$ and a maximum value of 0.001 $g_{benzene}/g_{diesel}$. If the maximum value for benzene in diesel is used to estimate the concentration of benzene at the point-of-injection, the resulting estimate is 17 times higher than that presented in the Draft Report.

- In this report, EPA used more current values for two of the parameters used to estimate the point-of-injection concentrations of BTEX compounds. Specifically, the estimates in this report use a density of the diesel fuel-gel mixture of 0.87 g/mL compared to 0.84 g/mL in the Draft Report, and a fraction of diesel fuel in gel of 0.60 g_{diesel}/g_{gel} compared to 0.52 g_{diesel}/g_{gel} in the Draft Report. The use of these more current values does not affect the order of magnitude of the revised point-of-injection calculations.

- The August 2002 Draft Report included estimates of the concentration of benzene at an idealized, hypothetical edge of the fracture zone located 100 feet from the point-of-injection. Based on new information and stakeholder input, EPA concluded that the edge of fracture zone calculation is not an appropriate model for reasons including:

- Mined-through studies reviewed by EPA indicated that hydraulic fracturing injection fluids had traveled several hundred feet beyond the point-of-injection.

- The assumption of well-mixed concentrations within the idealized fracture zone is insufficient. One mined-through study indicated an observed concentration of gel in a fracture that was 15 times the injected concentration, with gel found to be hanging in stringy clumps in many fractures. The variability in gel distribution in hydraulic fractures indicates that the gel constituents are unlikely to be well mixed in groundwater.

- Based on more extensive review of the literature, the width of a typical fracture was estimated to be much thinner than that used in the Draft Report (0.1 inch versus 2 inches). The impact of the reduced width of a typical fracture is that the calculated volume of fluid that can fit within a fracture is less. After an initial volume calculation using the new width, EPA found that the volume of the space within the fracture area may not hold the volume of fluid pumped into the ground during a typical fracturing event. Therefore, EPA assumes that a greater volume of fracturing fluid must "leakoff" to intersecting smaller fractures than what was assumed in the Draft Report, or that fluid may move beyond the idealized, hypothetical "edge of fracture zone." This assumption is supported by field observations in mined-through studies, which indicate that fracturing fluids often take a stair-step transport path through the natural fracture system.

- In the Draft Report, EPA approximated the edge of fracture zone concentrations considering only dilution. Based on new information and stakeholder input on the Draft Report, EPA does not provide estimates of concentrations beyond the point-of-injection in the final report. Developing such concentration values with the precision required to compare them to MCLs would require the collection of significant amounts of site-specific data. This data in turn would be used to perform a formal risk assessment, considering numerous fate and transport scenarios. These activities are beyond the scope of this Phase I study.

The remainder of this section includes a discussion of the following components of EPA's analysis:

- The concentrations of BTEX at the point-of-injection.

- The percentage of fracturing fluids recovered during the recovery process.

- The influence of the capture zone.

- Factors that would increase or decrease the concentrations of BTEX remaining in the subsurface.

The first step in EPA's analysis of the potential threat to USDWs from the injection of fracturing fluids was calculating the point-of-injection concentrations of BTEX introduced from diesel fuel in the gelling agent. In Step 2, EPA considered factors that affect the degree to which hydraulic fracturing fluids are recovered. Steps 3, 4, and 5 provide analyses of physical/chemical, hydrogeological, and biological processes that could affect the fate and transport of hazardous chemicals introduced into coal seams. These steps are summarized in Table 4-2.

4.3.1 Point-of-Injection Calculation

The formulations or "recipes" for fracturing fluids differ among service companies and among sites; the amount of fracturing fluid used will also vary. Thus, a range of point-of-injection concentrations likely exists. According to field paperwork obtained during EPA's site visits (Consolidated Industrial Services, Inc., 2001; Halliburton, 2001) and information provided by three service company scientists (BJ Services, 2001; Halliburton, 2001; Schlumberger, Ltd., 2001), between 4 and 10 gallons of diesel-containing gelling agent are added to each 1,000 gallons of water used in hydraulic fracturing, when diesel is used. In addition, the fraction of BTEX in diesel may range by up to two orders of magnitude (Potter and Simmons, 1998). The lower and upper ranges of the values presented in Potter and Simmons (1998), as well as the three different values cited for gelling agent, were used to estimate point-of-injection concentrations for each of three fracturing fluid recipes (i.e., the ratio of fracturing gel to water). The resulting 24 point-of-injection calculations are provided in Table 4-2. These estimates provide the basis for a qualitative assessment regarding whether a Phase II study is warranted.

The following example illustrates how EPA estimated the concentrations of BTEX at the point-of-injection. Due to the variations in the recipe used by service companies, EPA's analysis begins with three different possible scenarios, as follows:

- Low ratio: 4 gallons of gel per 1,000 gallons of water
- Medium ratio: 6 gallons of gel per 1,000 gallons of water
- High ratio: 10 gallons of gel per 1,000 gallons of water

The concentration of benzene in fracturing fluid at the point-of-injection ($[\text{benzene}]_{inj}$) can be calculated using the following equation:

$$[\text{benzene}]_{inj} = (r_{gw}) \times (\rho_{dg}) \times (f_{dg}) \times (f_{bd}) \times (3{,}785\ mL_{gel}/gal_{gel}) \times (1\ gal_{water}/3.785\ L_{water}) \times (10^6\ \mu g/g)$$

Where:

r_{gw} = the ratio of diesel fuel-gel mixture to injection water ($gal_{gel}/1{,}000\ gal_{water}$) ($4\ gal_{gel}/1{,}000 gal_{water}$, $6 gal_{gel}/1{,}000\ gal_{water}$, and $10\ gal_{gel}/1{,}000\ gal_{water}$ represent the low, medium, and high ratios, respectively)

ρ_{dg} = the density of the diesel fuel-gel mixture (g_{gel}/mL_{gel}) = 0.84 g_{gel}/mL_{gel} (Halliburton, 2002)

f_{dg} = the fraction of diesel fuel in the gel (g_{diesel}/g_{gel}) = 0.52 g_{diesel}/g_{gel} (Halliburton, 2002)

f_{bd} = the fraction of benzene in diesel fuel ($g_{benzene}/g_{diesel}$) = 0.000026 to 0.001 $g_{benzene}/g_{diesel}$ (Potter and Simmons, 1998)

$3{,}785\ mL_{gel}/gal_{gel}$ = volume conversion factor

$1\ gal_{water}/3.785\ L_{water}$ = volume conversion factor

$10^6\ \mu g/g$ = mass conversion factor

The concentration of benzene at the point-of-injection is calculated for the three gel/water ratios and the minimum and maximum concentrations of benzene in diesel fuel.

Using $r_{gw} = 4\ gal_{gel}/1{,}000 gal_{water}$ and $f_{bd} = 0.000026\ g_{benzene}/g_{diesel}$ as an example, $[\text{benzene}]_{inj}$ is calculated as follows:

$$[\text{benzene}]_{inj} = (4\ gal_{gel}/1{,}000 gal_{water}) \times (0.84\ g_{gel}/mL_{gel}) \times (0.52\ g_{diesel}/g_{gel}) \times (0.000026\ g_{benzene}/g_{diesel}) \times (3{,}785\ mL_{gel}/gal_{gel}) \times (1\ gal_{water}/3.785\ L_{water}) \times (1{,}000\ mL/L) \times (10^6\ \mu g/g) = 45\ \mu g/L$$

Table 4-2 summarizes the estimated injection concentrations of each BTEX constituent for the three assumed gel/water ratios and the minimum and maximum concentrations of BTEX in diesel fuel. It also presents the MCL for each compound. Many of the estimated concentrations of BTEX exceed the MCL at the point-of-injection.

Table 4-2 and the remainder of this section provide a qualitative assessment of the fate and transport processes that could attenuate the concentrations of BTEX in groundwater. Factors that would influence the availability of constituents of potential concern in fracturing fluids and decrease their concentrations include:

- Fluid Recovery - much of the fluid is eventually pumped back to the surface.
- Adsorption and entrapment - some of these constituents will undergo adsorption to the coal or become entrapped in the formation.

- Biodegradation - some fracturing fluid constituents, such as benzene, may undergo partial biodegradation.

4.3.2 Fracturing Fluid Recovery

Following the injection of fracturing fluids into the subsurface through coalbed methane wells (i.e., production wells), considerable amounts of the fracturing fluids are removed. During the recovery process, the injected fluids and ambient groundwater are pumped out of the formation through the production well to reduce formation pressure, enabling methane desorption and extraction. Palmer et al. (1991a) found that 61 percent of fracturing fluids were recovered based on samples collected from coalbed methane wells over a 19-day period. Their study predicted total recovery to be between 68 and 82 percent.

Palmer et al. (1991a) also discussed the possibility that a "check-valve effect" could trap some of the fracturing fluid on one side (i.e., upgradient, during production) of a collapsed or narrowed fracture, preventing the fluid from flowing back to the production well. This check-valve effect can occur in both natural and induced fractures when the fractures narrow again after the injection of fracturing fluid ceases, formation pressure decreases, and extraction of methane and groundwater begins.

Another factor preventing full recovery of injected fluids is the high injection pressure used during hydraulic fracturing operations. Fracturing fluids are forced into the subsurface under high pressure to enlarge and propagate existing fractures. The hydraulic gradients that cause fluids to flow away from the well during injection are much greater than the hydraulic gradients that occur during fluid recovery. As a result, some of the fracturing fluids will travel beyond the capture zone of the production well. The capture zone of a production well is the portion of the aquifer that contributes water to the well. The size of this zone will be affected by regional groundwater gradients, and by the drawdown caused by the well (USEPA, 1987). Fluids that flow beyond the capture zone of the production well generally are not recovered during the flowback process.

Gel contained in fracturing fluids may be unrecovered because its properties differ from that of water and highly soluble constituents of fracturing fluids. One mined-through study reviewed by EPA described evidence of gel clumps within many fractures (Steidl, 1993). One observed concentration of gel in a fracture was 15 times the injected concentration. When the fluids exist as undissolved gel, they may remain attached to the sides of the fractures or be trapped within smaller fractures or pores present in formations that surround the coalbed. The mined-through studies suggest that such fluids are unlikely to flow with groundwater during production, but they may present a source of gel constituents to flowing groundwater subsequent to fluid recovery. Fate and transport processes discussed later in this section can serve to reduce gel constituent concentrations that may result from trapped fluids. Mechanisms that may affect the recovery of fracturing fluids are discussed in section 3.3.2 of Chapter 3.

4.3.3 The Influence of the Capture Zone

The recovery process typically lasts approximately 10-20 years. During that time, groundwater within the production well's capture zone flows toward the production well. Assuming complete mixing, the predicted recovery of injected BTEX is between 68 and 82 percent (Palmer et al., 1991a). Thus, between 20 and 30 percent of the BTEX injected is expected to remain in the formation. It is reasonable to expect that most of the unrecovered fluid lies outside the capture zone and that the residual concentrations of BTEX within the capture zone are substantially less than the injection concentrations. Chemicals such as BTEX that are not recovered from within the capture zone during groundwater production may be diluted by groundwater that flows into the formation to replace production water. Additional attenuation from sorption and biodegradation may occur. Subsequent to production, dispersion and diffusion may serve to reduce residual BTEX concentrations. The fracturing fluids that flow beyond the capture zone are affected by regional groundwater flow and may be diluted by groundwater.

4.3.4 Fate and Transport Considerations

BTEX that has moved beyond the production well's capture zone is of the greatest concern. The fate and transport mechanisms that may affect BTEX concentrations beyond the capture zone are evaluated in this section. Factors that would likely decrease exposure concentrations and/or availability of BTEX include attenuation through groundwater flow dynamics, biological processes, and adsorption.

BTEX outside of the capture zone will likely be transported by groundwater flowing according to regional hydraulic gradients. This flow and transport are not influenced by production pumping. Nevertheless, mechanical dispersion will cause BTEX to spread horizontally and vertically in the aquifer, thereby reducing the concentrations. The degree of mechanical dispersion depends in part on the velocity of flow and increases with increased travel distance. Dilution can have a significant effect on the BTEX concentrations that could migrate to drinking water wells, especially if these wells are hundreds to thousands of feet from a hydraulically induced fracture. The process of molecular diffusion (i.e., the movement of BTEX from areas of higher to lower concentration due to the concentration differences) will further reduce BTEX concentrations. Collectively, mechanical dispersion and molecular diffusion are referred to as hydrodynamic dispersion (Fetter, 1994).

The biodegradation of diesel fuel constituents, including BTEX, has been studied in other geologic settings and laboratory studies and may lead to reductions in concentrations in coalbeds given the appropriate site conditions. No information was found about the occurrence of biodegradation or biodegradation rates of BTEX in coalbeds or surrounding rock. In order for biodegradation to occur, organisms capable of using BTEX as a food source must be present and conditions such as favorable pH, salinity, and sometimes the availability of oxygen, nitrogen, and phosphorous must be met to ensure bacterial survival. Generally, substantial benzene degradation occurs in aerobic environments. The levels of oxygen in a particular formation vary widely depending primarily on the depth of coalbeds from the surface. Data regarding biodegradation of benzene in an anaerobic environment indicates a range from no degradation to relatively slow degradation (USEPA, 1999).

As groundwater flows through a formation, chemicals such as BTEX may be retarded by adsorption. Although adsorption in coalbeds is likely, quantification of adsorption is difficult in the absence of laboratory or site-specific studies (due to competition for adsorption between BTEX and more lipophilic and less soluble constituents of diesel fuel and coal, and fracture thickness). Other processes, such as desorption of BTEX from the coal surface, and dissolution of BTEX from the gel phase may play a role in BTEX transport. Entrapment of gel in pore spaces and fractures may also influence the degree to which BTEX is available to groundwater. In some cases, the gel may be entrapped in such a way that it is neither available to flow back towards the production well nor flow towards a USDW in response to regional groundwater gradients.

According to the information listed on MSDSs provided to EPA, several of the constituents of potential concern listed in Table 4-1 can have toxic effects when people are exposed to sufficiently high concentrations through the susceptible route(s) of exposure (i.e., inhalation, ingestion, skin contact). However, only the BTEX compounds originating from diesel fuel are regulated under SDWA. None of the other constituents in Table 4-1 appear on the Agency's draft Contaminant Candidate List (CCL). The drinking water CCL is the primary source of priority contaminants for evaluation by EPA's drinking water program. Contaminants on the CCL are known or anticipated to occur in public water systems and may require regulations under SDWA. Information on the GSA study is available at http://www.epa.gov/fedrgstr/EPA-WATER/2004/April/Day-02/w7416.htm**.**

Further, EPA does not believe that the other Table 4-1 constituents potentially contained in fracturing fluids are introduced through coalbed methane fracturing in concentrations high enough to pose a significant threat to USDWs. First, it is EPA's understanding, based on conversations with field engineers and on witnessing three separate fracturing events, that fracturing fluids used for coalbed methane fracturing do not contain most of the constituents listed in Table 4-1. Second, if the Table 4-1 constituents were used, EPA believes some of the same hydrodynamic phenomena listed in steps 2 and 4 (flowback, dilution and dispersion), step 3 (adsorption and entrapment), and potentially step 5 (biodegradation) would minimize the possibility that chemicals included in the fracturing fluids would adversely affect USDWs.

4.4 Summary

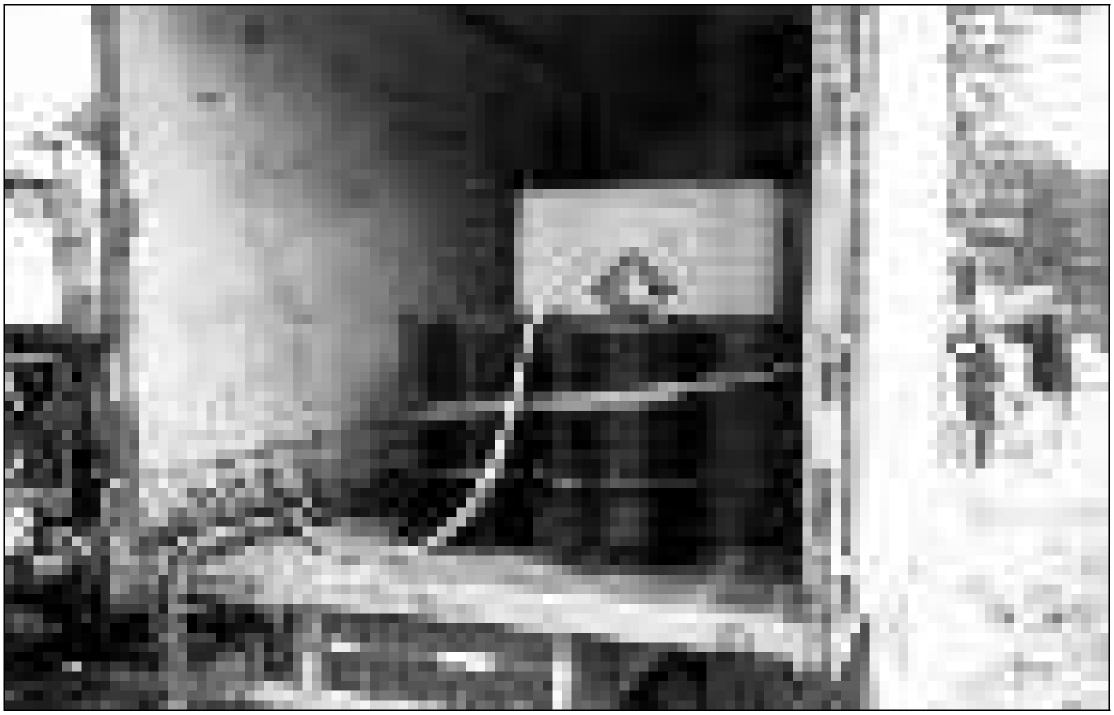
Fracture engineers select fracturing fluids based on site-specific characteristics including formation geology, field production characteristics, and economics. Hydraulic fracturing operations vary widely in the types of fracturing fluids used, the volumes of fluid required, and the pump rates at which they are injected. Based on the information EPA collected, water or nitrogen foam frequently constitutes the solute in fracturing fluids used for coalbed methane stimulation. Other components of fracturing fluids used to stimulate coalbed methane wells may contain only benign ingredients, but in some cases, they contain constituents such as diesel fuel that can be hazardous in their undiluted forms. Fracturing fluids are significantly diluted prior to injection.

Water with a simple sand proppant can be adequate to achieve a desired fracture at some sites. In some cases, water must be thickened to achieve higher proppant transport capabilities. Thickening can be achieved by using linear or cross-linked gelling agents. Cross-linkers are costly additives compared to simple linear gels, but a fluid's fracturing efficiency can be greatly improved using cross-linkers. Foam fracturing fluids can be used to considerably reduce the amount of injected fluid required. The reduced water volume requirement translates into a space and cost savings at the treatment site because fewer water tanks are needed. Foam fracturing fluids also promote rapid flowback and reduced volumes of flowback water requiring disposal.

The use of diesel fuel in fracturing fluids poses the greatest potential threat to USDWs because the BTEX constituents in diesel fuel exceed the MCL at the point-of-injection. Given the concerns with the use of diesel fuel, EPA recently entered into agreements with three major service companies to eliminate diesel fuel from hydraulic fracturing fluids injected directly into USDWs to stimulate coalbed methane production. Industry representatives estimate that these three companies perform approximately 95 percent of the hydraulic fracturing projects in the United States.

In situations when diesel fuel is used in fracturing fluids, a number of factors would decrease the concentration and/or availability of BTEX. These factors include fluid recovery during flowback, adsorption, dilution and dispersion, and potentially biodegradation of constituents. For example, Palmer et al. (1991a) documented that only about one-third of fracturing fluid that is injected is expected to remain in the formation. EPA expects fate and transport considerations would minimize the possibility that chemicals included in fracturing fluids would adversely affect USDWs.

Figures 4-1 and 4-2. Liquid nitrogen tanker trucks transport gas to the site for nitrogen foam fracturing. Nitrogen will travel through pipes to be mixed with water and a foaming agent at the wellhead prior to injection. The foam is used to create and propagate the fracture deep within the targeted coal seam.



Figures 4-3 and 4-4.
Chemicals are stored on site in a support truck. Fracturing fluid additives such as the foaming agent can be pumped directly from storage containers to mix tanks.

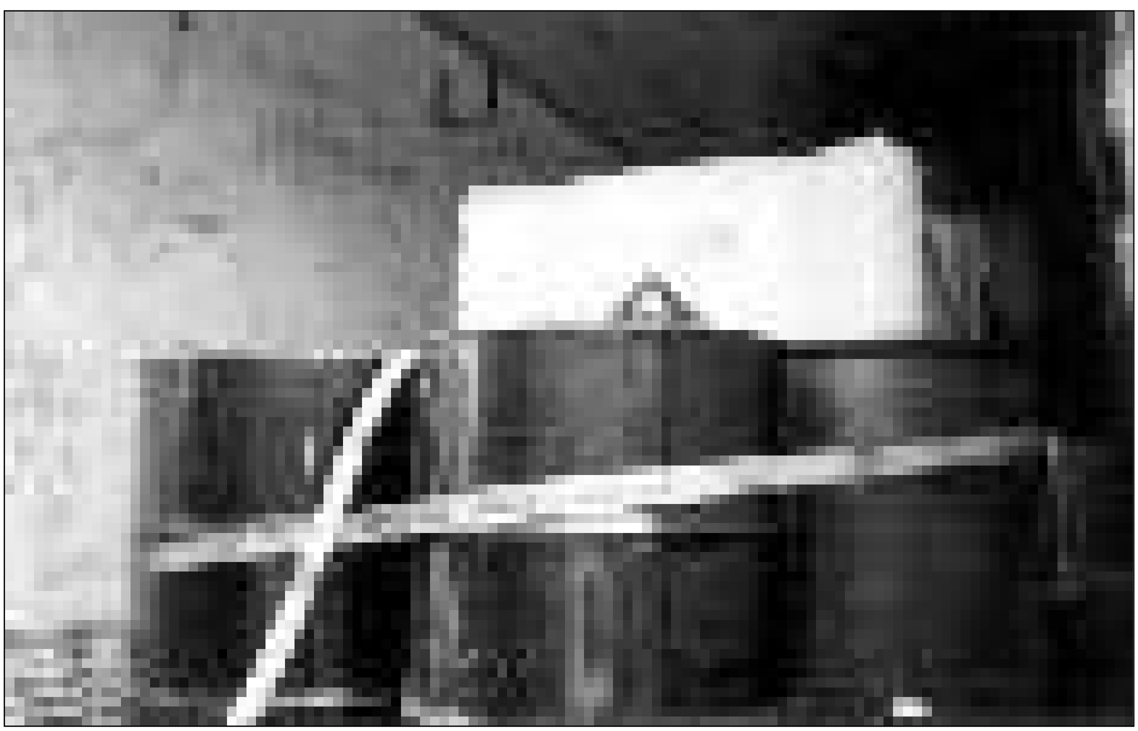


Figure 4-5.
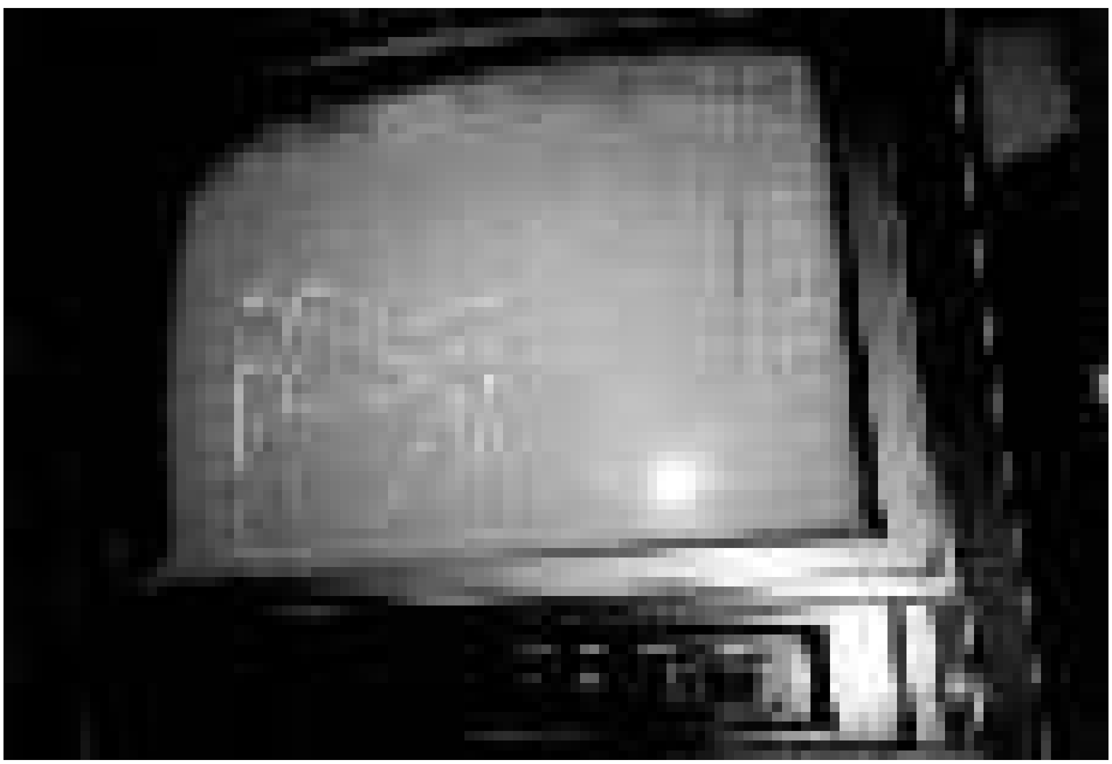
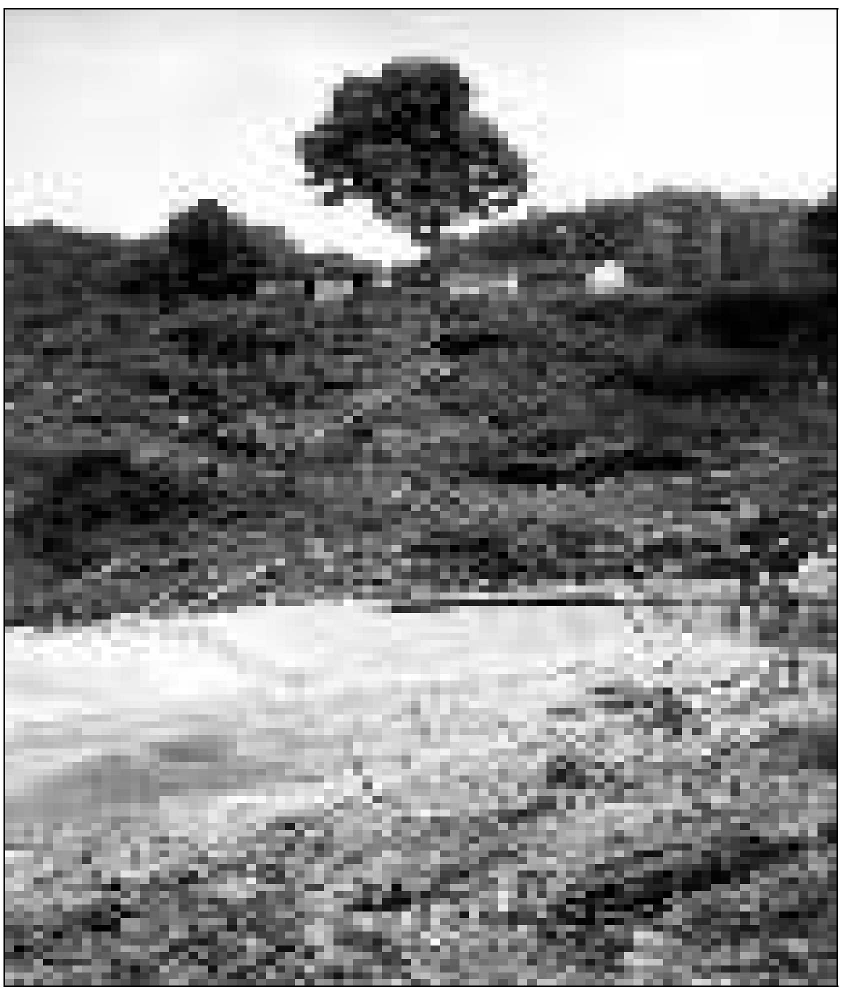
The fracturing fluid (water with additives) is stored on site in large, upright storage tanks. Each tank contains mix water imported from off-site, or formation water extracted directly from the gas well.

Figure 4-6.
Gelled water is pre-mixed in a truck-mounted mixing tank. Photograph shows a batch of linear, guar-based gel. This gel is used to transport the sand proppant into the fracture propagated by the nitrogen foam treatment.

Figure 4-7.
The fracturing fluids, additives, and proppant are pumped to the wellhead and mixed just prior to injection. The flow rate of each injected component is monitored carefully from an on-site control center.

Figures 4-8 and 4-9.
Electronic monitoring systems provide constant feedback to the service company's operators. Fluid flow rates and pressure buildup within the formation are monitored to ensure that fracture growth is safe and controlled.





Figures 4-10 and 4-11. Fluid that is extracted from the well is sprayed through a diffuser and stored in a lined trench until it is disposed of off-site or discharged.

Chapter 5
Summary of Coalbed Methane Basin Descriptions

As part of the Phase I study EPA conducted an extensive literature review to collect information regarding the major coal basins in the United States. Eleven major coal basins were identified in the United States and are shown in Figure 5-1 at the end of the chapter (those basins shaded in red have the highest coalbed methane production volumes). The goals of this review were to assess the following for each of the 11 major coal basins:

- The physical relationship between the coalbeds and the USDWs.
- Whether hydraulic fracturing is or has been used to stimulate coalbed methane wells in production basins.
- The types of fluids used to create the fractures.
- If possible, whether the potential for contaminants to enter a USDW exists.

This information is necessary to evaluate whether hydraulic fracturing is practiced within a basin and the types of fluids used in the fracturing process. More importantly, this information establishes whether the coal formations lie within a USDW, creating the potential for hydraulic fracturing fluid injection to threaten USDWs. A USDW is not necessarily currently used for drinking water and may contain groundwater unsuitable for drinking without treatment. In some cases, very little information was uncovered by EPA regarding certain topics for some of the basins.

Each of the 11 major basins is described in this chapter and in Table 5-1 (immediately following section 5.12 of this chapter). In addition, a more comprehensive description of the geology, hydrology, and coalbed methane production activity for each basin is provided in Attachments 1 through 11 of this report.

5.1 The San Juan Basin

The San Juan Basin covers an area of about 7,500 square miles straddling the Colorado-New Mexico state line in the Four Corners region (Figure 5-1). It measures roughly 100 miles long north to south and 90 miles wide. The Continental Divide trends north to south along the east side of the basin.

The major coal-bearing unit in the San Juan Basin is known as the Fruitland Formation. Coalbed methane production occurs primarily in coals of the Fruitland Formation, but some coalbed methane is trapped in the underlying and adjacent Pictured Cliffs sandstone. Many wells are completed in both zones. The coals of the Fruitland Formation are very thick compared to coalbeds in eastern basins: the thickest coals range from 20 to over 40 feet. Total net thickness of all coalbeds ranges from 20 to over 80 feet throughout the San Juan Basin, compared to 5 to 15 feet in eastern basins.

Coalbed methane wells in the San Juan Basin range from 550 to 4,000 feet in depth, and about 2,550 wells were operating in 2001 (Colorado Oil and Gas Conservation Commission and New Mexico Oil Conservation Division, 2001). The San Juan Basin is the most productive coalbed methane basin in North America. In 1996, coalbed methane production there averaged about 800 thousand cubic feet per day per well and totaled over 800 billion cubic feet (Bcf) for that year (Stevens et al., 1996). This total rose to 925 Bcf in 2000 (GTI, 2002)).

The majority of coalbed methane development and hydraulic fracturing in the northern portion of the San Juan Basin takes place within a USDW. The waters in parts of the Fruitland Formation usually contain less than 10,000 mg/L TDS, which is the water quality criterion for a USDW. In the northern half of the formation, most waters contain less than 3,000 mg/L, and wells near the outcrop produce water that contains less than 500 mg/L TDS.

Fracturing fluids used in the San Juan Basin include hydrochloric acid; slick water (water mixed with solvent); linear and crosslinked gels; and, since 1992, nitrogen- or carbon dioxide-based foams (Harper et al., 1985; Jeu et al., 1988; Holditch et al., 1988; Palmer et al., 1993b; Choate et al., 1993). Data are not readily available concerning fracture growth and height within the Fruitland Formation.

5.2 The Black Warrior Basin

The Black Warrior Basin is the southernmost of the three basins that compose the Appalachian Coal Region of the eastern United States. The basin covers about 23,000 square miles in Alabama and Mississippi. It is approximately 230 miles long from west to east and approximately 188 miles wide from north to south (Figure 5-1). Basin coalbed methane production is limited to the bituminous coalfields of west-central Alabama, primarily in Jefferson and Tuscaloosa Counties.

Coalbed methane production in the Black Warrior Basin is confined to the Pennsylvanian-aged Pottsville Formation. The ancient coastline of prehistoric Alabama was characterized by 8 to 10 “coal-deposition cycles” of rising and falling sea levels. Each cycle features mudstone at the base of the cycle (deeper water) and coalbeds at the top (emergence). Most coalbed methane wells tap the Black Creek/Mary Lee/Pratt cycles and range from 350 to 2,500 feet deep (Holditch, 1990).

Coalbed methane production in the Black Warrior Basin is among the highest in the United States. In 1996, about 5,000 coalbed methane wells were permitted in Alabama. In 2000, this number increased to over 5,800 wells (Alabama Oil and Gas Board, 2002). Coalbed methane wells have production rates that range from less than 20 to more than 1 million cubic feet (Mcf) per day per well (Alabama Oil and Gas Board, 2002). Between 1980 and 2000, coalbed methane wells in Alabama produced roughly 1.2 trillion cubic feet (Tcf) of gas. According to GTI, annual gas production was 112 Bcf in 2000 (GTI, 2002).

Some portions of the Pottsville Formation contain waters that meet the quality criterion of less than 10,000 mg/L TDS for a USDW. According to the Alabama Oil and Gas Board, some waters in the Pottsville Formation do not meet the definition of a USDW and have TDS levels considerably higher than 10,000 mg/L.

Early literature indicates that most of the wells in production in the early 1990s have been hydraulically fractured an average of two to six times to achieve acceptable production rates (Holditch et al., 1988; Holditch, 1990; Palmer et al., 1993a and 1993b).

5.3 The Piceance Basin

The Piceance Coal Basin is entirely within the northwest corner of the Colorado (Figure 5-1). The coalbed methane reservoirs are found in the Upper Cretaceous Mesaverde Group, which covers about 7,225 square miles of the basin.

The Mesaverde Group ranges in thickness from about 2,000 feet on the west to about 6,500 feet on the east side of the basin (Johnson, 1989). The depth to the methane-bearing Cameo-Wheeler-Fairfield coal zone is about 6,000 feet. Two-thirds of the coalbed methane occurs in coals deeper than 5,000 feet, and the Piceance Basin is one of the deepest coalbed methane areas in the United States (Quarterly Review, August 1993).

The depth of the coals in the Piceance Basin inhibits permeability, making it difficult to extract the coalbed methane. This, in turn, has slowed coalbed methane development in the basin. However, it is estimated that 80 trillion to 136 Tcf of coalbed methane are contained in the Cameo-Wheeler-Fairfield coal zone of the basin (Tyler et al., 1998). Total coalbed methane production was 1.2 Bcf in 2000 (GTI, 2002).

The Piceance Basin contains both alluvial and bedrock aquifers. Unconsolidated alluvial aquifers (narrow and thin deposits of sand and gravel formed primarily along stream courses) are the most productive aquifers in the Piceance Basin. The bedrock aquifers are known as the upper and lower Piceance Basin aquifer systems. The upper aquifer system is about 700 feet thick, and the lower aquifer system is about 900 feet thick. Water at depth in the Piceance Basin appears to be of poor quality, minimizing its chance of being designated a USDW. In general, the potable water wells in the Piceance Basin extend no further than 200 feet in depth, based on well records maintained by the Colorado Division of Water Resources. A composite water quality sample taken from 4,637 to 5,430 feet deep in the Cameo coal zone exhibited a TDS level of 15,500 mg/L (Graham, 2001).

Hydraulic fracturing is practiced in this basin. A variety of fluids are used for fracturing, including water with sand proppant and gelled water and sand. In some cases, hydraulic stimulations created multiple short (100-foot), fractures around the wells (Quarterly Review, August 1993).

It is unlikely that any USDWs and coals targeted for methane production (generally currently located at great depth, such as 4,000 feet below the ground surface and deeper) would coincide in this basin. The thousands of feet of stratigraphic separation between the coal gas bearing Cameo Zone and the lower aquifer system in the Green River Formation should prevent any of the effects from the hydrofracturing of gas-bearing strata from reaching either the upper or the lower bedrock aquifers.

Research suggests that exploration may target areas where groundwater circulation may enhance gas accumulation in the coal and associated sandstones (Tyler et al., 1998). Under these exploration and development conditions, a USDW located in shallower Cretaceous rocks near the margins of the basin could be affected by hydraulic fracturing. The depth of methane-bearing coals (about 6,000 feet) seems to indicate that, in the Piceance Basin, the chances of contaminating any overlying, shallower USDWs (no deeper than about 1,000 feet) from injection of hydraulic fracturing fluids and subsequent subsurface fluid transport are minimal. The coalbed methane producing Cameo Zone and the deepest known aquifer, the lower bedrock aquifer, have a stratigraphic separation of over 6,000 feet.

5.4 The Uinta Basin

The Uinta Coal Basin is mostly within eastern Utah; a very small portion of the basin is in northwestern Colorado (Figure 5-1). The basin covers approximately 14,450 square miles (Quarterly Review, August 1993). The Uinta Basin is stratigraphically continuous with the Piceance Basin of Colorado, but is structurally separated from it by the Douglas Creek Arch, an uplift near the Utah – Colorado state line.

Coal seams occur in the Cretaceous Mancos Shale and the Upper Cretaceous Mesaverde Group (Quarterly Review, 1993). Two major formations targeted for coalbed methane exploration are the Mancos Shale's Ferron Sandstone Member, which include the coals most targeted (approximately 90 percent of the time) for exploration (Petzet, 1996) and the Mesaverde Group's Blackhawk Formation, which contains about 14 coal zones (Petzet, 1996). The Ferron Coals are interbedded with sandstone and form a wedge of clastic sediment 150 to 750 feet thick. Depths to coal in the Ferron Sandstone range from 1,000 to over 7,000 feet below ground surface (Garrison et al., 1997). The Blackhawk Formation consists of coal seams interbedded with sandstone and a combination of shale and siltstone. Coals tapped in the Blackhawk Formation are 4,200 to 4,400 feet below the surface (Gloyn and Sommer, 1993).

Full-scale exploration in the Uinta Basin began in the 1990s (Quarterly Review, 1993). The database covering the Uinta Basin indicates that there are about 1,255 coalbed methane wells in production in the basin (Osborne, 2002). The coalbed methane potential of the Uinta Basin, revised by the Utah Geological Survey in the early 1990s, has been estimated to be between 8 trillion and more than 10 Tcf (Gloyn and Sommer, 1993).

At some locations, the groundwater in the Ferron Coals and Blackhawk Formations would not qualify as USDWs. According to the Utah Department of Natural Resources (DNR), Division of Oil, Gas and Mining, the water there varies greatly by location, each location having some TDS levels below and some above 10,000 mg/L (Utah DNR, 2002). In general, the quality of Blackhawk water is higher than Ferron water. For example, the most recent UIC application noted the combined quality of input water to be approximately 31,000 mg/L TDS for the Drunkards Wash Field (Ferron) and 9,286 mg/L TDS for the Castlegate Field (Blackhawk).

Fracturing fluid use is documented in the literature pertaining to the Uinta Basin. One company reported performing hydraulic fracturing stimulations using cross-linked borate gel with 250,000 pounds of proppant (Quarterly Review, 1993). Others report that they fractured wells with low-residue gel fracturing fluids and foams (Quarterly Review, 1993). GTI places the annual coalbed methane production in the Uinta Basin at 75.7 Bcf in 2000 (GTI, 2002).

The Blackhawk Formation is underlain by 300 feet of shale and sandstone, which separate it from the Castlegate Sandstone aquifer. It is underlain by similar geologic strata, which separate it from the Star Point Sandstone. Only in highly faulted areas is there a reasonable possibility that hydraulic fracturing fluids could migrate down to the Star Point Sandstone.

5.5 The Powder River Basin

The Powder River Basin is in northeastern Wyoming and southern Montana (Figure 5-1). The basin covers approximately 25,800 square miles (Larsen, 1989), approximately 75 percent of which is in Wyoming. Fifty percent of the Powder River Basin is believed to have the potential for coalbed methane production (Powder River Coalbed Methane Information Council, 2000). Annual production volume was estimated at 147 Bcf in 2000 (GTI, 2002). In 2002, wells in the Powder River Basin produced about 823 Mcf per day of coalbed methane (DOE, 2002).

Coalbeds in this region are interspersed at varying depths with sandstones, mudstone, conglomerate, limestone, and shale. The majority of the potentially productive coal zones range from about 450 feet to over 6,500 feet below ground surface (Montgomery, 1999). The uppermost formation is the Wasatch Formation, extending from land surface to 1,000 feet deep. Most coal seams in the Wasatch Formation are continuous and thin (6 feet or less). The Fort Union Formation lies directly below the Wasatch Formation and can be as much as 6,200 feet thick (Law et al., 1991). The coalbeds in this formation are typically most abundant in the upper portion, called the Tongue River member. This member is typically 1,500 to 1,800 feet thick, of which up to a composite total of 350 feet of coal can be found in various beds. The thickest of the individual coalbeds is over 200 feet (Flores and Bader, 1999). Recent estimates of coalbed methane reserves in the Powder River Basin range from 7 trillion to 40 Tcf (Montgomery, 1999; PRCMIC, 2000).

The Fort Union Formation that supplies municipal water to the City of Gillette is the same formation that contains the coals that are developed for coalbed methane. The coalbeds contain and transmit more water than the sandstones. The sandstones and coalbeds have been used for the production of both water and coalbed methane. The water produced from the coalbeds meets the quality criterion for USDWs of less than 10,000 mg/L TDS.

EPA's understanding is that hydraulic fracturing currently is not widely used in this region due to concerns about the potential for increased groundwater flow into the coalbed methane production wells (due to fracturing of impermeable formations adjacent to the coal, and the creation of a hydraulic connection to adjacent aquifers) and the collapse of open hole wells in coal upon dewatering. According to the available literature, where hydraulic fracturing has been used in this basin, it has not been an effective method for extracting methane. Hydraulic fracturing has been done primarily with water, or gelled water and sand, although recorded use of a solution of potassium chloride was identified in the literature.

5.6 The Central Appalachian Basin

The Central Appalachian Coal Basin is the middle of three basins that compose the Appalachian Coal Region of the eastern United States. It includes parts of Kentucky, Tennessee, Virginia, and West Virginia (Figure 5-1) and covers approximately 23,000 square miles. The greatest potential for methane development is in a small, 3,000-square-mile area in southwest Virginia and south central West Virginia (Kelafant, et al., 1988).

The coal basin consists of six Pennsylvanian age coal seams (Zebrowitz et al., 1991, and Zuber, 1998). These coal seams typically occur as multiple coalbeds or seams that are widely distributed (Zuber, 1998). The coal seams, from oldest to youngest (West Virginia/Virginia name), are the Pocahontas No. 3, Pocahontas No. 4, Fire Creek/Lower Horsepen, Beckley/War Creek, Sewell/Lower Seaboard, and Iager/Jawbone (Kelafant et al., 1988). The Pocahontas coal seams include the Squire Jim and Nos. 1 to 7; Nos. 3 and 4 are the thickest and cover the most area. Most of the coalbed methane (2.7 Tcf) occurs in the Pocahontas seams (Kelafant et al., 1988). In southwest Virginia and south central West Virginia, target coal seams achieve their greatest thickness and occur at depths of about 1,000 to 2,000 feet (Kelafant et al., 1988).

The Nora Field in southwestern Virginia is one of the better-known coalbed methane production fields. According to the Virginia Division of Gas and Oil, over 700 coalbed methane wells were drilled in the Nora Field in 2002 (Virginia Division of Gas and Oil, 2002). The Virginia Division of Gas and Oil also indicated that, in 2002, more than 1,800 coalbed methane wells were drilled in southwestern Virginia's Buchanan County (VA Division of Gas and Oil, 2002.) GTI reported that the entire basin produced 52.9 Bcf of gas in 2000 (GTI, 2002).

Because most of the coal strata dip, a coalbed methane well's location in the basin may determine if hydraulic fracturing during the well's development will affect the water quality of surrounding USDW. For instance, on the northeastern side of the basin, the depth to the Pocahontas No. 3 coalbed is less than 500 feet. This depth gradually increases to over 2,000 feet farther westward across this portion of the basin, in the direction of the dip of the coal seam. Therefore, a well tapping this seam in the eastern portion of the basin may be within a USDW, but a well tapping the seam in the western portion of the basin may be below the base of a

USDW. In addition, the base of the freshwater is not flat, but rather undulating. These factors indicate that the relationship between a coalbed and a USDW must be determined on a site-specific basis.

Hydraulic fracturing is a common practice in this region. Foam and water are the fracturing fluids of choice, and sand serves as the proppant. Additives can include hydrochloric acid, scale inhibitors, and microbicides. Pocahontas Oil & Gas, a subsidiary of Consol Energy, Inc., invited EPA personnel to a well where a hydraulic fracturing treatment was being performed by Halliburton Energy Services, Inc. Halliburton staff said that typical fractures extend from 300 to 600 feet from the well bore in either direction, but that fractures have been known to extend from as few as 150 feet to as many as 1,500 feet in length (Halliburton Inc., Virginia Site Visit, 2001). According to the fracturing engineer on-site, fracture widths range from one-eighth of an inch to almost one and one-half inches (Halliburton, Inc., Virginia Site Visit, 2001).

Since some coalbed methane exploration has moved to shallower seams, the Commonwealth of Virginia has instituted a voluntary program concerning depths at which hydraulic fracturing may be performed (Virginia Division of Oil and Gas, 2002). The program involves an operator's determination of the elevation of the lowest topographic point and the elevation of the deepest water well within a 1,500-foot radius of any proposed extraction well (Wilson, 2001). Hydraulic fracturing should occur at least 500 feet beneath than the lower of these two points.

5.7 The Northern Appalachian Basin

The Northern Appalachian Coal Basin is the northernmost of the three basins that make up the Appalachian Coal Region of the eastern United States. It includes parts of Pennsylvania, West Virginia, Ohio, Kentucky, and Maryland (Figure 5-1). The basin lies completely within the Appalachian Plateau geomorphic province and covers approximately 43,700 square miles (Adams et al., 1984, as cited by Pennsylvania Department of Conservation and Natural Resources, 2002). The Northern Appalachian basin trends northeast to southwest. The Rome Trough, a major graben structure, forms the southeastern and southern structural boundaries. The basin is bounded on the northeast, north, and west by outcropping Pennsylvanian-aged sediments (Kelafant et al., 1988).

The six Pennsylvanian-aged coal zones composing the Northern Appalachian Coal Basin are the Brookville-Clarion, Kittanning, Freeport, Pittsburgh, Sewickley, and Waynesburg. These coal units are within the Pottsville, Allegheny, and the Monongahela Groups (Kelafant et al., 1988). Coal seam depths range from surface outcrops to as much as 2,000 feet below ground surface, with most coal occurring at depths shallower than 1,000 feet (Quarterly Review, 1993). These depth differences arise due to the dip of the coalbeds. The total thickness of the Pennsylvanian-aged coal system averages 25 feet; however, better developed seams within the coal zones can increase in thickness by up to twice the average (Quarterly Review, 1993).

Coalbed methane has been produced in commercial quantities from the Pittsburgh coalbed of the Northern Appalachian Coal Basin since 1932 (Lyons, 1997), after the discovery of the Big Run

Field in Wetzel County, West Virginia, in 1905 (Hunt and Steele, 1991). As of 1993, O'Brien Methane Production, Inc. had at least 20 wells in Pennsylvania's southern Indiana County (Quarterly Review, 1993). Coalbed methane production development in the Northern Appalachian Basin has lagged, however, due to insufficient reservoir knowledge, inadequate well-completion techniques, and coalbed methane ownership issues revolving around whether the gas is owned by the mineral owner or the oil and gas owner (Zebrowitz et al., 1991). Discharge of produced waters has also proven to be problematic (Lyons, 1997) for coalbed methane field operators in the Northern Appalachian Coal Basin. Total coalbed methane production stood at 1.41 Bcf in 2000 (GTI, 2002). As of October 2002, 185 coalbed methane wells were producing coalbed methane in Pennsylvania (Pennsylvania Department of Conservation and Natural Resources, 2002).

The Northern Appalachian Basin is situated in the Appalachian Plateau's physiographic province. The primary aquifer in this area is a Pennsylvanian sandstone aquifer underlain by limestone aquifers (USGS, 1984). Water quality data from eight historic Northern Appalachian Coal Basin projects show that estimated TDS levels ranged from 2,000 to 5,000 mg/L at depths of 500 to 1,025 feet below ground surface (Zebrowitz et al., 1991), well within EPA's water quality criterion of 10,000 mg/L TDS for a USDW (40 CFR §144.3). Depths to the bottoms of the USDWs vary greatly in the basin and are better determined on a site-specific basis.

Hydraulic fracturing fluids used in the Northern Appalachian Basin have included water and sand, and nitrogen foam and sand (Hunt and Steele, 1991). The Christopher Coal Company/Spindler Wells Project, which took place from 1952 to 1959, stimulated 1 well with 12 quarts of nitroglycerin (Hunt and Steele, 1991). In the Vesta Mines Project of Washington County, Pennsylvania, the United States Bureau of Mines used gelled water and sand to complete 5 wells in the Pittsburgh Seam (Hunt and Steele, 1991).

Because most of the coal strata dip, a well's location in a basin determines whether the well is coincident with a USDW. For example, in the Pittsburgh Coal Group in Pennsylvania, the depth to the top of the coal group varies from outcrop to about 1,200 feet in the very southwestern corner of the state (Kelafant et al., 1988). The approximate depth to the bottom of the USDW is 450 feet. Therefore, production wells operating down to approximately 450 feet could potentially be hydraulically connected to the USDW.

5.8 The Western Interior Coal Region

The Western Interior Coal Region comprises three coal basins, the Arkoma, the Cherokee, and the Forest City Basins, and encompasses portions of six states: Arkansas, Oklahoma, Kansas, Missouri, Nebraska, and Iowa (Figure 5-1). The Arkoma Basin covers about 13,500 square miles in Arkansas and Oklahoma. The Cherokee Basin is part of the Cherokee Platform Province, which covers approximately 26,500 square miles (Charpentier, 1995) in Oklahoma, Kansas, and Missouri. The Forest City Basin covers about 47,000 square miles (Quarterly Review, 1993) in Iowa, Kansas, Missouri, and Nebraska.

In the Arkoma Basin, major middle-Pennsylvanian coalbeds occur within the Hartshorne, McAlester, Savanna, and Boggy Formations (Quarterly Review, 1993). The Hartshorne coals of the Hartshorne Formation are the most important for methane production in the Arkoma Basin. Their depth ranges from 600 to 2,300 feet in two productive areas of southeastern Oklahoma (Quarterly Review, 1993). In the Cherokee Basin, the primary coal seams targeted by operators are the Riverton Coal of the Krebs Formation and the Weir-Pittsburg and Mulky coals of the Cabaniss Formation (Quarterly Review, 1993). The Riverton and Weir-Pittsburg seams are about 3 to 5 feet thick and range from 800 to 1,200 feet deep, while the Mulky Coal, which ranges up to 2 feet thick, occurs at depths of 600 to 1,000 feet (Quarterly Review, 1993). Individual coal seams in the Cherokee Group of the Forest City Basin range from a few inches to about 4 feet thick, with seams up to 6 feet thick (Brady, 2002; Smith, 2002). Depths to the top of the Cherokee Group coals range from approximately the surface to 230 feet below ground surface in the shallower portion of the basin, in southeastern Iowa, to about 1,220 feet in the deeper part of the basin, in northeastern Kansas (Bostic et al., 1993).

As of March 2000, there were 377 coalbed methane wells in the Arkoma Basin of eastern Oklahoma, ranging in depth from 589 to 3,726 feet (Oklahoma Geological Survey, 2001). The Arkoma Basin contains an estimated 1.58 to 3.55 Tcf of gas reserves, primarily in the Hartshorne coals (Quarterly Review, 1993). In the Cherokee Basin, unknown amounts of coalbed methane gas have been produced with conventional natural gas for over 50 years (Quarterly Review, 1993). Targeted coalbed methane production increased in the late 1980s, and at least 232 coalbed methane wells had been completed as of January 1993 (Quarterly Review, 1993). The Cherokee Basin contains an estimated 1.38 Mcf of gas per square mile (Stoeckinger, 1989) in the targeted Mulky, Weir-Pittsburg, and Riverton coal seams of the Cherokee Group (Quarterly Review, 1993). In total, the basin contains approximately 36.6 Bcf of gas. However, the Petroleum Technology Transfer Council (1999) indicates that there are nearly 10 Tcf of gas in eastern Kansas alone (PTTC, 1999). The Forest City Basin was relatively unexplored in 1993, with about 10 coalbed wells concentrated in Kansas' Atchison, Jefferson, Miami, Leavenworth, and Franklin Counties (Quarterly Review, 1993). The Forest City Basin contains an estimated 1 Tcf of gas (Nelson, 1999). For the entire region, coalbed methane production was 6.5 Bcf in 2000 (GTI, 2002).

According to the National Water Summary (1984), there are no principal aquifers in the portions of Oklahoma and Arkansas in the Arkoma Basin, only small alluvial aquifers bounding rivers. Water quality test results from the targeted Hartshorne seam in Oklahoma have shown the water to be highly saline (Quarterly Review, 1993). The base of fresh water in Arkansas is about 500 to 2,000 feet below ground surface (Cordova, 1963). However, Cordova (1963) does not define "fresh water." While the majority of the Cherokee Basin does not contain a principal aquifer, the Ozark and Douglas aquifers are contained within the basin (National Water Summary, 1984). The confined Ozark Aquifer, composed of weathered and sandy dolomites, typically contains water wells that extend from 500 to 1,800 feet in depth (National Water Summary, 1984). The usually unconfined Douglas Aquifer is a sandstone channel of the Pennsylvanian Age (National Water Summary, 1984). Wells are usually 5 to 400 feet deep in this aquifer. In Kansas, depth to the base of the Ozark Aquifer is roughly 1,750 feet below ground surface (Ozark Aquifer Base Map, 2001). In Oklahoma, the Cherokee Basin also contains the Garber-Wellington and

Vamoosa-Ada aquifers (National Water Summary, 1984). Water well depths in these two aquifers usually range from 100 to 900 feet (National Water Summary, 1984). The Forest City Basin contains the Jordan Aquifer, the Dakota Aquifer, and glacial drift, alluvial, and Paleozoic-aged rock aquifers. Wells in these aquifers commonly range in depth from 300 to 2,000 feet, 100 to 600 feet, 10 to 300 feet, 10 to 150 feet, and 30 to 2,200 feet, respectively (National Water Summary, 1984). Throughout the Western Interior Coal Region, water quality sampling has shown TDS levels to range from 500 to 40,000 mg/L (Missouri Division of Geological Survey and Water Resources, 1967).

Hydraulic fracturing is common in the Western Interior Coal Basin. Fracturing fluids such as linear gel, acid, and nitrogen foam were used extensively in the Western Interior coal region before 1992, and slick water treatments became common in 1993. Hydraulic fracturing is still practiced in the basin.

Based on depths to the Hartshorne Coal (0 to 4,500 feet in Arkansas) and the base of fresh water (500 to 2,000 feet in Arkansas), it appears that coalbed methane extraction wells in the Arkoma Basin could be coincident with potential USDWs in Arkansas (Andrews et al., 1998; Cordova, 1963). Based on maps provided by the Oklahoma Corporation Commission (2001) showing the depths of the 10,000 mg/L TDS groundwater quality boundary in Oklahoma, coalbed methane wells and USDWs would most likely not coincide in Oklahoma. This is based on depths to coals typically greater than 1,000 feet (Andrews et al., 1998) and depths to the base of the USDW typically shallower than 900 feet (OCC Depth to Base of Treatable Water Map Series, 2001).

In the Cherokee Basin, coalbed methane wells targeting the Cherokee Group coals in Kansas coincide with USDWs. Depths to the top of coalbeds range from 800 to 1,200 feet (Quarterly Review, 1993) while the depth to the base of fresh water is estimated at 1,750 feet (Mapped information from the Kansas Data Access and Support Center (DASC), 2001a). More information concerning water quality is required prior to any determination of coalbed methane well/USDW co-location in Missouri. However, current levels of coalbed methane activity are minimal in that state. In addition, since only a very small portion of the Cherokee Basin falls within Missouri, this portion of the basin needs to be delineated more precisely to see which USDWs are in this small part of the basin. Last, in the Forest City Basin, there appears to be little relationship between water supplies and coalbeds that may be used for coalbed methane extraction. However, aquifer and well information from the National Water Summary (1984) indicates that a co-location of the two could exist in Nebraska. More information is needed to define the relationship between coalbeds and USDWs in the Forest City Basin.

5.9 The Raton Basin

The Raton Basin covers about 2,200 square miles in southeastern Colorado and northeastern New Mexico (Figure 5-1). It is the southernmost of several major coal-bearing basins along the eastern margin of the Rocky Mountains. The basin extends 80 miles north to south and as much as 50 miles east to west (Stevens et al., 1992). It is an elongate, asymmetric syncline, 20,000 to 25,000 feet thick in the deepest part.

There are two major coal formations in the Raton Basin, the Vermejo and the Raton. The Vermejo coals range from 5 to 35 feet thick, while the Raton coal layers range from 10 to more than 140 feet thick. Although the Raton Formation is much thicker and contains more coal than the Vermejo Formation, individual coal seams in the Raton are less continuous and generally thinner.

Methane resources for the basin have been estimated at approximately 10.2 Tcf in the Vermejo and Raton Formations (Stevens et al., 1992). As of 1992, about 114 coalbed methane exploration wells had been drilled in the basin (Quarterly Review, 1993). According to GTI, the average coalbed methane production rate of wells in the Raton Basin was close to 300 thousand cubic feet per day, and annual production in 2000 was 30.8 Bcf (GTI, 2002).

The coal seams of the Vermejo and Raton Formations developed for methane production also contain water that meets the criterion for a USDW. The underlying Trinidad Sandstone and other sandstone beds in the Vermejo and Raton Formations, as well as intrusive dikes and sills, also contain water of sufficient quality to be used as drinking water.

Coalbed methane well stimulation using hydraulic fracturing techniques is common in the Raton Basin. Records show that fracturing fluids used are typically gels and water with sand proppants. Hemborg (1998) showed that in most cases water yield decreased dramatically as methane production continued over time. However, some wells exhibited increased water production as methane production continued or increased. Two causal factors were suggested (Hemborg, 1998) for the rise in water production:

1. Well stimulation had increased the well's zone of capture to include adjacent water-bearing sills or sandstones that were hydraulically connected to recharge areas, or;

2. Well stimulation had created a connection between the coal seams and the underlying water-bearing Trinidad Sandstone.

5.10 The Sand Wash Basin

The Sand Wash Basin is in northwestern Colorado and southwestern Wyoming. It is part of the Greater Green River Coal Region, which includes the Washakie Basin, the Great Divide (Red Desert) Basin, and the Green River Basin (Figure 5-1). These sub-basins are separated by uplifts caused by deformation of the basement rock. For example, the Sand Wash Basin is separated from the adjacent Washakie Basin by the Cherokee Arch, an anticline ridge that runs east to west along the Colorado – Wyoming border. The Greater Green River Coal Region, in total, covers an area of approximately 21,000 square miles. The Sand Wash Basin covers approximately 5,600 square miles, primarily in Moffat and Routt Counties of Colorado.

The coal-bearing formations in the region include the Iles, Williams Fork, the Fort Union, and the Wasatch Formations. The total thickness of the coal seams in these formations can be up to 150 feet (Quarterly Review, 1993). Of all the formations, the Williams Fork is the most significant coal-bearing unit because it has the thickest and most extensive coalbeds. Coal-bearing strata are 5,000 feet deep along the basin's western portions and outcrop along its southern and eastern margins. The coal seams are interbedded with sandstones and shale. The thickest total coal deposits in the Williams Fork Formation, up to 129 feet, are centered on Craig, CO. These deposits are composed of several separate seams up to 25 feet thick interspersed between layers of sedimentary rock.

Coalbed methane resources in the Sand Wash Basin have been estimated at 101 Tcf. Approximately 90 percent of this gas is in the Williams Fork Formation. Approximately 24 Tcf of coalbed methane are located less than 6,000 feet below ground surface (Kaiser et al., 1994a). Some investigation and very limited commercial development of this resource have occurred, mostly in the late 1980s and early 1990s. Records from the Colorado Oil and Gas Commission indicate that approximately 31 Bcf of coalbed methane was produced in Moffat County during 1995 (Colorado Oil and Gas Conservation Commission, 2001). There appears to be no commercial production at present (GTI, 2002). Development of coalbed methane resources in the Sand Wash Basin has been slower than in many other areas due to limited economic viability. The need for extensive dewatering in most wells has been a limiting factor, compounded by relatively low coalbed methane recovery. In recent years, permits for new gas wells have been issued, indicating that there may be some continued interest in this area (Colorado GIS, 2001).

Kaiser and Scott (1994) summarized their extensive investigation of groundwater movement within the Fort Union and Mesaverde Group. The Mesaverde Group is a highly transmissive aquifer. The coal seams within the group may be the most permeable part of the aquifer. Lateral flow within the Fort Union Formation is slower. Groundwater quality in the basin varies greatly. Typically, chloride and TDS concentrations within the coal-bearing Mesaverde Group are low and potentially within potable ranges in the eastern portion of the basin, implying the existence of a USDW. TDS concentrations increase as the water migrates toward the central and western margins of the basin. TDS concentrations significantly higher than the 10,000 mg/L USDW water quality standard have been detected in the western portion of the basin.

The use of fracturing fluids, specifically water and sand proppant, has been reported for this basin. No record of any other fluid types has been noted. Although variable, the water quality within the fractured coals indicates the presence of USDWs within the coalbeds.

5.11 The Washington Coal Regions (Pacific and Central)

The Pacific Coal Region (Figure 5-1) is approximately 6,500 square miles and lies along the western and eastern flanks of the Cascade Range, from Canada into northern Oregon within the Puget downwarp structure. Bellingham, Seattle, Tacoma, and Olympia in Washington, and Portland, Oregon, lie in or adjacent to the sub-basins. The Central Coal Region (Figure 5-1) primarily lies within the Columbia Plateau, between the Cascade Range to the west and the Rocky Mountains to the east, in Idaho. This region extends from the Okanogan highlands to the north to the Blue Mountains to the south, and encompasses approximately 63,320 square miles.

The coal-bearing deposits of the Pacific and the Central Coal Regions are Cretaceous to Eocene Age and formed within fluvial and deltaic depositional environments prior to the uplift of the Cascade Mountain Range. The thick coalbeds of the Pacific and Central Basins are thought to result from peat accumulations in poorly drained swamps of the lower deltas, while the thinner coalbeds probably formed in the better drained upper deltas (Buckovic, 1979 as cited by Choate et al., 1980). The complex stratigraphy and structural deformation of the coals of the Pacific Coal Region are major obstacles to the exploration and development of gas fields. Although the coals of the Central Coal Region may not be as greatly deformed and unpredictable as those in the Pacific Coal Region, they are obscured by the Columbia River Basalt Group, in which individual basalt flows up to 300 feet thick can cover thousands of square miles.

The occurrence of methane in groundwater is one factor leading to the identification of the gas potential in Washington. Methane in groundwater occurs in the basalts, but only in confined aquifers (porous or fractured zones near the top or bottom of a basalt layer) and is thought to have migrated upward from underlying coalbeds. Choate et al. (1980) estimated coalbed methane resources for four target sub-basins representing 1,800 square miles of the Pacific Coal Region to be 0.3 trillion to 24 Tcf. Methane had been encountered in 67 oil and gas exploration wells drilled in this region by 1984. Gas was found at depths of less than 500 feet in 25 wells, less than 1,000 feet in 38 wells, and less than 2,000 feet in 50 wells. Pappajohn and Mitchell (1991) estimated the coalbed methane potential of the Central Coal Region to be more than 18 Bcf per square mile. The operation of the Rattlesnake Hills gas field between 1913 and 1941 in the western part of the Central Coal region indicates that greater potential for development may exist. According to the available literature, there were no producing fields in either the Pacific Coal Region or the Central Coal Region in Washington as of 2000 (GTI, 2001).

Water supply wells and irrigation wells in the Columbia River Basalts and water wells in numerous different lithologies in the Pacific Coal Region have been recognized as containing methane. Data demonstrating the co-location of a coal seam and a USDW were found for Pierce County, where methane gas test well results report TDS levels far less than the 10,000 mg/L USDW water quality threshold (Dion, 1984). These aquifers can be classified as USDWs. Data demonstrating the co-location of a coal seam and a USDW was found for Pierce County, where methane gas test well results report TDS levels of 1,330 to 1,660 mg/L, which is far less than the USDW classification limit (Dion, 1984). Development of methane in the Central Coal Region may have some impact on highly productive basalt aquifers already used as large sources of irrigation water for agriculture (Dion, 1984).

Hydraulic fracturing of coalbed methane wells using sand and nitrogen foam treatments has been documented (Quarterly Review August, 1993). However, optimal stimulation and completion methods for use in the structurally difficult Pacific gas region are yet to be applied and proven.

5.12 Summary

Hydraulic fracturing of coalbed methane production wells has been documented in each basin, although it is not widely practiced in the Powder River, Sand Wash Basin, or the Washington Coal Regions. Ten of the eleven major coal basins in the United States are located at least partially within USDWs. The literature also indicates that hydraulic fracturing may have increased or have the potential to increase the communication between coal seams and adjacent aquifers in two of the basins: the Powder River and Raton Basins. This may be the explanation for higher than expected withdrawal rates for production water in the Raton Basin following some fracturing treatments. In the Powder River Basin, concerns over the creation of such a hydraulic connection are cited as one reason why hydraulic fracturing of coalbed methane reservoirs is not widely practiced in the region.

Chapter 6
Water Quality Incidents

While Chapters 3 through 5 describe the theoretical and technical background for the potential contamination of USDWs from hydraulic fracturing fluid injection into coalbed methane wells, this chapter summarizes citizens' accounts of water quality and quantity incidents. These reports reflect the opinions of citizens living near coalbed methane operations who expressed concerns about contaminated drinking water wells and wells experiencing water quantity impacts such as reduced production. EPA has, through letters and telephone calls, contacted and been contacted by citizens who believed their water wells were affected by coalbed methane production in the San Juan, Black Warrior, Central Appalachian, and Powder River Basins. Stakeholders commenting on the study methodology (65 FR 45774 (USEPA, 2000)) asked that EPA consider personal experiences regarding coalbed methane impacts on drinking water wells in addition to data from formal studies.

As a result of the stakeholder comments, EPA published a request in the *Federal Register* (66 FR 39396 (USEPA, 2001)) for information from the public, as well as governmental and regulatory agencies, regarding incidents of groundwater contamination believed to be associated with hydraulic fracturing of coalbed methane wells. In addition, the Agency notified over 500 local and county agencies in areas of potential coalbed methane production making them aware of the *Federal Register* notice, but EPA received no information regarding citizen complaints from these officials. Therefore, EPA believes it knows the major geographic areas where citizens have reported problems that they attribute to coalbed methane development. These areas are concentrated in the most active basins: the San Juan, Black Warrior, Central Appalachian, and Powder River Basins. The Agency has included relevant information from the water quantity and quality incident reports that it has received.

Many of the reported incidents (such as impacts to water supply quantities or the effects of discharged groundwater extracted during the coalbed methane production process) are outside of the scope of SDWA and beyond the scope of this Phase I of the study. However, all incidences reported in response to the *Federal Register* request are included so that this study can be as inclusive as possible with respect to reported incidences and not inadvertently exclude a relevant reported incident. This study is specifically focused on assessing the potential for contamination of USDWs from the injection of hydraulic fracturing fluids into coalbed methane wells, and determining based on these findings, whether further study is warranted.

It is important to note that activities or conditions other than hydraulic fracturing fluid injection may account for some of the reported incidences of the contamination of drinking water wells. These potential causes include surface discharge of fracturing and production fluids, poorly sealed or poorly installed production wells, and improperly abandoned production wells.

For this phase of the study (Phase I), EPA consulted with state agencies to determine if they had received reports of groundwater problems, to learn of any follow-up steps typically taken by the state, and to determine the states' overall findings regarding any impacts that hydraulic fracturing of coalbed methane wells may have had on groundwater.

This chapter summarizes correspondence EPA has had with individual citizens and states, organized by basin, as follows:

- San Juan Basin (Colorado and New Mexico).
- Powder River Basin (Wyoming and Montana).
- Black Warrior Basin (Alabama).
- Central Appalachian Basin (Virginia and West Virginia).

6.1 The San Juan Basin (Colorado and New Mexico)

For over a decade, citizens in the San Juan Basin region have reported that coalbed methane development has resulted in increased concentrations of methane and hydrogen sulfide in their water wells. Other complaints about coalbed methane development include the loss of water, the appearance of anaerobic bacteria in water wells, and the transient appearance of particulates in well water. In conversations with EPA, most citizens and local government officials did not specify hydraulic fracturing as the cause of well water problems. Summaries of reported incidents and state follow-up are discussed in sections 6.1.1 and 6.1.2, respectively.

EPA reviewed the BLM study summarizing the history of methane seeps, citizen complaints, and follow-up investigations related to conventional gas and coalbed methane development in the San Juan Basin to determine if they contained information pertaining to coalbed methane hydraulic fracturing and its impact, if any, on the quality of water in drinking water aquifers in the basin. A summary of pertinent findings is provided in section 6.1.3.

6.1.1 Summary of Reported Incidents

- EPA spoke with a former county employee who, earlier in his career, had worked for Exxon performing hydraulic fracturing jobs (Holland, 1999). As a county employee, he took measurements for methane and hydrogen sulfide inside homes in response to citizen complaints. He indicated that there were no significant problems until the shallowest formation of coal (the Fruitland Formation) began being developed. He believed that the main route of contamination is from older, poorly cemented wells, and he estimated that hundreds of wells have been affected. He said the biggest problems associated with the apparent effects of coalbed methane development are the explosive levels of methane and the toxic levels of hydrogen sulfide in homes. In his opinion, this is due to the removal of water, rather than to hydraulic fracturing.

- The San Juan Citizens Alliance estimated that hundreds of private water wells have been affected by coalbed methane production in the area of Durango, CO. These complaints include the following:

  - A lawyer representing several Durango citizens whose wells were contaminated, allegedly due to coalbed methane development, said there have always been methane seeps in the river, which have manifested as bubbling water (McCord, 1999). In the early 1980s, however, people began to see increased concentrations of natural gas in their water wells shortly after companies began producing methane from the Fruitland Formation.

  - One individual reported that two of his wells were degraded because of increased methane levels. According to this individual, his neighbor's pump house door was blown off, presumably as a result of explosive levels of methane. Amoco bought three ranches after county officials tested indoor air and found extremely high levels of methane. This individual also told EPA staff that an area of the Southern Ute tribal land has increased levels of hydrogen sulfide at the surface. He reported he had also heard of black water due to pulverized coal.

  - Another private well owner claimed that her neighbors' wells are contaminated by gas infiltration from dewatering. First methane contaminates the well, then hydrogen sulfide, then anaerobic bacteria. She claimed that data exists showing that methane concentrations in water have increased by 1,000 parts per million (ppm).

- EPA Region 8 received letters from citizens concerned that coalbed methane development had contaminated their water with methane and hydrogen sulfide.

- During a visit to Durango, CO, EPA met with several citizens who claimed to have experienced problems with their water due to coalbed methane development. Most of the citizens experienced water loss, but two well owners from New Mexico claimed that the quality of their water was affected by hydraulic fracturing. According to their accounts, the water turned cloudy with grayish sediment a day or two after nearby fracturing events. Eventually, the well water returned to its normal appearance.

EPA also toured the area during that visit. EPA staff viewed areas where patches of grass and trees were turning brown and dying. In some places, large, old-growth trees located within the patch indicated that the area previously had prolonged normal soil conditions. Many citizens and some local officials believed that the areas suffered from increased methane and decreased air in the soil gas in the shallow root zone.

- A La Plata County official reported that citizens have called to complain that well water flow decreases when coalbed methane wells are hydraulically fractured (Keller, 1999). He reported that "a lot" of people are hauling water due to water loss. The county official said that, in two separate reports, well owners noticed problems with their well water approximately 2 weeks after nearby fracturing events. They reportedly believe hydraulic fracturing is responsible because the timing of the water loss coincides with the fracturing. Citizens know when gas producers fracture wells because they can see and hear the operation, which involves several trucks, tanks, manifolds, and mobile trailers. The county official noted that the formation being developed, the Fruitland Formation, is located approximately 2,400 feet below ground surface (bgs), and water wells are generally drilled from 100 feet to 200 feet bgs. He qualified his statements by indicating that wells do go dry for a variety of reasons.

- EPA contacted the Colorado Department of Health (CDH), which has primacy for the UIC Program under SDWA. An official with whom EPA spoke said CDH believes that water removal associated with coalbed methane development has caused problems in private water wells (Bodnar, 1999).

- EPA received one complaint from a citizen living in the Raton Basin in Trinidad, CO. She reported that water wells in her area have begun to decline in production and quality, often producing more and more gas. She believes the decline of water wells in her area is due to dewatering associated with coalbed methane production.

6.1.2 State Agency Follow-Up in the San Juan Basin

Colorado Oil and Gas Conservation

The Colorado Oil and Gas Conservation Commission (COGCC) is responsible for environmental issues related to oil and gas production in the state. The COGCC responds to every complaint called in to its office (Baldwin, 2000).

The COGCC staff believes that increased methane concentrations in water wells and buildings in some areas are partially due to old, improperly abandoned gas wells and older, deeper conventional gas wells in which the Fruitland Formation was not completely isolated. The state bases its opinions on monitoring and studies conducted in the San Juan Basin in response to complaints (see section 6.1.3). According to COGCC officials, the state's mitigation program focused on sealing old, improperly abandoned gas wells and appears to have reduced methane concentrations in approximately 27 percent of the water wells sampled. They believe that methane concentrations will decrease over time in other water wells where the source of the methane was gas wells. There are other areas of the San Juan Basin where the methane in water wells is produced by methanogenic bacteria in the aquifer. Methane concentrations in water wells in these areas probably will not decrease.

Officials cite studies that use stable carbon and hydrogen isotopes of methane and gas composition to differentiate between thermogenic methane from the Fruitland, Mesaverde, and Dakota Formations, and biogenic methane that is produced in shallower formations by naturally occurring methanogenic bacteria. By 1998, approximately two-thirds of the water wells for which gas isotopic analyses had been performed appeared to contain biogenic gas, while one-third appeared to contain thermogenic gas.

The state also noted that, in the interior basin, 1,100 feet of shale separates the Fruitland Formation and the shallow formations in which private wells are completed.

New Mexico Oil Conservation Division

EPA spoke with a District Geologist employed by the New Mexico Oil Conservation Division (NMOCD). He said that several years ago the office received many complaints that methane had contaminated water wells (Chavez, 2001). The state held water fairs at which anyone could have his or her water tested. In addition, the state initiated a program for cemented wells (some active, some abandoned) that prohibited open holes 100 feet above the casing string. The District Geologist indicated that the program seemed to solve the problem and that NMOCD has not received many subsequent complaints.

6.1.3 Major Studies That Have Been Conducted in the San Juan Basin

As noted previously, EPA reviewed a BLM study on the San Juan Basin to determine if it contained information pertaining to coalbed methane hydraulic fracturing and its impact, if any, on the quality of water in drinking water aquifers in the basin. EPA's review of this report focused on the two potential mechanisms by which hydraulic fracturing may affect the quality of USDWs: 1) direct injection of hydraulic fracturing fluids into a USDW or injection of fracturing fluids into a coal seam already in hydraulic communication with a USDW (e.g., through a natural fracture system), and 2) creation of a hydraulic connection between the coalbed formation and an adjacent USDW. The reports did not specifically address hydraulic fracturing, and only very little information indirectly addresses the question specific to this study: *Does the injection of hydraulic fracturing fluids into coalbed methane wells contaminate USDWs*?

The studies provided information on evidence that a hydraulic connection exists between coalbeds in the Fruitland Formation and overlying shallow aquifers and on possible conduits that may be the basis of the hydraulic connection. For example, the presence in a shallow aquifer of methane documented to be from the underlying Fruitland Formation is indirect evidence of a hydraulic connection, through some type of conduit, between the Fruitland Formation and shallower formations.

Evidence that a hydraulic connection exists between coalbeds and the shallow aquifer

The U.S. Department of the Interior's BLM (1999) provides a history of gas seeps and methane contamination of drinking water wells in the San Juan Basin. This section will review the evidence that indicates the existence of a hydraulic connection between the deep coalbeds and shallow USDWs.

Even prior to oil and gas drilling operations, shallow water wells in the San Juan Basin produced methane gas. Some wells in the Cedar Hill, NM, area of the basin were reported to have a strong sulfur odor. Some shallow water wells around the basin rim penetrated the Fruitland and Menefee coalbeds and produced methane (BLM, 1999). Thus, coalbed methane was the source of at least some of the observed methane contamination. Water from the Fruitland coalbed discharges in the western part of the basin and migrates upward across the Kirtland shale into the Animas and San Juan Rivers (Stone et al., 1983). In areas such as La Plata County, CO, along the northern and western rims of the basin, the methane presumably moves through natural fractures.

In the interior of the basin, gas seeps were observed in pastures in the Animas River Valley south of Durango near Bondad, CO, and Cedar Hill, NM, in the early to mid-1980s. Bubbles were also observed in the Animas River and in the tap water of rural properties in these areas. Methane was responsible for explosions in several pump houses. A landowner in New Mexico reported that gas was bubbling out of his alfalfa field and in the Animas River in 1985. Gas seeps were likely the cause of patches of dead grass growing in soils overlying the Mesaverde sandstone (BLM, 1999). Thus, conduits between methane-containing units and the surface were present both at the rim and in the interior of the basin.

After coalbed methane production began in the basin in the late 1980s, a local citizens' group voiced concerns that natural gas contamination of drinking water wells had increased in La Plata County. One study reported that 34 percent of the 205 domestic water wells tested in the county showed measurable concentrations of methane (BLM, 1999). This appears to indicate that there is a conduit for fluid to flow to the shallower USDW and its drinking water wells.

Shortly after the start of coalbed methane production in the basin, 11 coalbed methane wells were drilled within 2 miles of the Pine River Ranches Subdivision at the rim of the San Juan Basin. Nine to 35 feet of alluvium separate the surface from the Fruitland Formation coals in this area. A number of problems were reported following the onset of coalbed methane production. A man who complained that his well was contaminated with methane saw streams of gas bubbles in the nearby Los Pinos River. His report of methane contamination was confirmed by the San Juan Regional Authority (SJRA), which investigated reported contamination of this well and nearby wells. The other wells were also contaminated with methane. Two of the 4 residences near the 11 coalbed methane wells contained explosive levels of methane in crawl spaces (BLM, 1999). The methane sampled in the shallow wells and the bubbling river and the high concentrations of methane detected in residences suggest that coalbed methane was following some conduit from the Fruitland Formation to the surface or to shallow USDWs.

Evidence that methane in shallow drinking water wells originates in the Fruitland Formation (location of the coalbeds targeted by hydraulic fracturing)

Several lines of evidence show that methane detected in alluvial wells is not a result of sewage-derived methane contamination (BLM, 1999). Rather, the methane in the domestic wells studied originates either in conventional gas reservoirs such as the Dakota sandstone and the Lewis Shale or in the coals of the Fruitland Formation.

The composition of the gas in samples from shallow, private drinking water wells was analyzed to confirm the well owners' observations. The data obtained showed that the methane in approximately half of the samples appeared to have originated in the Fruitland Formation coalbeds and not from other possible sources such as septic tanks (BLM, 1999).

Similar sampling and analyses conducted in an additional study cited by BLM (1999) concluded that gas in a domestic well in alluvium overlying the Fruitland Formation had the same gas composition and carbon-13 isotope ratio as gas from a nearby gas well also in the Fruitland Formation. This study found that C13 isotopic signatures of individual near-surface gas samples correlated with production gas from discrete formations beneath the study area (BLM, 1999). In addition, an area resident's well contained 680 ppm TDS, primarily sodium bicarbonate. Fruitland-produced water has the same composition, although other domestic wells in the area do not. (TDS values tend to be in the 100 to 200 ppm in these other domestic wells.) Both the gas and the water analyses indicate that the shallow aquifer in the area (from which the methane-contaminated domestic wells draw drinking water) is in hydraulic communication with the deeper Fruitland Formation coalbeds.

Possible conduits for fluid movement from the coalbeds to the aquifer

Several studies have assessed possible natural or manmade conduits to account for the confirmed occurrence of methane in wells tapping the shallow aquifer that overlies the deeper coalbeds in the Fruitland Formation. Possible pathways enabling methane to move from a deep source to a shallow aquifer include natural fractures, hydraulically induced fractures, disposed of produced water from coalbed methane wells, and poorly constructed, sealed, or cemented conventional gas wells, coalbed methane wells, shallow drinking water wells, and cathodic protection wells installed to protect oil and gas pipelines from corrosion (BLM, 1999).

The history of documented gas seeps and methane occurrence in water wells indicates that natural fractures probably serve as conduits in parts of the basin where coal formations are near or at the surface and in the interior of the basin, where the coal formations are deeper. These conduits may enable hydraulic fracturing fluids to travel from targeted coalbeds to shallow aquifers. However, there is no unequivocal evidence that this fluid movement is occurring and, even given the presence of these possible conduits, other hydrogeologic conditions (such as certain pressure gradients, etc.) would be required for fluid movement from targeted coalbeds to shallow aquifers.

A study comparing soil-gas-methane concentrations adjacent to 352 gas-well casings and 192 groundwater wells found that the gas-well annuli (i.e., the spaces between the steel well casings and the walls of the drilled bore holes) were frequently the reason methane moved from the coalbeds to the near-surface environment (BLM, 1999). Thus, gas-well annuli are clearly one type of conduit for movement of methane from deeper sources up to overlying shallow aquifers.

The possibility of leaking gas wells acting as conduits through which methane flows from the Fruitland Formation to shallow aquifers was investigated by a joint Colorado Oil and Gas Conservation Commission/BLM study (BLM 1999). One hundred twenty water wells were tested for methane before and after nearby gas wells were “remediated” (better sealed). The study concluded that the relationship between gas well remediation and lower methane concentrations in drinking water was “complex” and may have been affected by the lingering presence of methane in drinking water after gas well remediation. More than half the water wells showed no significant changes in methane occurrence, a quarter showed lower methane levels, and one-tenth showed increased methane.

In summary, there appears to be evidence that methane seeps and methane in shallow geologic strata and water wells may occur because the methane moves through a variety of conduits. These conduits include natural fractures; poorly constructed, sealed, or cemented manmade wells used for various purposes. No reports provide direct information regarding hydraulic fracturing. Methane, fracturing fluid, and water with a naturally high TDS content could possibly move through any of these conduits. In some cases, improperly sealed gas wells have been remediated, resulting in decreased concentrations of methane in drinking water wells.

6.2 The Powder River Basin (Wyoming and Montana)

EPA spoke with several individuals familiar with coalbed methane activity in the Powder River Basin area who believe coalbed methane production is causing water quantity issues. These individuals have reported that dewatering during coalbed methane production resulted in loss of water from wells and in flooding problems on the surface. Many of the drinking water wells in the Powder River Basin are screened and completed in the same formation being dewatered for methane production. According to a consulting hydrogeologist, as much as 1 million gallons of water are pumped from each coalbed methane production well during its lifetime. Consequently, the aquifer has dropped 200 feet in some areas (Merchat, 1999). EPA has also learned that, as of 1999, oil and gas companies have drilled 2,000 wells in the Powder River Basin, and they reportedly plan to drill 15,000 in total (Merchat, 1999). However, deeper aquifers are available, and the oil and gas companies have drilled new water wells in those aquifers for private individuals.

Reports of incidents in the Powder River Basin are summarized below. However, hydraulic fracturing is performed infrequently in the Powder River Basin, and no one living in that area has reported problems relating to the process. Many of the complaints relate to water quantity issues, which are beyond the scope of this study.

EPA contacted the state and local offices of the Wyoming Health Department and the Water Quality Division of the Wyoming Department of Environmental Quality to determine if these departments had received complaints of water quality degradation due to coalbed methane production. Local authorities reported one complaint of black sediments in drinking water, but most concerns centered on water loss and flooding caused by large quantities of water discharged at the surface (Heath, 1999). There has been discussion among stakeholders regarding the handling of large volumes of water brought to the surface during coalbed methane production. Some individuals remain concerned about the consequences of dewatering aquifers, which include loss of the resource, effects on soil chemistry, flooding, and the potential for coalbed fires and subsidence.

EPA spoke with a consultant for the Powder River Basin Resource Council (PRBRC), a citizen's group formed around environmental issues associated with coalbed methane production (Merchat, 1999). He stated that the biggest concern among people in the area is loss of water. However, some have had problems with increased methane content in their water. He said people reported methane in the water results in frothing and bubbles. The water is generally used for agricultural purposes and for drinking water. He said that each methane well produces millions of gallons of water in its lifetime. The discharge of water has created new ponds and swamps that are not naturally occurring in that region. The secondary effects from pumping water are subsidence and clinker beds (burning coal). When underground coal catches fire from lightning, it burns until it reaches groundwater. However, if there is no groundwater, the fire will continue to burn. The cost of manually extinguishing those fires is enormous. Furthermore, the burning of the coal can leave behind benzo(a)pyrene and other polycyclic aromatic hydrocarbons that are toxic and/or carcinogenic and could affect drinking water.

EPA Region 8 is participating in a study that addresses the environmental effects of all aspects of coalbed methane development and not just hydraulic fracturing.

6.3 The Black Warrior Basin (Alabama)

The *LEAF v. EPA* case arose from an alleged water quality degradation related to activities in Alabama. As discussed in Chapter 1, the Eleventh Circuit Court's 1997 decision in *LEAF v. EPA,* 118F.3d 1467, held that because hydraulic fracturing of coalbeds to produce methane is a form of underground injection, Alabama's EPA-approved UIC Program must effectively regulate this practice (11th Cir, 1997). In response to the Court's decision, Alabama supplemented its rules governing the fracturing of wells to include additional requirements that govern the protection of USDWs during the hydraulic fracturing of coalbed methane. Summaries of reported incidents are presented in section 6.3.1 below.

6.3.1 Summary of Reported Incidents

- In the drinking water well case that precipitated *LEAF v. EPA*, an individual complained that drinking water from his well contained a milky white substance and had strong odors shortly after a fracturing event. He also reported that six months after the fracturing event his water had increasingly bad odors and occasionally contained black coal fines. The EPA Administrative Record regarding the Alabama Class II UIC Program contains other similar descriptions of well water problems.

- Another Alabama citizen reported to EPA problems with her drinking water well that began in 1989. In her letter, the citizen reported that her property was located near a coalbed methane gas well and that there was coal mining in the area. She wrote that she believes hydraulic fracturing of the coalbed methane well adversely affected her drinking water well, and coal resource exploitation in the area caused various, significant environmental damage. The individual believed that the hydraulic fracturing contributed to well contamination because, shortly after a fracturing event, her kitchen water contained globs of black, jelly-like grease and smelled of petroleum. She said her drinking water turned brown and contained slimy, floating particles. She reported that her neighbors also said their water smelled like petroleum.

  She included, as an attachment, a letter from the Alabama Oil and Gas Board (OGB) approving the use of proppants tagged with radioactive material. Their approval was based on the hydrogeology and the absence of water wells in the immediate area, the depths of the coal intervals to be fractured, well construction, and adherence to a program designed to monitor and contain radioactive material at the surface. Also attached was a letter from EPA Region 4 describing analytical results for samples the Agency collected from her drinking water well on June 26, 1990. The results indicated no purgeable and extractable organic compounds were detected. In addition, the letter said that a water/oil inter-phase detector was used to determine if petroleum products were floating in the well, and none was detected.

- An Alabama homeowner complained to the Natural Resources Defense Council that recovered hydraulic fracturing fluid from a nearby coalbed methane well installation was allowed to drain from the coalbed methane well site to a location near her home. She claimed that this fluid was initially obtained from an abandoned strip-mining quarry that had been used as a landfill for municipal and industrial waste. As this fluid drained from the fracturing site, the homeowner asserted, it killed all animal and plant life in its path. She further stated that shortly after this fracturing event and the associated runoff, her 110-foot deep drinking water well became contaminated with brown, slimy, petroleum-smelling fluid similar to the discharged fracturing fluid from the coalbed methane well site.

- In response to EPA's July 2001 call for information on water quality incidents (found in Water Docket W-01-09), an individual reported that her drinking water well had become filled with methane gas, causing it to hiss (66 FR 39396 (USEPA, 2001)); the tap water became cloudy, oily, and had a strong, unpleasant odor. In addition, the tap water left behind an oily film and contained fine particles. The drinking water well owner had her well tested by a private consultant, who confirmed the presence of methane.

  The Alabama OGB tested this drinking water well, but only looked for naturally occurring contaminants. EPA also sampled and tested this drinking water well, but not until 6 months after the event. No mention is made of the analytical results obtained from the drinking water well by these agencies.

6.3.2 State Agency Follow-Up (Alabama Oil and Gas Board)

LEAF v. EPA originated in Alabama. The water well that was reportedly contaminated as a result of hydraulic fracturing operations was sampled independently by the Alabama OGB, the Alabama Department of Environmental Management (ADEM), and EPA Region 4. Water analyses performed by these agencies indicated that the water well had not been contaminated as a result of the fracturing operation. The Alabama OGB reported to EPA that it investigates every complaint it receives, and it does not believe that hydraulic fracturing has affected water wells. Investigations include research into historical water quality data, some of which pre-dates coalbed methane activity. Such historical information is important because the coal-bearing Pottsville Formation often contains high concentrations of iron. Groundwater from this formation may contain iron-reducing bacteria, which can sometimes result in such water having an unpleasant taste or odor, or containing a white or red-brown, stringy, gelatinous material (Valkenburg and others, 1975, as cited by the Alabama OGB, 2002). In addition, sudden iron staining can occur in water with a history of good quality. Water well yield can also decline due to the presence of iron-reducing bacteria in high concentrations.

According to the Alabama OGB, one factor considered in each investigation is whether historical data are available on water quality in a particular area, including data that pre-date coalbed methane activity. Published reports and open-file data show that the quality of water in the coal-bearing Pottsville Formation can vary from good to very poor. Data collected from the 1950s through 1970s in localities throughout a large area where the Pottsville Formation has served as a source of water contain reports of water having "bad taste," "bad odors," "oily films or sheens," and waters causing "red stains" and "black stains" (Geological Survey of Alabama, 1930s to Present; Johnston, 1933, as cited by the Alabama OGB, 2002).

The Alabama OGB reported to EPA that it has investigated several complaints of methane gas in water wells. In each instance, the Alabama OGB determined that the water well problem was unrelated to coalbed methane extraction operations, which often were not occurring in the areas of reported water problems. Moreover, in some areas methane gas was reported in water wells many years before the advent of underground mining and the commercial development of this resource (Geological Survey of Alabama, 1930s to Present, as cited by the Alabama OGB, 2002). The problem of methane gas in water wells has generally occurred where water wells, usually less than 200 feet deep, penetrated gas-bearing coal strata, particularly following low rainfall years that caused a lowering of water tables. In these areas, there commonly had been a recent increase in the drilling of water wells and an acceleration in the rates of water withdrawal from the aquifer. When sufficient amounts of water are removed from these water wells, methane can begin to desorb from the coal seams and be produced.

Alabama's regulations have been approved by EPA for incorporation into Alabama's Class II UIC Program. Operators must provide written certification to the Board that the proposed fracturing operation will not occur in a USDW or that the fracturing fluids do not exceed the MCLs in 40 CFR §141 Subparts B and G. Fracturing is prohibited from ground surface to 299 feet bgs. For all fracture jobs performed between 300 feet and 749 feet bgs, the company must perform a reconnaissance of fresh-water supply wells within ¼ mile of the well to be fractured, submit a fracturing program to the OGB, and perform a cement bond log analysis. For fracturing events performed between 750 feet and 1,000 feet bgs, only a cement bond log is required. For fracturing events performed below 1,000 feet bgs, operators must submit to the Alabama OGB the depth to be fractured, well construction information, cementing specifications, and logs identifying overlying, impervious strata.

In Alabama, Rule 400-3-8-.03 states that coalbeds shall not be hydraulically fractured until written approval of the Oil and Gas Supervisor has been obtained. The Supervisor must be notified when an approved fracturing operation is to occur so that an agent of the Board may be present. In order to receive approval, operators must submit details of the proposed fracturing operation. The Board's staff evaluates each proposal for compliance to ensure USDW protection. Basic information that must be submitted with an operator's proposal to hydraulically fracture a well includes details on the depths of coalbeds to be fractured; construction of the well, including casing and cementing specifications; a geophysical log showing the type and thickness of impervious strata overlying the uppermost coalbed to be fractured; and, if the operation is to be performed in a USDW-bearing interval, a statement certifying that fracturing fluids will not exceed the MCLs of federally mandated primary drinking water regulations (40 CFR §141 Subparts B and G). In addition to the basic information, a fracturing program, a water well inventory within a ¼-mile radius, and a cement bond log must be provided with fracturing proposals in the depth interval 300 to 749 feet. Since water supply wells are generally shallower than coalbeds, Alabama's Rule 400-3-8-.03 was designed to increasingly strengthen the requirements for USDW protection with decreasing depths of proposed fracturing operations. Furthermore, the fracturing of coalbeds shallower than 300 feet is prohibited.

6.4 The Central Appalachian Basin (Virginia and West Virginia)

EPA became aware of several complaints relating to the effects of coalbed methane production on sources of drinking water in the southwestern portion of Virginia through correspondence initiated by citizens. Information about water quality incidents was gathered through meetings and telephone conversations with members of the Virginia Division of Oil and Gas within the Department of Mines, Minerals and Energy (VDMME); local health officials; and representatives of a county citizen's group. In total, VDMME provided EPA with over 70 "Complaint Detail Reports" (registered between 1990 and 2001) that related to drinking water source impacts by coalbed methane development.

Although the majority of the incidents outlined in the complaints pertain to water-loss issues, approximately one-quarter relate to water quality. Virginians living near coalbed methane production areas reported private well and spring water contamination evidenced by oily films, soaps, iron oxide precipitates, black sediments, methane gas, and bad odor and taste. Reports of water loss in the well ranged from noticeably reduced supply rates to total loss of water from domestic drinking water wells. Summaries of reported incidents and state follow-up are discussed in sections 6.4.1 and 6.4.2, respectively.

6.4.1 Summary of Virginia Incidents

- The state received complaints of soap bubbles flowing from residential household fixtures. VDMME attributes soap coming out of water faucets to the drilling process associated with both conventional wells and coalbed methane wells. Soaps are used to extract drilling cuttings from the borehole because the foam expands, rises, and, as it rises, carries the cuttings to the surface (Wilson, 2001). These soaps may migrate from the borehole into the drinking water zone that supplies private wells during drilling of the shallow portion of the hole and before the required groundwater casing is cemented in place. In the few occurrences of soap contamination, water was provided until the soap was completely purged from the contributing area surrounding their water well.

- In early August 2001, EPA met with approximately 15 to 20 residents of Buchanan and Dickenson Counties in Virginia. Coalbed methane production activity is steadily increasing in the area surrounding Buchanan County since the coal reserves in this area have proven to be extremely profitable sources for coalbed methane in recent years (Wilson, 2001). The subjects of the citizen complaints were very similar to those logged in the VDMME complaint reports. Residents described the presence of black sediments, iron precipitates, soaps, diesel fuel smells, and increased methane gas in drinking water from their wells. One resident brought a water sample collected from her drinking water well. The water was translucent with a dark gray color and with dark black suspended sediment. Several other citizens reported drinking water supplies diminishing or drying up entirely. One resident of Buchanan County said that he had an ample water supply from his drinking well for over 54 years, until shortly after coalbed methane wells were installed on his property. He reported that within 60 days of the coalbed methane well installations, his 276-foot deep drinking water supply well, which used to produce over 20 gallons per minute of potable flow, dried up. The resident mentioned that over 380 homes in the region do not have potable water as a result of coalbed methane mining activities.

  Most of the residents said that their complaints to the state usually resulted in investigations without resolution. Some residents mentioned that the gas companies were providing them with potable water to compensate for the contamination or loss of their drinking water wells. However, the residents said that this was not adequate compensation for the impacts to, or loss of, their private drinking water supplies.

- EPA was able to record numerous complaints through telephone conversations and e-mails with Virginia residents, who reported that they believed their drinking water wells had been affected by coalbed methane industry activities. All the logged complaints were from Buchanan and

Dickenson Counties. Complaints include water loss, soapy water, diesel odors, iron and sulfur in wells, rashes from showering, gassy taste, and murky water. One report discusses a miner who was burned by a fluid, possibly hydrochloric acid used in hydraulic fracturing, that infiltrated a mineshaft. Another report describes the contamination of a stream and the resulting fish kills caused by the runoff from drilling fluids. One complainant explained that several thousand wells had "gone dry, overnight." According to the individuals EPA spoke with, compensation to homeowners for these impacts is in the form of money, newly drilled wells to replace dry or contaminated wells or temporary provision of potable water, which is supplied "until things clear out."

6.4.2 State Agency Follow-Up (VDMME)

VDMME, Division of Gas and Oil, is responsible for responding to environmental issues associated with oil and gas development; it investigates every water problem reported. Responses may include an interview with the citizen reporting the problem, a site visit, water well testing, or a review of the physical aspects of the water well and surrounding activities. According to Robert Wilson of VDMME, his agency tests for contaminants that may be introduced by drilling such as chlorides, oil and grease, and volatile organics. The results of those analyses are compared to baseline values. VDMME witnesses surface casing and plugging jobs as part of its oversight duties. VDMME reviews information from drilling and completion reports to assist with investigations into complaints.

Based on investigations of the more than 70 complaints received, VDMME believes that coalbed methane production has not affected private drinking water wells. VDMME recognizes soap migrating into drinking water wells, but considers this only a transient problem. While a number of complaints report a noticeable reduction in or a total loss of drinking water supply, in almost all cases, the state investigator determined that the water loss was not likely to be caused by local hydraulic fracturing events or coalbed methane production activity because:

- The distance from the private well to the nearest coalbed methane well is too far (1,500 feet or more) to have any impact.
- There is no hydrologic connection between the water contribution zones of the private and coalbed methane wells; therefore, it is physically impossible for coalbed methane wells to affect private drinking water wells.
- The well was constructed according to VDMME regulatory guidelines; therefore, a sufficient buffer exists between the private well and the coalbed methane well.

- The existing supply was reduced because of recent drought conditions in the region.

- The complainant experienced mechanical difficulty with his or her pumping system, which led to a reduction in pumped water; however, the supply was not affected.

According to VDMME, these citizen complaints refer to incidents that can occur during the drilling of any type of well, not just coalbed methane. The few incidents of this kind were equally divided between conventional wells and coalbed wells (VDMME, 2002).

6.5 Summary

In this chapter, EPA has presented information (in addition to technical, conceptual, or theoretical information presented previously) on personal experiences with regard to coalbed methane activities and their potential (or perceived potential) to impact drinking water wells. These personal accounts of potential incidences in four producing coal basins across the United States do not present scientific findings. However, the body of reported problems considered collectively suggest that water quality (and quantity) problems might be associated with some of the production activities common to coalbed methane extraction. These activities include surface discharge of fracturing and production fluids, aquifer/formation dewatering, water withdrawal from production wells, methane migration through conduits created by drilling and fracturing practices, or any combination of these. Other potential sources of drinking water problems include various aspects of resource development, naturally occurring conditions, population growth and historical practices.

In several of the coalbed methane investigation areas, local agencies concluded that hydraulic fracturing could not affect drinking water wells. Generally, these conclusions were based on there being a significant horizontal and/or vertical distance between the coalbed methane production wells and the drinking water wells.

Chapter 7
Conclusions and Recommendations

Under SDWA, EPA's UIC Program is responsible for ensuring that fluids injected into the ground do not endanger USDWs. The goal of the Phase I study was to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into coalbed methane wells, and to determine, based on these findings, whether further study is warranted.

EPA's approach for evaluating the potential for contamination of USDWs was an extensive information collection and review of empirical and theoretical data. EPA reviewed water quality incidents potentially associated with hydraulic fracturing and evaluated the theoretical potential for hydraulic fracturing to affect the quality of USDWs through one of two mechanisms:

1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

7.1 Reported Water Quality Incidents

Citizens from Wyoming, Montana, Alabama, Virginia, Colorado, and New Mexico contacted EPA because they were concerned that their water wells were affected by coalbed methane production. The major geographic areas where citizens reported experiencing problems due to coalbed methane development are concentrated in the coal basins with the most coalbed methane activities – the San Juan, Black Warrior, Central Appalachian, and Powder River Basins. This study was initiated, partly, in response to those citizens' concerns. EPA followed-up on letters and telephone calls from citizens and resulting leads to understand specific complaints and citizens' concerns.

EPA published a *Federal Register* notice (66 FR 39396 (USEPA, 2001) requesting information on water quality incidents believed to be associated with hydraulic fracturing of coalbed methane wells. EPA notified over 500 local and/or county agencies in areas with potential coalbed methane production activity to make them aware of the *Federal Register* notice requesting information on coalbed methane-related complaints. The Agency received no information on complaints from these officials.

EPA reviewed responses and follow-up actions conducted by state agencies to address groundwater complaints involving coalbed methane. Hydraulic fracturing is not widely practiced in the Powder River Basin (which includes Wyoming and Montana) and concerned citizens from that area reported surface water and groundwater quantity problems rather than specifying hydraulic fracturing as a problem. Studies of groundwater quality in the San Juan Basin (which includes parts of Colorado and New Mexico) do not address hydraulic fracturing directly. However, problems with groundwater quantity and quality in Colorado may have plausible explanations other than hydraulic fracturing activities. For example, natural fractures, and poorly constructed, sealed, or cemented wells used for various purposes, may provide conduits for methane to move into shallow geologic strata and water wells, or even to surface water (BLM, 1999). The New Mexico Oil Conservation Division reported that citizens began reporting increased levels of methane in their water wells after coalbed methane development began in the San Juan Basin. New Mexico initiated a plugging and abandonment program to seal old, improperly abandoned production wells, which appears to have mitigated the problem (Chavez, 2001).

EPA also obtained individual incident reports from Virginia. None of Virginia's follow-up investigations provided evidence that hydraulic fracturing of coalbed methane wells had caused drinking water well problems. Incidents in Alabama were investigated by the Alabama Oil and Gas Board, the Alabama Department of Environmental Management, and EPA Region IV. Samples from drinking water wells did not test positive for constituents found in fracturing fluids. After reviewing all the available data and incident reports, EPA sees no conclusive evidence that water quality degradation in USDWs is a direct result of injection of hydraulic fracturing fluids into coalbed methane wells and subsequent underground movement of these fluids.

7.2 Fluid Injection Directly into USDWs or into Coal Seams Already In Hydraulic Communication with USDWs

To determine if USDWs are threatened by the direct injection of fracturing fluids into a USDW, EPA: 1) reviewed information on 11 major U.S. coal basins mined for coalbed methane to determine if coal seams lie within USDWs, and 2) identified components of fracturing fluids. EPA also used the information on the 11 major U.S. coal basins as well as information collected on water quality incidents potentially associated with hydraulic fracturing to determine if coal seams are already in hydraulic communication with USDWs. Hydraulic fracturing has been, or is being, performed in every basin reviewed. As summarized in Table 5-1 in Chapter 5, evidence suggests that coalbeds in 10 of the 11 major coal basins in the United States are located at least partially within USDWs. The coalbeds in the Piceance Basin in Colorado, however, are several thousand feet below USDWs, and are unlikely to be in hydraulic communication with USDWs.

Hydraulic fracturing fluids injected into coalbed methane wells consist primarily of water, or inert nontoxic gases, and/or nitrogen foam and guar (a naturally occurring substance derived from plants). According to information gathered from MSDSs, on-site reconnaissance of fracturing jobs, and interviews with service company employees, some hydraulic fracturing fluids may contain constituents of potential concern. Table 4.1 in Chapter 4 lists examples of chemicals found in hydraulic fracturing fluids according to the MSDSs. Constituents of potential concern include the following substances either alone or in combination: bactericides, acids, diesel fuel, solvents, and/or alcohols. Although the largest portion of fracturing fluid constituents is nontoxic (>95% by volume), direct fluid injection into USDWs of some potentially toxic chemicals does take place.

For example, potentially hazardous chemicals are introduced into USDWs when diesel fuel is used in fracturing fluids in operations targeting coal seams that lie within USDWs. Diesel fuel contains constituents of potential concern regulated under SDWA – benzene, toluene, ethylbenzene, and xylenes (i.e., BTEX compounds). However, the threat posed to USDWs by introduction of these chemicals is reduced significantly by coalbed methane production's dependence on the removal of large quantities of groundwater (and injected fracturing fluids) soon after a well has been hydraulically fractured. EPA believes that this groundwater production, combined with the mitigating effects of dilution and dispersion, adsorption, and potentially biodegradation, minimize the possibility that chemicals included in the fracturing fluids would adversely affect USDWs.

Because of the potential for diesel fuel to be introduced into USDWs, EPA requested, and the three major service companies agreed, to eliminate diesel fuel from hydraulic fracturing fluids that are injected directly into USDWs for coalbed methane production. Industry representatives estimate that these three companies perform approximately 95 percent of the hydraulic fracturing projects in the United States. These companies signed an MOA on December 15, 2003 and have indicated to EPA that they no longer use diesel fuel as a hydraulic fracturing fluid additive when injecting into USDWs for coalbed methane production (USEPA, 2003).

7.3 Breach of Confining Layer

The second mechanism by which hydraulic fracturing may affect the quality of USDWs is fracturing through a hydrologic confining layer, and creation of a hydraulic communication between a coal seam and an overlying USDW. If sufficiently thick and relatively unfractured shale is present, however, it may act as a barrier not only to fracture height growth, but also to fluid movement.

A hydraulic fracture will propagate perpendicularly to the minimum principal stress. In some shallow formations, the least principal stress is the overburden stress; thus, the hydraulic fracture will be horizontal. In deeper reservoirs, the least principal stress will likely be horizontal; thus, the hydraulic fracture will be vertical. In general, horizontal fractures are most likely to exist at shallow depths (less than 1,000 feet) (Nielsen and Hansen, 1987 as cited in Appendix A: DOE, Hydraulic Fracturing). Most coal seams currently used for methane production are relatively shallow compared to conventional oil production wells, but still lie deeper than 1,000 feet.

Hydraulic fracturing may have increased or have the potential to increase the communication between coal seams and adjacent formations in some instances. For example, in the Raton Basin, some fracturing treatments resulted in higher than expected withdrawal rates for production water. Those increases, according to literature published by the Colorado Geologic Survey, may be due to well stimulations creating a connection between targeted coal seams and an adjacent sandstone aquifer (Hemborg, 1998). In the Powder River Basin, concerns over the creation of such a hydraulic connection are cited as one reason why hydraulic fracturing of coalbed methane reservoirs is not widely practiced in the region. Some studies that allow direct observation of fractures (i.e., mined-through studies) also provided evidence that fractures move through interbedded layers, sometimes taking a stair-step pathway through complex fracture systems, and sometimes enter or propagate through geologic strata above the coal (i.e., roof rock) (Diamond, 1987a and b; Diamond and Oyler, 1987; Jeffrey et al., 1993).

Fracture height is important to the issue of whether or not hydraulic fracturing fluids can affect USDWs because shorter fractures are less likely to extend into a USDW or connect with natural fracture systems that may transport fluids to a USDW. The extent of a fracture is controlled by the characteristics of the geologic formation (including the presence of natural fractures), the volume and types of fracturing fluid used, the pumping pressure, and the depth at which the fracturing is being performed. Deep vertical fractures can propagate vertically to shallower depths and develop a horizontal component (Nielsen and Hansen, 1987, as cited in Appendix A: DOE, Hydraulic Fracturing). In these “T-fractures,” the presence of coal fines or a zone of stress contrast may cause the fracture to “turn” and develop horizontally, sometimes at the contact of the coalbed and an overlying formation (Jones et al., 1987b; Morales et al., 1990).

The low permeability of relatively unfractured shale may help to protect USDWs from being affected by hydraulic fracturing fluids in some basins. At some sites, shale may act not only as a hydraulic barrier, but also as a barrier to fracture height growth. Shale’s ability to act as a barrier to fracture height growth is due primarily to the stress contrast between the coalbed and the higher-stress shale (see Appendix A)

Another factor controlling fracture height can be the highly cleated nature of some coalbeds. In some cases, highly cleated coal seams will prevent fractures from growing vertically. When the fracture fluid enters the coal seam, it is contained within the coal seam's dense system of cleats and the growth of the hydraulic fracture will be limited to the coal seam (see Appendix A).

Mined-through studies indicate many hydraulic fractures that penetrate into, or sometimes through, formations overlying coalbeds can be attributed to the existence of pre-existing natural fractures. However, given the concentrations and flowback of injected fluids, and the mitigating effects of fate and transport processes, EPA does not believe that possible hydraulic connections under these circumstances represent a significant potential threat to USDWs.

7.4 Conclusions

Based on the information collected and reviewed, EPA has concluded that the injection of hydraulic fracturing fluids into coalbed methane wells poses little or no threat to USDWs and does not justify additional study at this time. This decision is consistent with the process outlined in the April, 2001 Final Study Design, in which EPA indicated that it would determine whether further investigation was needed after analyzing the Phase I information. Specifically, EPA determined that it would not continue into Phase II of the study if the investigation found that no hazardous constituents were used in fracturing fluids, hydraulic fracturing did not increase the hydraulic connection between previously isolated formations, *and* reported incidents of water quality degradation were attributed to other, more plausible causes.

Although potentially hazardous chemicals may be introduced into USDWs when fracturing fluids are injected into coal seams that lie within USDWs, the risk posed to USDWs by introduction of these chemicals is reduced significantly by groundwater production and injected fluid recovery, combined with the mitigating effects of dilution and dispersion, adsorption, and potentially biodegradation. Additionally, EPA has reached an agreement with the major service companies to voluntarily eliminate diesel fuel from hydraulic fracturing fluids that are injected directly into USDWs for coalbed methane production.

Often, a high stress contrast between adjacent geologic strata results in a barrier to fracture propagation. This may occur in those coal zones where there is a geologic contact between a coalbed and a thick, higher-stress shale that is not highly fractured. Some studies that allow direct observation of fractures (i.e., mined-through studies) indicate many fractures that penetrate into, or sometimes through, formations overlying coalbeds can be attributed to the existence of pre-existing natural fractures. However, and as noted above, given the concentrations and flowback of injected fluids, and the mitigating effects of dilution and dispersion, fluid entrapment, and potentially biodegradation, EPA does not believe that possible hydraulic connections under these circumstances represent a significant potential threat to USDWs.

EPA also reviewed incidents of drinking water well contamination believed to be associated with hydraulic fracturing and found no confirmed cases that are linked to fracturing fluid injection into coalbed methane wells or subsequent underground movement of fracturing fluids. Although thousands of coalbed methane wells are fractured annually, EPA did not find confirmed evidence that drinking water wells have been contaminated by hydraulic fracturing fluid injection into coalbed methane wells.

Public Comment and Response Summary for the Study on the Potential Impacts of Hydraulic Fracturing of Coalbed Methane Wells on Underground Sources of Water

I. INTRODUCTION

The United States Environmental Protection Agency's (EPA's) Office of Ground Water and Drinking Water completed its Phase I study, which assesses the potential for contamination of underground sources of drinking water (USDWs) from the injection of hydraulic fracturing fluids into coalbed methane (CBM) wells. EPA (or the Agency) began collecting information on hydraulic fracturing in the fall of 2000. Based on the information collected and reviewed, EPA has concluded that the injection of hydraulic fracturing fluids into CBM wells poses little or no threat to USDWs and does not justify additional study at this time.

The draft report, titled, "Draft Evaluation of Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reservoirs" (hereafter referred to as the draft report), was made available for public comment by an announcement in the *Federal Register* on August 28, 2002.[1] The 60-day public comment period officially ended on October 28, 2002.

The Agency received and reviewed comments from 105 commenters. Several of these were signed by multiple parties (which were counted as one commenter), including a few coalitions of environmental organizations. The commenters include private citizens; environmental and citizen groups; government agencies at the local, state, and national levels; oil and gas companies; trade associations; and four other commenters that do not fit these categories. Table 1 below provides a listing of these commenters.

[1] Docket Identification numbers are assigned by the Water Docket in order to track each public comment with a unique identification number. Note that if a comment has a prefix of "II-D2," it indicates that the comment was received after the October 28, 2002 comment deadline. Comments with the following docket logs were updates, repeats, or clarifications of other comments: II-D1.91; II-D2.03; II-D2.04; and II-D2.05.

[2] An electronic version of each public comment is available through EPA's electronic public docket and comment system, EPA Dockets at http://www.epa.gov/edocket/. Each comment begins with the prefix "OW-2001-0002-". Edocket numbers were assigned to comment materials, as well as other relevant background documents in the order they were posted to the edocket Web site.

The remainder of this document contains summaries of the major public comments and EPA's responses related to the Agency's August 2002 report. The document is divided into seven other major sections as follows:

- **Section II: Scope of the Study** discusses public comments and EPA's responses on areas not included in the study, the literature used for the review, the number of coal basins included in the study, citizen complaints regarding water well contamination, and the peer review panel who reviewed the initial draft of the report.

- **Section III: Fracturing Fluids** describes public comments and EPA's responses related to the components of fracturing fluids, EPA's comparison of the concentration of fracturing fluid constituents to maximum contaminant levels (MCLs), EPA's estimates for the concentrations of fracturing fluid chemicals at the point-of-injection and the edge of the fracture zone, the amount of fracturing fluids that is recovered from CBM reservoirs, the amount of fracturing fluids used in hydraulic fracturing procedures, and the movement of "stranded" fluids in the coalbed formations.

- **Section IV: Fracture Behavior and Practices** discusses comments raised and EPA's responses to these comments regarding fracture growth, multiple fracturing of the same well, the relationship of drinking water wells to hydraulic fracturing activities, and differences in state geology.

- **Section V: Regulation of Hydraulic Fracturing Practices** describes comments and the Agency's responses regarding the states' authority over hydraulic fracturing practices, and the regulation of hydraulic fracturing under the Safe Drinking Water Act (SDWA).

- **Section VI: Language Used in the Report** summarizes specific comments and the Agency's responses related to the use of the term "USDW" in the report, use of scientific terms, and the tone of the language in the report.

- **Section VII: Chapter-Specific Comments** describes comments and the Agency's response regarding the glossary, executive summary, and Chapters 1 through 7 that were not already covered under Sections II through VI of this document.

- **Section VIII: Basin Descriptions** describes comments that pertain to the basin-specific descriptions in Attachments 1 through 11 of the report and EPA's response to these comments. The comments and responses in Section VIII do not include comments that were already discussed in Sections II through VII of this document.

II. SCOPE OF THE STUDY

A. Areas Not Included in the Review

1. Focus of the Report

Summary of Comments: One commenter indicated that the report should have focused on the possible impacts to human health instead of the hydraulic fracturing process. This commenter added that Chapter 4 of the report should have focused on dose-response curves and not on the properties of hydraulic fracturing fluids. The commenter also stated that EPA should have been able to conduct this analysis because the Agency should have access to research conducted on the toxicity of all constituents used in CBM production.

Another commenter stated that the study did not address the uncertainty in the risk assessment due to omissions and errors in the data used for the study. This commenter indicated that some of the reasons for these omissions and errors could be inadequate reporting by private well owners and counties, inadequate testing, and inadequate enforcement which would result in an underassessment of risk. This commenter also indicated that the report does not address risk resulting from deviations and failures in drilling, fracturing, and monitoring practices, especially for newer wells, or sufficiently address the testing error for volatile chemicals used in hydraulic fracturing.

EPA Response: The Phase I study was not intended to be a risk assessment, but rather, to be a fact-finding effort based primarily on existing literature to assess the potential threat to USDWs from the injection of hydraulic fracturing fluids into CBM wells and to determine based on these findings, whether additional study is warranted. The study is tightly focused on hydraulic fracturing of CBM wells and does not include other aspects of drilling or CBM production. EPA reviewed water quality incidents potentially associated with hydraulic fracturing, as well as evaluated the theoretical potential for hydraulic fracturing to affect USDWs. EPA researched over 200 peer-reviewed publications, interviewed approximately 50 employees from industry and state or local government agencies, and communicated with approximately 40 citizens and groups who are concerned that CBM production affected their drinking water wells.

For the purposes of this study, EPA assessed USDWs impacts by the presence or absence of documented drinking water well contamination cases caused by CBM hydraulic fracturing, clear and immediate contamination threats to drinking water wells from CBM hydraulic fracturing, and the potential for CBM hydraulic fracturing to result in USDW contamination based on two possible mechanisms described below.

1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

EPA's report includes a discussion of the types of fracturing fluids and additives, and fluid volumes that may be used in hydraulic fracturing operations. This discussion is intended to provide further background on the hydraulic fracturing process. In addition, the study provides a review of the fate and transport of injected fluids in the subsurface in order to determine whether a detailed risk assessment is warranted.

2. Monitoring

Summary of Comments: Several commenters questioned how EPA could decide whether hydraulic fracturing poses a risk to USDWs without collecting or reviewing monitoring data. Several commenters wanted EPA to proceed to Phase II of the study and to install monitoring wells in areas where hydraulic fracturing of CBM wells was occurring. One commenter recommended that, at a minimum, EPA identify whether any type of monitoring has been conducted by consulting firms, local or state agencies, or members of the academic community, and if this monitoring exists, to include the results in the report.

Another commenter recommended that EPA, in cooperation with the National Academy of Science (NAS), conduct unannounced inspections of hydraulic fracturing projects in order to collect samples of hydraulic fracturing fluids, and observe and measure the total volume of injected hydraulic fracturing fluid. This commenter also recommended that EPA establish reference doses (RfDs) and MCLs for all chemicals currently used in hydraulic fracturing fluids in significant volumes.

EPA Response: EPA has researched and reviewed a variety of monitoring information that may be related to the issue of possible conduits for fracturing fluid transport into USDWs. These data are discussed in Chapter 6 of the report. For example, EPA reviewed a 1999 Bureau of Land Management (BLM) report which focused on monitoring and data interpretation of methane concentrations in groundwater in the San Juan Basin area. EPA reviewed this report to determine if it contained information pertaining to hydraulic fracturing of CBM and its impacts, if any, to the quality of water in drinking water aquifers in this basin.

Chapter 6 of the report provides a detailed discussion of citizen complaints and state responses to their concerns. Complaints were responded to by various state agencies, and many of those responses included testing of water for contaminants. For example, the Virginia Department of Mines, Minerals and Energy is responsible for: responding to environmental issues associated with oil and gas development (including CBM); investigating all reported water problems; and testing water samples for contaminants that may be introduced by drilling (such as chlorides, oil and grease, and volatile organics).

EPA disagrees that monitoring data is needed to determine whether a Phase II study is warranted. As discussed in the previous response, EPA conducted an extensive literature review, conducted numerous interviews, reviewed water quality incidents potentially associated with hydraulic fracturing, and evaluated the theoretical potential for hydraulic fracturing to affect USDWs. EPA's decision that the injection of hydraulic fracturing fluids into CBM wells poses little or no threat to USDWs and does not justify additional study at this time is consistent with the process outlined in the April, 2001 Final Study Design. In its final study design, EPA indicated that the Agency would make a determination regarding whether further investigation was needed after analyzing the Phase I information.

EPA has recently taken a specific and important measure to address one of the primary concerns regarding hydraulic fracturing fluid – the use of diesel fuel. During EPA's research, the Agency realized that diesel is sometimes used a component of fracturing fluids and is of specific concern because it contains BTEX compounds (benzene, toluene, ethylbenzene, and xylenes) for which MCLs have been established under SDWA. Because of the potential problem diesel can cause, EPA requested its removal from hydraulic fracturing fluids. On December 15, 2003, EPA entered into a Memorandum of Agreement (MOA) with three major service companies – BJ Services Company, Halliburton Energy Services, Inc., and Schlumberger Technology Corporation – to voluntarily eliminate diesel fuel from hydraulic fracturing fluids that are injected directly into USDWs for CBM production. If necessary, these companies will select replacements that will not cause hydraulic fracturing fluids to endanger USDWs. Industry representatives estimate that these three companies conduct an estimated 95 percent of the hydraulic fracturing projects in the United States. These three have indicated to EPA that they no longer use diesel fuel as a hydraulic fracturing fluid additive when injecting into USDWs.

EPA, through its Underground Injection Control (UIC) Program, as authorized under SDWA Part C, Sections 1421-1426), is responsible for ensuring that fluids injected into the ground do not endanger USDWs or cause a public water system (PWS) to violate its drinking water standards due to the contamination of a USDW by these injected fluids. Most states have primary enforcement authority (primacy) for implementation of the UIC Program, and thus have the authority under SDWA to place controls on any injection activities that may threaten USDWs. 40 CFR 145.12, Requirements for Compliance Evaluation Programs, requires that authorized states have programs for periodic inspections of injection operations. States may also have additional authorities by which they can regulate hydraulic fracturing. While surprise inspections are not specifically mandated, state programs have a responsibility to conduct inspections, as necessary, to determine compliance with permit conditions, and to verify the accuracy of monitoring data and other information. EPA requires that all UIC inspectors be certified in, and that inspectors be knowledgeable about, proper operation of injection facilities, protection of USDWs, and SDWA requirements.

Regarding the establishment of RfDs and MCLs for all hydraulic fracturing fluid chemicals used in significant volumes, EPA follows an established procedure for identifying the contaminants for which these standards will be set. The Contaminant Candidate List (CCL) and the Unregulated Contaminant Monitoring Regulation (UCMR) are the primary review mechanisms by which EPA identifies drinking water contaminants which pose the most urgent threat to public health. The CCL process uses the best available information on contaminants of concern and emerging contaminants to prioritize according to potential public health threat, and identify candidates for possible regulation. The UCMR provides occurrence information for determining human exposure, establishing the baseline for health effects and economic analyses, contaminant co-occurrence analyses, and treatment technology evaluation (related to the CCL contaminants). After identifying the top priorities for regulatory determination, EPA begins the process of determining RfDs and associated enforceable standards for protection of public health.

3. Use of Modeling Results

<u>Summary of Comments:</u> One commenter recommended that EPA compare the results of hydraulic fracturing after the process to "modeling" conducted before the process to "provide some degree of predictability of the impact of the fracturing before the actual work is done."

This commenter also recommended that any modeling should consider the effect of other existing activities and conditions that could affect the outcome of the model (e.g., existing oil and gas wells, water wells, location and type of surface structures). This commenter also stated that consideration of the impact of these "man induced activities and conditions" should be an integral part of any fracture program and of any analysis of CBM fracturing impact. This commenter stated that the fracturing process and fluids alone may not cause "harm" within the study's parameters, but when coupled with the existing "man induced conditions" could cause "considerable damage and risk."

EPA Response: As discussed in Chapter 3 of the report, operators use a number of techniques to estimate fracture dimensions to design fracture stimulation treatments. Operators have a financial incentive to keep the hydraulically induced fracture generally within the target coal zone, so that expenditures on hydraulic horsepower, fracturing fluids, and proppants are minimized. For precise and statistically reliable measurements, however, fracture height and length can be measured (as opposed to modeled) accurately by microseismic monitoring. Tiltmeter measurements can also provide fracture height and length measurements somewhat accurately. The results of hydraulic fracturing "after the process" have also been investigated in the mined-through studies by the U.S. Bureau of Mines and others. These studies provide important, directly-measured characteristics of hydraulic fracturing in coal seams and surrounding strata. In addition, paint tracer studies conducted as part of mined-through studies can provide lower bound estimates on the extent of fluid movement.

During its analysis of the threat of CBM fracturing practices on USDWs, EPA considered the impact of human activities (such as improperly sealed or abandoned wells). Chapter 6 of the report summarizes citizen complaints and resulting investigations by state agencies into possible impacts of hydraulic fracturing on drinking water wells and surface waters. In some cases, improperly sealed gas wells have been remediated, resulting in decreased concentrations of methane in drinking water wells.

B. Literature Used for the Study

Summary of Comments: Some commenters indicated that the literature used for the study was outdated. Another commenter questioned whether the search terms that the Agency used to find references for the report would locate "health-related" literature. This commenter also questioned whether the acronym "USDW" and/or "underground sources of drinking water" was used as a search term. Another commenter stated that the report was "simply a compilation of existing data, with no new information, references, or conclusions."

EPA Response: The search terms used by the Agency did not include health-related terms because the study's goals did not include conducting a human-health risk assessment or conducting a new investigation into the toxicity of any of the components of hydraulic fracturing fluids.

As stated in the study design (66 FR 39396)[2], EPA focused the study on a review of existing data. EPA's literature search included publications and documents that were publically available as of December 2000/January 2001. EPA reviewed over 200 peer-reviewed publications. Much of the appropriate literature comes from the mid-1990s when funding was available for this kind of research. EPA also reviewed additional studies recommended by commenters and the peer review panelists, and incorporated information from these documents into the study, when appropriate. Further, EPA obtained information for the study through interviews with approximately 50 employees from industry and state or local government agencies, and communication with approximately 40 citizens and groups who are concerned that CBM production affected their drinking water wells.

C. Basins Included in the Study

Summary of Comments: One commenter questioned why EPA's report only included 11 basins. This commenter indicated that there are 16 separate basins considered to have CBM resources in the lower 48 states. Further, the commenter stated that the Illinois Basin, which was not discussed in the study, is a major coal-bearing region in the central Midwest.

EPA Response: EPA's literature search did not find any CBM activity or hydraulic fracturing in the Illinois Basin. Other basins which have little or no current CBM production activity (e.g., Alaska) were also omitted from the study.

D. Citizen Complaints/Instances of Water Well Contamination

Summary of Comments: Many commenters stated that EPA and state agencies have not done an adequate job of investigating citizen complaints related to contamination of water wells near hydraulically fractured CBM wells. Some commenters also stated that the Agency disregarded these complaints by concluding in its draft report that hydraulic fracturing of CBM wells poses a low risk. Some commenters also believed that the volume of complaints was enough to warrant the need for the Agency to continue its study. One commenter criticized the Agency for only having a 30-day collection period associated with the July 30, 2001 *Federal Register* notice in which the Agency requested information on groundwater contamination incidents that could be due to hydraulic fracturing of CBM wells. This commenter added that EPA's outreach efforts were unlikely to have reached the general public, and also recommended that EPA set up hotlines and make resources available to "allow immediate, comprehensive investigations of citizen complaints related to hydraulic fracturing impacts on USDWs."

Conversely, others commenters indicated that based on the volume of hydraulic fracturing activities, that if the threat to public health from hydraulic fracturing of CBM wells were significant, confirmed instances of water well contamination would exist. Some of these

---

[2] US Environmental Protection Agency. 2001. Underground Injection Control; Request for Information of Ground Water Contamination Incidents Believed To Be Due to Hydraulic Fracturing of Coalbed Methane Wells. *Federal Register*. Vol. 66, No. 146. p. 39396, July 30, 2001.

commenters indicated that EPA's report should acknowledge the 1998 study conducted by the Ground Water Protection Council (GWPC), "Survey Results On Inventory and Extent of Hydraulic Fracturing in Coalbed Methane Wells in the Producing States," GWPC (December 15, 1998) because this survey of state oil and gas regulators provides further support for EPA's study conclusions.

EPA Response: The response of state agencies and EPA to citizen complaints are documented in Chapter 6. EPA has responded to complaints, particularly at the Regional level. For instance, in the Powder River Basin, located in Wyoming and Montana, citizen complaints dealt primarily with water quantity issues, which were beyond the scope of this study. EPA Region 8 is participating in a study that addresses the environmental effects of all aspects of CBM development and not just hydraulic fracturing. In response to citizen complaints, the Alabama Department of Environmental Management and EPA Region 4 also conducted independent sampling on wells in the Black Warrior Basin. Water analyses indicated that the wells had not been contaminated as a result of the hydraulic fracturing activities.

In some regions responses to citizen complaints are made primarily at the state level. For example, the Colorado Department of Health and the Colorado Oil and Gas Conservation Commission (COGCC) responds to many complaints. In Colorado, the primary response of the COGCC to citizen complaints has been the remediation of old, improperly sealed gas wells. The remediation of such wells has reduced methane concentrations in approximately 27 percent of the water wells sampled. Reduction of methane concentrations in many of the additional wells is expected over time due to the COGCC's efforts.

Regarding public outreach efforts need improvement, EPA has made considerable efforts to ensure its outreach and communications reach the general public. In addition to making the August 2002 draft available for public comments, EPA's outreach steps included:

- Publishing *Federal Register* notices (EPA's primary mechanism for communicating with the public):
    - requesting comment on how an EPA study should be structured (65 FR 45774)[3];
    - requesting information on any impacts to groundwater believed to be associated with hydraulic fracturing (66 FR 39396) (see footnote 2) including a mailing to over 200 county agencies making them aware of the *Federal Register* notice; and
    - requesting comments on the August 2002 draft of the study (67 FR 55249) (see footnote 1).

- Holding a public meeting on August 24, 2000, to obtain additional stakeholder input on the study. Several of these commenters recommended that EPA's study include accounts of personal experiences with regard to CBM impacts on drinking water wells. These experiences are discussed in Chapter 6.

[3] US Environmental Protection Agency. 2000. Underground Injection Control (UIC) Program; Proposed Coal Bed Methane (CBM) Study Design. *Federal Register*. Vol. 65, No. 143. p. 45774, July 25, 2000.

- Providing periodic updates for stakeholders, including citizens groups, in the form of written communication; and

- Maintaining a Web site where stakeholders can view the project documents; get updates on the progress of the project (including announcements of the release of *Federal Register* notices); and provide information to EPA.

Regarding the comment that EPA only provided 30 days for the public to provide information on CBM-related groundwater contamination incidents following the July 30, 2001 *Federal Register* notice, note that the Agency has considered all complaints received from the public, regardless of the time at which EPA received them. In addition, EPA's Web site www.epa.gov/safewater/uic/cbmstudy.html has a link to a form that allows people to submit information on the potential effects of hydraulic fracturing.

In response to the commenter's suggestion regarding hotlines, EPA has its Safe Drinking Water Hotline, which callers within the United States may reach at (800) 426-4791. Citizens are welcome to contact EPA or the states regarding these issues.

Regarding the comment about the volume of CBM activities and lack of confirmed instances of water well contamination, during its review, EPA found no confirmed cases that are linked to fracturing fluid injection into CBM wells or subsequent underground movement of fracturing fluids. Although thousands of CBM wells are fractured annually, EPA did not find confirmed evidence that drinking water wells have been contaminated by hydraulic fracturing fluid injection into CBM wells. EPA has included language to that effect in its final report, "Evaluation of Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reservoirs", June 2004, EPA document number: EPA 816-R-04-003 (hereafter referred to as final report).

E. Peer Review Panel

Summary of Comments: Many commenters questioned the composition of EPA's peer review panel, who reviewed the initial draft report. These commenters stated that this panel was heavily biased toward industry that has a stake in the outcome of the study. These commenters recommended that EPA convene a panel that is free of conflict of interest. Some recommended using members of the NAS as panelists.

One commenter indicated that he could not ascertain the composition of the panel although Appendix B of the report is supposed to contain a table with the list of the peer review panel. Another commenter stated that EPA made it very difficult for the public to obtain a copy of the peer review report, and that these comments were not attached in an appendix as originally promised.

EPA Response: EPA has a formal Agency Peer Review Policy that establishes the criteria and requirements for independent evaluation of scientific and technical studies and documents. Consistent with that policy, the Agency established a seven-member technical expert peer review panel, who performed a technical review of the study. Panel members were selected by identifying individuals with scientific or technical expertise in hydraulic fracturing through reviewing peer-reviewed publications in scientific journals and through communications with professional societies, trade and business associations, state organizations, and other federal agencies. EPA considered over 20 candidates before selecting 7 individuals based on their experience in the fields of hydraulic fracturing, rock mechanics, and/or natural gas production, and for their varying perspectives (industry, state government, academia, and a national laboratory). The charge to this committee was to review the report to determine if: 1) the report is complete, thorough, and accurate; and 2) the scientific/technical studies reviewed are applied in a sound, unbiased manner.

EPA posted the list of these reviewers and their qualifications on its Web site at www.epa.gov/safewater/uic/cbmstudy.html. EPA inadvertently omitted the table that identifies the peer reviewers in Appendix B of the draft report. This table is included in the final report.

III. FRACTURE FLUIDS

A. Components of Fracturing Fluids

1. Health Effects

Summary of Comments: Many commenters were concerned about the amount and health effects of certain chemicals used in hydraulic fracturing fluids and cited these concerns as reasons to continue the study. Some argued that very small quantities of toxic chemicals, such as benzene or methyl tert butyl ether (MTBE), could contaminate millions of gallons of groundwater.

Other commenters were concerned about the way in which the constituents of fracturing fluids and their potential health effects were presented in the draft report. For example, one commenter wanted the report to clearly convey the following: a wide variety of fracturing fluids exist, the health effects identified in the report apply to only some of the constituents that may or may not be present in the fracturing fluid, the health effects are associated with the product in its "pure form," and all the fluids additives are greatly diluted during fracturing operations.

EPA Response: As discussed in section II.A.2, EPA has recently entered into agreements with three major service companies to voluntarily eliminate diesel fuel from hydraulic fracturing fluids injected directly into USDWs for CBM production. Compounds such as benzene are components of diesel. These agreements will significantly reduce the use of diesel fuel in hydraulic fracturing fluids that are injected directly into USDWs for CBM production.

Chapter 4 of the final report provides a general description of the fate and transport processes which would minimize potential exposure to chemicals used in hydraulic fracturing fluids. Based on a 1991 fracturing fluid recovery study conducted in coal by Palmer et al., as much as 68 to 82 percent of the fracturing fluids may be removed when the methane is extracted.[4] This study is discussed in Chapter 3 of the report. As detailed in Chapter 4 of the report, the

[4] Palmer, I.D., Fryar, R.T., Tumino, K.A., and Puri, R. 1991. Comparison between gel-fracture and water-fracture stimulations in the Black Warrior basin; Proceedings 1991 Coalbed Methane Symposium, University of Alabama (Tuscaloosa), pp. 233-242).

unrecovered fluids will undergo processes that may limit their availability, concentration, and movement. These fluids may be significantly diluted and dispersed as they are transported through the subsurface. They may also interact chemically or physically with geologic material which may retard their movement and further disperse their concentrations.

EPA identified fluids and fluid additives commonly used in hydraulic fracturing through literature searches, reviews of relevant material safety data sheets (MSDSs) provided by service companies, and discussions with field engineers, service company chemists, and state and federal employees. The draft and final reports provide a discussion of the wide variety of hydraulic fracturing fluids that may be used. Table 4-1 of the report lists components that may be contained in fracturing fluids based on MSDSs. The final report emphasizes that not all fracturing fluid constituents, identified in Table 4-1 of this report, may be present in fracturing fluids, that the potential human health effects presented in the table apply to these compounds in their pure form, and that these compounds are significantly diluted prior to use.

An environmental impact statement (EIS) prepared by the BLM also identified MTBE as a compound that may be found in fracturing fluid (U.S. Department of the Interior, CO State BLM, 1998).[5] However, EPA was unable to find any indications in the literature, on MSDSs, or in interviews with service companies that MTBE is used in fracturing fluids to stimulate CBM wells.

2. Diesel Fuel

Summary of Comments: Several commenters supported EPA's recommendation that the industry use "water-based" alternatives in lieu of hazardous constituents such as diesel fuel. Some argued that EPA should make this a requirement and not a recommendation. Some of these commenters pointed to EPA's recommendation to "remove any threat whatsoever" from hydraulic fracturing fluid as a contradiction to the study's conclusions and as a reason to continue the study.

Conversely, several commenters indicated that there are valid reasons for using certain chemicals to enhance CBM production and that in choosing alternatives, the CBM well operators must take into account the specific geologic conditions of the site. These commenters recommended that EPA "encourage flexibility" with respect to the production of methane. One of these commenters noted that the draft report suggests that water-based alternatives are: currently available, feasible, and acceptable substitutes for diesel-based gels. This commenter indicated that the report findings should recognize that more research is needed on these potential alternatives. This commenter added that not all of the potential alternatives to the use of diesel may be water-based, citing polymer-based alternatives as one possibility. This commenter recommended that the term "water-based alternatives" be changed to read "non-diesel-based alternatives."

---

[5] U.S. Department of the Interior, Bureau of Land Management, Colorado State Office. 1998. Glenwood Spring Resource Area: Oil & Gas Leasing Development, Draft Supplemental Environmental Impact Statement, June 1998.

One commenter indicated that in the State of Alabama, diesel is not used nor is it approved for hydraulic fracturing. The commenter added that service companies in his state primarily use a linear gel composed of guar gum, a surfactant, and silica.

EPA Response: The discussion of potential alternatives to the use of diesel is not included in the final report because it is outside the scope of the study. Instead, the report highlights the MOA with three major service companies to voluntarily eliminate the use of diesel fuel in hydraulic fracturing fluids injected directly into USDWs for the purpose of CBM production and if necessary, select replacements that will not cause hydraulic fracturing fluids to endanger USDWs (see the response to comment in section II.A.2).

Regarding the comment on the use of diesel in the State of Alabama, Table A2-1 in Attachment 2 of the draft and final report indicates that diesel is not used in that state.

3. MTBE

Summary of Comments: Several commenters were concerned about the use of MTBE in fracturing fluids. Many of them included the following statement in their comments: "only 28 tablespoons of MTBE could contaminate millions of gallons of groundwater."

One commenter indicated that the report contains several inconsistent statements regarding MTBE as a component of fracturing fluids. This commenter noted that in Chapter 4 of the draft report, EPA states that, based on its literature reviews and interviews with service companies, the Agency did not find any evidence that MTBE is used in fracturing fluids. This commenter also indicated that later in the same chapter, EPA states that "some gelling agents can contain hazardous substances including . . . [MTBE.]," and cites as its source a Supplemental EIS issued by BLM. This commenter provided arguments why he believed that the supplemental EIS was in error in listing MTBE as a potential component in fracturing fluids. This commenter further recommended that EPA should not have used this EIS as a source for identifying constituents in fracturing fluids or at a minimum, should have indicated the shortcomings associated with using this type of document to determine the components of fracturing fluids. This commenter provided a detailed discussion of some of the problems with using this particular EIS.

EPA Response: As stated in the response to comment in section III.A.1, an EIS prepared by the Colorado State BLM (1998) identified MTBE as a compound that may be found in fracturing fluid. EPA found no information in the literature, MSDSs, or through interviews with service companies indicating that MTBE is used in fracturing fluids to stimulate CBM wells. MTBE is not used during the manufacture of diesel fuel. It is generally only added to gasoline. However, in an effort to be fully inclusive of all the Agency's literature search findings, EPA included the information found in the EIS and noted that EPA was not able to confirm MTBE use in fracturing fluids.

B. Comparison of Concentrations of Hydraulic Fracturing Fluid Components to MCLs

Summary of Comments: A few commenters questioned the appropriateness of EPA's use of MCLs to compare the projected concentrations of fracturing fluids that may be injected into

USDWs. The commenters argued that MCLs apply to "treated water" and that the water associated with the formations in which hydraulic fracturing occurs would not be suitable for drinking water without first being treated.

EPA Response: Under the mandate of SDWA, EPA establishes MCLs as enforceable maximum permissible levels for contaminants in drinking water, to ensure the safety of public drinking water supplies. Because the concern about contamination relates to USDWs, which are actual or future supplies of drinking water for human consumption, MCLs are used in this study as standard reference points to compare calculated or anticipated levels of contaminants in hydraulic fracturing fluids and in the subsurface. MCLs provide a context for discussions regarding the concentrations of individual contaminants.

C. Concentrations of Constituents in Fracturing Fluids/Fluid Recovery Rates

1. Estimates of Concentrations of Constituents in Fracturing Fluids

Summary of Comments: EPA received several comments on its estimates of the concentrations of the constituents of concern in fracturing fluids that may be present at the point-of-injection and at the edge of the fracture zone. Many commenters were alarmed about the estimated concentrations of some of these constituents such as benzene because they were above the MCL. Further, some were concerned that EPA had revised its estimates since publication of the report. Conversely, other commenters indicated that EPA had overstated these concentrations. Each of these comments is discussed in more detail below.

One commenter indicated that EPA's estimates for the constituents of concern at the edge of the fracture zone, which assume a dilution factor of 30, still exceed drinking water standards for benzene, aromatics, 1-methylnapthalene, and methanol. This commenter added that EPA estimated high concentrations for the estimated point-of-injection for some chemicals for which drinking water standards have not yet been developed. This commenter acknowledged that these concentrations will be reduced as they mix with groundwater; however, he stated that very small amounts of some chemicals like benzene and MTBE can contaminate millions of liters of groundwater. Further, this commenter noted that most CBM wells are hydraulically fractured more than once, and therefore, "the groundwater in which it resides," will receive multiple doses of the fracturing fluids chemicals. The commenter stated a figure from the report that between 50,000 and 350,000 gallons of fracturing fluids are typically used in coalbed fracture treatments. Another commenter indicated that the report does not recognize that some of the constituents in fracturing fluids may affect human health at very low concentrations. This commenter added that with the potentially thousands of CBM wells being developed, the problem is magnified.

Several commenters claimed that EPA revised its calculations after the draft report was released. Some of these commenters indicated that EPA changed its scientific and policy conclusions under pressure from industry. One commenter provided detailed comments on the revised calculations. This commenter argued that EPA changed some of the parameters that were used in the draft report (such as length and height of a fracture, volume of injected hydraulic fracturing fluids, percentage of unrecovered hydraulic fracturing fluids) and they resulted in smaller estimated concentrations, including a revised estimate for benzene that does not exceed the MCL. This commenter questioned the basis for EPA's revising its estimates.

Other commenters were concerned that EPA did not adequately explain the assumptions used to generate its calculations. For example, one commenter indicated that it was unclear whether EPA based its estimates at the edge of the fracture zone on a specific fracture length or fracture radius. Some commenters also stated that EPA did not consider factors that would influence the availability and decrease the concentrations of the constituents at the edge of the fracture zone. These factors included: the recovery of the majority of the fracturing fluid, the relatively low permeability of coalbed formations will limit the movement of groundwater away from the wellbore, the coal will adsorb some of the constituents onto its surfaces, acids react with certain rock constituents and become spent, and some fracturing fluid constituents such as benzene will biodegrade. Some commenters also recommended that EPA's report should further emphasize that any constituents of concern in fracturing fluids are present only in very minimal amounts.

One commenter indicated that EPA had "significantly mischaracterized the nature of its estimates at both the point-of-injection and the edge of the fracture zone" because EPA had used a "worst case" scenario for estimating these concentrations. The commenter stated that, although the report indicates that EPA used mid-range values, the Agency used the maximum amount of diesel fuel that service companies reported to EPA instead of an average value. This commenter also explained why he believed that some of the point-of-injection concentrations that were presented in Table 4-2 of the draft report, such as that estimated for methanol, appeared to be inconsistent with the discussion in the text. Further, this commenter also recommended that EPA include its newer calculations in the report.

<u>EPA Response:</u> The values presented in the draft report are oversimplified estimates based on dilution alone and are not accurate enough to predict that a 30 times decrease is above or below the MCL. In the final report, EPA has revised its procedure for assessing the potential effect of fracturing fluid constituents on USDWs from that presented in the August 2002 draft as follows:

- The draft report included point-of-injection calculations for all constituents that may be contained in fracturing fluids. The final report focuses only on those constituents for which MCLs are established (i.e., BTEX compounds).

- EPA has revised the fraction of BTEX compounds in diesel used to estimate the point-of-injection concentrations from a single value to a documented broader range of values for the fraction of BTEX in diesel fuel. For example, the fraction of benzene in diesel was revised from $0.00006 g_{benzene}/g_{diesel}$ to a range with a minimum value of $0.000026\ g_{benzene}/g_{diesel}$ and a maximum value of $0.001\ g_{benzene}/g_{diesel}$. If the maximum value for benzene in diesel is used to estimate the concentration of benzene at the point-of-injection, the resulting estimate is 17 times higher than that presented in the draft report.

- In the final report, EPA used more current values for two of the parameters used to estimate the point-of-injection concentrations of BTEX compounds. Specifically, the estimates in this report use a density of the diesel fuel-gel mixture of 0.87 g/mL compared to 0.84 g/mL in the draft report, and a fraction of diesel fuel in gel of 0.60 g_{diesel}/g_{gel} compared to 0.52 g_{diesel}/g_{gel} in the draft report. The use of these more current values does not affect the order of magnitude of the revised point-of-injection calculations.

- The August 2002 draft report included estimates of the concentration of benzene at an idealized, hypothetical edge of the fracture zone located 100 feet from the point-of-injection. Based on new information and stakeholder input, EPA concluded that the edge of fracture zone calculation is not an appropriate model for reasons including:

  - Mined-through studies reviewed by EPA indicated that hydraulic fracturing injection fluids had traveled several hundred feet beyond the point-of-injection.

  - The assumption of well-mixed concentrations within the idealized fracture zone is insufficient. One mined-through study indicated an observed concentration of gel in a fracture that was 15 times the injected concentration, with gel found to be hanging in stringy clumps in many fractures. The variability in gel distribution in hydraulic fractures indicates that the gel constituents are unlikely to be well mixed in groundwater.

  - Based on more extensive review of the literature, the width of a typical fracture was estimated to be much thinner than that used in the draft report (0.1 inch versus 2 inches). The impact of the reduced width of a typical fracture is that the calculated volume of fluid that can fit within a fracture is less. After an initial volume calculation using the new width, EPA found that the volume of the space within the fracture area may not hold the volume of fluid pumped into the ground during a typical fracturing event. Therefore, EPA assumes that a greater volume of fracturing fluid must "leakoff" to intersecting smaller fractures than what was assumed in the draft report, or that fluid may move beyond the idealized, hypothetical "edge of fracture zone." This assumption is supported by field observations in mined-through studies, which indicate that fracturing fluids often take a stair-step transport path through the natural fracture system.

- In the draft report, EPA approximated the edge of fracture zone concentrations considering only dilution. Based on new information and stakeholder input on the draft report, EPA does not provide estimates of concentrations beyond the point-of-injection in the final report. Developing such concentration values with the precision required to compare them to MCLs would require the collection of significant amounts of site-specific data. This data in turn would be used to perform a formal risk assessment, considering numerous fate and transport scenarios. These activities are beyond the scope of Phase I of this study.

- In Chapter 4 of the final report, EPA provides a qualitative evaluation of the fate and transport of unrecovered fracturing fluids on residual concentrations of BTEX in groundwater. EPA describes in Chapter 4 how subsurface flow would significantly disperse and dilute BTEX compounds in groundwater, minimizing potential exposure to these constituents. BTEX compounds may also interact chemically or physically with geologic material which may retard their movement and further disperse their concentrations.

See also EPA's response to comment in section III.A.1 of this document.

No data or conclusions in the final report or in any previous draft were altered to accommodate any industry parties, states, environmental groups, or others. This study was a thorough and transparent data collection and technical evaluation exercise. The report and its conclusions were prepared by career technical staff at EPA.

The study was designed based upon a transparent process including public comment on the conceptual study design which included comments from state drinking water and oil and gas agencies, industry, environmental groups, and private citizens. EPA consulted with experts in the United States Geological Survey and the Department of Energy. Consistent with principles of good science, a draft of the study was subjected to a technical peer review from hydraulic fracturing experts. The conclusions of the study were not submitted for review to any private sector parties.

2. Fluid Recovery Rates

Summary of Comments: Many commenters were concerned that a large percentage of fracturing fluid remains behind and is available to potentially migrate into USDWs, citing these concerns as a reason to continue EPA's study. Some commenters indicated that EPA was inconsistent in the recovery percentages that the Agency cited in the report. Two commenters noted that the recovery experiment that is referenced in the report only ran for 19 days and that additional fracturing fluids may be recovered after that time. Another commenter stated that one fluid recovery rate (i.e., 61 percent) should not be "indiscriminately applied to over 14,000 CBM wells."

Some commenters cited a study by three Amoco scientists in which the study found "that a significant volume of fracturing fluids is not withdrawn." These commenters explained that the scientists found that the gelling agents used in the fracturing fluids remained in the coal samples although they had been flushed with water and strong acids. The commenters argued that, since these chemicals are not fully recovered, they could "serve as continuous sources of groundwater contamination."

EPA Response: Section III.A.1 provides a discussion of processes that can limit the availability, concentration, and movement through groundwater of unrecovered fracturing fluids. EPA has ensured that the recovery percentages cited in the report are both internally consistent and consistent with the literature reviewed. Three studies on recovery rates of hydraulic fracturing fluids were reviewed in Chapter 3 of the report. Only one of these studies, Palmer et al., 1991, involved hydraulic fracturing of coalbeds (refer to footnote 1 for the study reference). Thus, the Palmer study was considered the most relevant of the three studies for the purposes of this report. The final report clarifies that the recovery rate of 61 percent was based on a 19-day flowback period. Palmer et al., 1991, predicted recovery rates as high as 82 percent over a longer recovery period.

Regarding the study by three Amoco scientists, EPA contacted one of the commenters to obtain a copy of the study to review.[6] The commenter was unable to provide the study and EPA's additional library research efforts were also unsuccessful at obtaining this study.

3. Amount of Fracturing Fluids

Summary of Comments: Some commenters were concerned about the volume of fracturing fluids used in a "typical fracturing job" and cited the following statement from the report, "Coalbed fracture treatments typically use 50,000 to 350,000 gallons of various fracturing fluids, and from 75,000 to 320,000 pounds of sand as proppant... ." Others questioned the accuracy of the quantities of fracturing fluid and proppant cited in the report, stating that these figures were more consistent with a massive hydraulic fracture. Another commenter stated that the unique properties that make many coal formations effective receptacles for methane also allow them to hold large quantities of water. This commenter stated that injection of hydraulic fracturing fluids into USDWs risks permanent contamination of these USDWs because fracturing fluids often contain large amounts of toxic chemicals.

EPA Response: EPA has clarified in the final report that more typical injection volume may be closer to a maximum of 150,000 gal/well, and a median value of 57,500 gal/well. These values are based on average injection volume data provided by Halliburton for six CBM locations.

Refer to section III.A.1 regarding factors that would influence the availability, concentration, and movement of fracturing fluids and their constituents.

4. Movement of Fracturing Fluids

Summary of Comments: Some commenters stated that unrecovered fracturing fluids will flow toward the well because of the pressure gradients. Others noted that this was only true while the well was in production. These commenters argued that once pumping stops, the aquifer will attempt to resume a normal flow pattern and the remaining hydraulic fracturing fluids will move freely within the coalbed formation.

EPA Response: Chapter 4 of the final report has been expanded to more clearly explain:

- hydraulic gradients that occur during injection versus those during fluid recovery;
- the significance of the capture zone of the production well on fracturing fluid recovery (i.e., the portion of the aquifer that contributes water to the well); and
- the movement of fracturing fluids (and what influences their movement) both inside and outside the capture zone.

---

IV. FRACTURE BEHAVIOR AND PRACTICES

A. Fracture Growth

Summary of Comments: EPA received many comments on the statements in its report that, "Vertical fracture heights in coalbeds have been measured in excess of 500 feet and lengths can reportedly reach up to 1,500 feet." Some of these commenters stated that these distances indicate the potential for communication with and contamination of USDWs. Other commenters believed that these measurements were incorrect. Some commenters also discussed whether confining layers act as barriers to vertical fracture growth.

One commenter described in detail why he believed that confining layers above and below the hydraulically fractured coal formations would also be fractured and permeated by fluids. This commenter noted that the fracture heights cited in the report exceed the thickness of the thickest coal formations identified in the report. In addition, this commenter noted that the report indicates that some of the coal seams are bounded by sandstone and conglomerate (which have different lithological properties, and therefore different fracturing properties, than shale). Further, he indicated that the report supports his position that the risk for migration of fracturing fluids into adjacent USDWs is significant because it indicates that "Stimulation fluids in coal penetrate from 50 to 100 feet away from the fracture and into the surrounding formation. In these and other cases, when stimulation ceases and production resumes, these chemicals may not be completely recovered and pumped back to the CBM well, and, if mobile, may be available to migrate through an aquifer." This commenter also noted that the report shows that many of the coal formations are located in mountainous regions such as the Rocky Mountains and Appalachian Mountains. The commenter stated that the rock formations in these regions, including the coal formations, have been subjected to intense orogenic and tectonic stress resulting in regional, systematic fractures and faults. The commenter argued that it is likely that coal formations, and other rocks above and below them, are characterized by cracks and fractures, and that because of these deformation features, rates of groundwater transport tend to be higher.

One commenter indicated that the report's description of how fractures travel is incorrect (i.e., they travel horizontally vs. vertically). This commenter added that there is some vertical expansion as the fracture moves horizontally but that this is not the primary direction of fracturing. This commenter stated that their state geologists estimate vertical fracture heights at 50 to 60 feet. Another commenter provided detailed comments on the studies that were conducted on fracture height growths. This commenter indicated that he had been involved in numerous fracture experiments (in all types of reservoirs) where the fracture height has actually been measured (using microseismic or downhole tiltmeter), as well as in mineback tests where hydraulic fractures have been excavated. Based on his experience, the fracture height has always been less than or equal to the height that would be predicted by just using stresses in the various layers (which the commenter indicated was the only factor considered in all the references used in the draft report). The commenter reported that in some cases, the differences were factors of two or three. This commenter also provided detail on factors that influence fracture height growth, such as horizontal stress in the coal, the horizontal stress in the surrounding layers, the characteristics of the layering, and the type of hydraulic fracturing fluids being pumped.

Another commenter noted that the discussion on fracture dimensions in the report was based on literature from 1993 and earlier, but acknowledged that there were "virtually no post-1993 published reports on hydraulic fracturing." The commenter recommended that EPA contact operators, service companies, and state regulatory agencies for current practices and models. Further, this commenter noted that newer data based on more sophisticated FracPro models are available for many basins. He added that, in his state, model results indicate that fracture height is "generally less than 100 feet, whereas fracture half length is typically between 150 and 700 feet." This commenter also noted that the report should state that the fracture heights have been "modeled" not "measured" because vertical fracture heights have never been fully measured in the field.

EPA Response: EPA has revised Chapter 3 to provide clarification on the characterization of fracturing behavior during hydraulic stimulations. The statement that fractures have been "measured in excess of 500 feet and lengths can reach up to 1,500 feet" has been removed because it refers to modeled estimates, rather than direct measurements. Instead, the results of 22 mined-through studies have been summarized, because they provide direct measurements of the dimensions of hydraulic fractures, as well as lower bounds on the extent of fracturing fluid movement. Chapter 3 has also been revised to better distinguish between fracture characterizations based on modeling vs. those that are directly measured.

In addition, EPA has revised Chapter 3 to clarify the issue of hydraulic barriers and barriers to fracture growth above coalbeds. EPA agrees with the commenter that when shales overlying targeted coals are extensively fractured, they may not act as barriers to hydraulic fracture growth or as hydraulic barriers. On the other hand, thick, relatively unfractured shale may present a barrier to upward fracture growth because of the stress contrast between the coalbed and the overlying shale. Deep vertical fractures can propagate vertically to shallower depths and develop a horizontal component. In the formation of these "T-fractures," the fracture tip may fill with coal fines or intercept a zone of stress contrast, causing the fracture to turn and develop horizontally, sometimes at the contact of the coalbed and an overlying formation.

B. Multiple Fractures

Summary of Comments: Some commenters raised concern over the statement in the draft report that "each well, over its lifetime is fractured several times" and urged EPA to continue to Phase II of the study. Others questioned the accuracy of EPA's statement that wells are fractured multiple times. One commenter indicated that in their state, most wells have not been re-fractured multiple times but that instead, two to four coal groups were generally fractured in each well.

EPA Response: EPA has revised the statements regarding multiple stimulations in Chapter 3. In the draft report EPA stated that "many coalbeds are refractured at sometime after the initial treatment." The text has been revised to indicate that the literature on refracturing that was reviewed pertains only to the Black Warrior Basin. EPA's extensive literature review did not find any information indicating that wells are fractured multiple times in any basin other than the Black Warrior Basin.

C. Relationship of Drinking Water Wells to Hydraulic Fracturing Activities

Summary of Comments: Some commenters were concerned about the potential for fracturing fluids to contaminate USDWs due to the high occurrence of coal reservoirs within USDWs. One commenter cited a statement from the report "if coalbeds are located within USDWs, then any fracturing fluids injected into coalbeds have the potential to contaminate the USDW." The commenter added that the report indicates that as much as 91 percent of U.S. coal reservoirs may be located within USDWs.

Two commenters indicated that hydraulic fracturing activities take place at depths far below groundwater sources used as drinking water sources. One of these commenters added that his company's records show that it conducts hydraulic fracturing at shallow depths, (i.e., less than 300 feet below ground surface), in less than one percent of all hydraulic fracturing jobs. This commenter provided this as one reason that he believed that hydraulic fracturing is unlikely to pose a threat to drinking water.

EPA Response: EPA found that 10 of the 11 coal basins, included in the study, may lie, at least in part, within USDWs. Given the concerns associated with the use of diesel fuel and the introduction of BTEX constituents into USDWs, EPA negotiated an MOA with three major hydraulic fracturing service companies for the voluntary elimination of diesel fuel in hydraulic fracturing fluids injected directly into USDWs for the purpose of CBM production. Nevertheless, even when fracturing fluids are injected directly into coalbeds located in USDWs, fracturing fluid components are likely to be significantly diluted and dispersed, as well as subject to other fate and transport processes (discussed in Chapter 4) which are likely to lower their concentrations or prevent their mobility underground. Also see the response to comment in section III.A.1.

D. Differences in State Geology

Summary of Comments: Several commenters indicated that the report did not adequately address the variability present in the different geologic formations that are subject to hydraulic fracturing, and therefore, did not address the possible impacts associated with that variability regarding regional groundwater flow and/or the occurrence and distribution of CBM resources, on assessing the potential threat of hydraulic fracturing on USDWs. One commenter indicated that to accurately represent the threats to USDWs, risk levels should be "differentiated based on modeling and actual data on similar geologic conditions."

EPA Response: EPA agrees that variability of geologic formations and regional groundwater flow are key to the assessment and understanding of the potential threat to USDWs posed by hydraulic fracturing. The study findings and conclusions are based on literature from each of the 11 major coal basins in the United States. In addition, the draft and final report contains separate attachments which discuss basin-specific geologic and hydrogeologic investigations related to each of the 11 basins. The discussions provided were intended to characterize regional coal basin methane production with respect to its effect on USDWs and to supplement the generalized information provided within the body of the report. EPA also agrees that if modeling risk levels, the variability of geologic conditions should be considered. However, such a modeling exercise is beyond the scope of the current study.

V. REGULATION OF HYDRAULIC FRACTURING PRACTICES

A. States' Authority

Summary of Comments: Several commenters recommended that EPA expand its discussion in the final report of the states' role in regulating hydraulic fracturing. Others suggested clarifying the language from the draft report regarding states' authority to regulate hydraulic fracturing. For example, one commenter indicated that EPA's statement, "States with primacy for their UIC program enforce and have the authority to place controls on any injection activities that may threaten USDW's" implies that state UIC Programs can or would regulate hydraulic fracturing. The commenter recommended that EPA add clarifying language that removes the implication that hydraulic fracturing is commonly regulated under UIC Programs.

One commenter stated that the report was inaccurate in its description of Virginia's authority to place restrictions on the depth at which hydraulic fracturing can occur. The commenter indicated that the "restrictions" are instead voluntary procedures. The commenter also clarified the purpose of these procedures.

EPA Response: EPA did not conduct a systematic review of state regulations of hydraulic fracturing and, therefore, has no basis for expanding its discussion of the state's role in the regulation of hydraulic fracturing. However, the Agency added clarifying language regarding the state's ability to regulate hydraulic fracturing. EPA also added clarifying wording to the report regarding Virginia's voluntary program.

B. Regulation of Hydraulic Fracturing under SDWA

Summary of Comments: Several commenters wanted EPA to regulate hydraulic fracturing of CBM wells under SDWA and did not believe that recommended measures such as using "water-based alternatives" instead of diesel were sufficient. One commenter stated that based on *Legal Environmental Assistance Foundation, Inc. v. U.S. E.P.A.*, 118 F.3d 1467, 1470 (11th Cir. 1997), EPA is to decide how to regulate hydraulic fracturing under SDWA, and not to determine whether "further investigation was necessary to evaluate any potential threats" before EPA acts. Another commenter was concerned whether EPA was using the presence of documented cases of "health harm from non-regulation" as the criterion for determining whether to regulate hydraulic fracturing injection activities under SDWA. This commenter argued that the purpose of the UIC Program is "to forestall and prevent such harm by isolating the injected fluids from aquifers that are or could be developed as USDWs"; and therefore, using proven harm as a regulatory threshold goes against the purpose and intent of the law.

Conversely, other commenters indicated that EPA should "recognize the need for industry to be allowed reasonable flexibility in the means that its uses to produce CBM." These commenters also indicated that under 42 U.S.C. § 300h(b)(2), Congress intended that EPA not impose restrictions through the UIC Program that interfere with or impede activities related to oil and gas development unless such restrictions are essential for preventing endangerment of drinking water sources. Another commenter specifically recommended that UIC permits not be required for hydraulic fracturing practices.

EPA Response: Based on the information collected and reviewed, EPA has determined that the injection of hydraulic fracturing fluids into CBM wells poses little or no threat to USDWs. Continued investigation under a Phase II study is not warranted at this time. The lack of confirmed incidents of drinking water well contamination due to hydraulic fracturing fluid injection from past hydraulic fracturing activities was one among many factors EPA considered. If threats to USDWs from hydraulic fracturing of CBM wells were significant, EPA would expect to have found confirmed instances of drinking water well contamination from the practice. Although thousands of CBM wells are fractured annually, EPA did not find confirmed evidence that drinking water wells have been contaminated by the injection of hydraulic fracturing fluids into CBM wells.

EPA's recent agreements with three major service companies, discussed in section II.A.2, will significantly reduce the use of diesel fuel in hydraulic fracturing fluids that are injected directly into USDWs for CBM production.

It is important to note that states with primary enforcement authority (primacy) for their UIC Programs implement and enforce their regulations, and have the authority under SDWA to place additional controls on any injection activities that may threaten USDWs. States may also have additional authorities by which they can regulate hydraulic fracturing. With the expected increase in CBM production, the Agency is committed to working with states to monitor this issue.

VI. LANGUAGE USED IN THE REPORT

A. Use of the Term "USDW"

Summary of Comments: Some commenters indicated that EPA used the term "USDW" too broadly. In particular, one commenter indicated that the report "carelessly utilizes the USDW term in the context of hydrocarbon bearing formations." This commenter added that these hydrocarbon-bearing aquifers subjected to hydraulic fracturing are unlikely to be used for drinking water, especially without treatment for two reasons: 1) the high total dissolved solids level of the waters in these formations; 2) the waters in these formations may be considered an "exempted aquifer" under SDWA because the aquifer is mineral, hydrocarbon, or geothermal energy producing, or can be demonstrated to be commercially producible. This commenter also stated that the inferences in the report, that some risks may be attributed to hydraulic fracturing, conflict with "the reality that such a formation would not be used for water supply without treatment, if it were ever to be used."

EPA Response: EPA disagrees that it has applied the term "USDW" too broadly in the report. SDWA mandates the protection of USDWs from injection activities – "if such injection may result in the presence in underground water which supplies or can reasonably be expected to supply any PWS of any contaminant, and if the presence of such contaminant may result in such system's not complying with any national primary drinking water regulation or may otherwise adversely affect the health of persons." The broad definition of a USDW by Congress was to ensure that future USDWs would be protected, even where those aquifers were not currently used as a drinking water source or could not be used without some form of water treatment such as desalination. It is also important to note that an exempted aquifer is a USDW, but is exempt from regulation.

B. Use of Scientific Terms

Summary of Comments: A few commenters provided corrections to some of the terminology used in the report. One commenter felt that there was a general misuse of geologic terminology in the report, and specifically indicated that the geologic terms "system," "formation," and "seams" should not have been used interchangeably. This commenter provided other specific clarifications or corrections to some of the discussions in the report (e.g., Section 3.1 regarding the depositional history of coal-bearing rocks in the United States).

EPA Response: EPA appreciates the careful review of the report by many of the commenters. EPA has revised some of the terminology used in the report and incorporated some of the clarifications suggested by the commenters.

C. Use of Qualifying Language

Summary of Comments: Both the commenters that supported EPA's conclusions and those who opposed it indicated that the tone of the language used throughout the report conflicted with EPA's conclusions. Commenters cited examples of this language that included the following:

- "Based on the information collected, the potential threats to USDWs posed by hydraulic fracturing ***appear to be low*** and do not justify additional study.";
- ..."the ***apparent risk*** to public health from hydraulic fracturing is not compelling enough to warrant expending resources on a phase II effort"; and
- "***the apparent threat*** to public health from hydraulic fracturing."

One of the commenters indicated that this language showed "a weak articulation of EPA's confidence in its own report." Many of the commenters who were opposed to EPA's findings, pointed to EPA's qualified statements as a reason to continue the study.

Another commenter, who supported EPA's findings, stated that the primary definition of the word, "apparent," is, "something that is clearly seen or understood, obvious, self-evident, glaring." This commenter, among others who supported the Agency's findings, recommended that EPA replace all uses of the word "apparent" when describing the threat posed to USDWs by hydraulic fracturing with words that more accurately describe the low likelihood of this threat.

EPA Response: In the final report, EPA has eliminated the use of the word "apparent" and "appears" to describe its study conclusions and has made the language more consistent with the report's results.

VII. CHAPTER-SPECIFIC COMMENTS

This summary of chapter-specific comments focuses mainly on those comments that have not been summarized within the issue-specific Sections II through VI of this document. Comments were received on almost every chapter of the document, ranging from minor editorial suggestions, to factual corrections. EPA appreciates the thorough comments that were submitted regarding the contents of the hydraulic fracturing report. The Agency has considered all comments, researched the accuracy of some comments (where necessary), and incorporated comments where appropriate.

A. Glossary

Summary of Comments: One commenter submitted recommended changes to the list of acronyms and abbreviations, and the glossary pertaining to "M"; "KCl"; "pad"; and the phrase, "wells that have been 'screened-out' cannot be used for gas production."

EPA Response: After reviewing and checking on the accuracy of the above comments, EPA incorporated changes to the glossary and list of acronyms, where appropriate.

B. Other Executive Summary Comments

Summary of Comments: EPA received many comments that were specific to the executive summary of the report, including recommendations for revising the text, tables, and figures. A few commenters suggested that the language regarding the findings and conclusions of the study needs to be clearer and stronger (e.g., qualifiers such as "appear to be low" and "persuasive evidence" weakens the conclusions). Another suggested that, in general, the executive summary and the main document need to point out that not all USDWs are currently being used nor will they ever be used as sources of drinking water. Some commenters felt that the executive summary was inappropriately long and provided suggestions for making the section shorter, including eliminating all tables from this section. Many commenters provided specific editorial comments.

A few commenters expressed concern regarding the "graphic language" in Table ES-2 *(Summary of MSDSs for Hydraulic Fracturing Fluid Additives)* used to describe the health effects of fracturing fluids, and noted that they felt it may be unnecessarily alarming, and potentially misleading to readers (i.e., it does not clarify that the health effects only pertain to some constituents that may or may not be present in the fracturing fluids). Commenters added that Table ES-2 suggests that linear gel delivery systems always contain diesel and does not indicate that fluid additives are greatly diluted. One commenter felt that the information provided in Table ES-4 *(Evidence in Support of Coal-USDW Co-Location in U.S. Coal Basins)* was too general, and believed that the information should just be presented in the more detailed sections from which it was summarized. Other commenters were concerned that the information provided in Table ES-5 *(Summary of Reported Incidents that Associate Water Quality/Quantity with Coalbed Methane (CBM) Activity)* could be misleading to the public.

One commenter felt that the executive summary figures in general were "confusing and misleading." Other commenters questioned the accuracy and clarity of Figure ES-2 *(Graphical Representation of the Hydraulic Fracturing Process in Coalbed Methane Wells)*, which depicts drinking water wells drawing down into coal seams. One commenter questioned the accuracy of the illustrations in Figures ES-3 *(Direct Fluid Injection into a USDW (Coal within USDW))* and ES-4 *(Fracture Creates Connection to USDW)* regarding the depth of the water wells and the direction of fluid migration (i.e., fracturing fluids are shown to be flowing away from the well bore toward the drinking water wells). The commenter pointed out that the descriptive text on page ES-10 conflicts with the depiction of fluid migration in Figure ES-4.

EPA Response: EPA has reviewed and considered all comments regarding the executive summary of the document. The Agency originally designed the executive summary to be a stand-alone document. Because many readers of such a document (such as Congress or the leaders of various stakeholder organizations) may have limited time to dedicate to the review of a large technical document, EPA included essential summary information, including tables and figures, in the executive summary. However, based on the comments received, EPA has pared down the executive summary by taking out most of the tables and summarizing key information from these tables in narrative form. EPA incorporated many of the specific suggestions related to the figures (e.g., decreasing the depth of drinking water wells), and in some instances, provided clarifying language to explain the figures.

C. Other Chapter 1 Comments (Introduction)

Summary of Comments: A few commenters provided comments regarding the Introduction to the hydraulic fracturing report. Comments included questions about the accuracy of the figures, and how they were depicted: groundwater flow; the relation between well depths and coal seams; and the point-of-injection for the fracturing fluids. One commenter objected to the statement that the study was "based on a high level of interest of stakeholders..." when it was the commenters' understanding that it was based only on a "handful" of complaints.

EPA Response: The statement that the study was "based on a high level of interest of stakeholders..." is an accurate statement but the term "stakeholders" was vague. To be more descriptive, Chapter 1 of the final report indicates that a reason for conducting the study was "concerns voiced by individuals who may be affected by coalbed methane development. . ." The Agency addressed each of the other comments by either incorporating suggested language or making relevant clarifications in the document language and figures.

D. Other Chapter 2 Comments (Methodology)

No substantive comments received on this chapter.

E. Other Chapter 3 Comments (Characteristics of CBM Production and HF Practices)

Summary of Comments: EPA received several comments regarding the information in Chapter 3. In particular, several commenters questioned the study's assumptions regarding recovery rates and fracture heights. A more detailed summary of the comments received on these topics can be found in sections III.C.2 and IV.A, respectively. One commenter had several specific questions regarding statements made in this chapter, including: the meaning of the term "conventional coal mines"; statements regarding the number of CBM wells in Alabama; the discussion of the origin of CBM; the statement that "coal has very little natural permeability"; contradictions between the discussion of fluids migration in this chapter compared to that shown in Figures ES-4 and 1-3; accuracy and clarity of statements regarding the rate of fluid recovery; and the statement that many CBM wells are re-fractured.

EPA Response: EPA appreciates the detailed comments that were submitted regarding Chapter 3 of the hydraulic fracturing report. The Agency made several editorial corrections and clarifications to this chapter based on these comments. A more detailed response regarding recovery rates, fracture heights, and re-fracturing of the same wells can be found in sections III.C.2, IV.A, and IV.B, respectively.

F. Other Chapter 4 Comments (HF Fluids)

Summary of Comments: Comments specific to Chapter 4 of the report included questions about the calculation of the constituents of concern at the point-of-injection, and other editorial comments and suggestions.

EPA Response: In response to comments received on Chapter 4, EPA has incorporated clarifying language regarding its calculations of BTEX compounds at the point-of-injection. Other editorial corrections and clarifications have also been incorporated. For a discussion of how EPA revised its procedure for assessing the potential effect of fracturing fluid constituents on USDWs from that presented in the draft report, refer to section III.C.1.

G. Other Chapter 5 Comments (Basin Descriptions)

Summary of Comments: Several comments were received regarding the basin descriptions, including updates from a few states on the numbers of wells in the applicable basins. One commenter suggested additional references that should be used to correct some of the statements regarding the Pottsville Formation. The other four commenters each provided specific editorial suggestions on one of the following four basins: the Central Appalachian Basin, the Northern Appalachian Basin, the Uinta Basin, and the Powder River Basin.

EPA Response: EPA has incorporated the updated well information provided by states. All other editorial comments were considered, and most were incorporated. Other basin-specific issues are discussed in section VIII of this document.

H. Other Chapter 6 Comments (Water Quality Incidents)

Summary of Comments: Several comments were received regarding the water quality incidents chapter of the report. Commenters made specific editorial suggestions, and provided clarifications about specific complaints, additional information about how their state investigates complaints, and information about state-specific hydraulic fracturing regulations. One commenter stated that the discussion of the Pottsville, Allegheny, Conemaugh, and Monongahela Groups were "oversimplified" and questioned the conflicting use of the terms "cyclothem" and "complex" when describing the depositional environments of the Allegheny Group.

A few commenters expressed concern that the descriptions of public complaints (including the information summarized in Table 6-2) are presented in the report as if the information was factual, without linking the complaints to actual findings following the state and EPA investigations. One commenter indicated that EPA does not present any data from state agencies, which suggests to the commenter that no real scientific studies were conducted. Commenters recommended that the complaints be immediately followed by a summary of the evaluation and resolution of the complaint. One recommendation was that, if kept in the report, the information be moved to an appendix.

Finally, some commenters felt that EPA was contradictory regarding the question of whether hydraulic fracturing of CBM wells threaten USDWs. For example, one commenter indicated that EPA had concluded in Chapter 6 that there is insufficient evidence to determine if there is a link between fracturing and USDW contamination. However, elsewhere in Chapter 6, EPA states that "water quality problems might be associated with some of the variety of production activities common to CBM extraction. These production activities include... methane migration through conduits created by drilling and fracturing practices..."

<u>EPA Response:</u> In response to stakeholder's comments on EPA's original study methodology, EPA compiled citizen complaints and reported incidences of CBM impacts on drinking water wells and included these accounts in Chapter 6 of the report. In the final report, EPA has clarified the rationale for including citizen complaints in its report.

The final report also clarifies that many of the reported impacts (such as impacts to water supply quantities and effects of discharge of groundwater extracted in the CBM production process) included in Chapter 6 are outside of the scope of SDWA and beyond the scope of the Phase I study. The goal of the Phase I study was to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into CBM wells, and to determine based on these findings if further study is warranted. EPA also incorporated information that was provided by states regarding incident reports, and state-specific regulations. Finally, the Agency took Table 6-2 out of the document because, as suggested by some commenters, summarizing citizen complaints in a tabular format oversimplified this information, and created a potential for misinterpretation. The information in Table 6-2 is presented in detail in the main body of Chapter 6.

See also EPA's response to comment in section II.D of this document regarding other issues pertaining to water contamination incidents and citizen complaints.

I. Other Chapter 7 Comments (Conclusions and Recommendations)

<u>Summary of Comments:</u> Most comments received regarding Chapter 7 of the report also relate back to prior report chapters. Several commenters had specific suggestions or questions regarding the conclusions and recommendations section of the report. Some of these commenters agreed with the conclusions of the study, but recommended that EPA put more emphasis on the conclusions, and include information about the findings of the study earlier in the document. Specifically, commenters suggested that, at the beginning of the document, EPA include a statement clarifying that: "EPA finds no evidence of harm from hydraulic fracturing

while investigating the reported incidents that spurred the study." These commenters felt that EPA's findings that Phase II of the study is unnecessary, and that little or no public health threat is posed by hydraulic fracturing should be more strongly stated in the conclusions of the report.

Note that commenter opinions regarding Chapter 7 of the report do not reflect the overall commenter perspectives regarding the outcome and conclusions of the study. Most of the commenters expressed opinions regarding the study's conclusions, but did not state them within the context of Chapter 7.

EPA Response: EPA has reviewed all commenter suggestions regarding Chapter 7, and incorporated the majority of these comments where appropriate. Other revisions to Chapter 7, which relate back to changes in previous chapters, have been made in order to ensure internal consistency within the document.

VIII. BASIN DESCRIPTIONS

This summary of basin-specific comments focuses mainly on those comments that have not been summarized within the issue-specific Sections II through VI of this document. Many comments were received that provided minor editorial suggestions and factual corrections regarding basin descriptions. The Agency has considered all comments, researched the accuracy of some comments (where necessary), and incorporated public comments where appropriate.

A. San Juan Basin

Summary of Comments: One commenter provided suggested edits and corrections pertaining to the San Juan Basin geology, hydrology and USDW identification, and CBM production activity. This commenter also provided additional references.

EPA Response: EPA reviewed and considered all suggested edits and corrections and has incorporated revisions to the San Juan Basin descriptions. EPA also reviewed the additional references provided by the commenter, and incorporated additional pertinent information.

B. Black Warrior Basin

Summary of Comments: One commenter provided a variety of editorial comments and factual clarifications regarding the Black Warrior Basin. Examples of information the commenter questioned include: coal thickness; total dissolved solids levels; number of active Class II wells in this area; fracture height vs. length; and chemical components of fracturing fluids.

EPA Response: EPA has incorporated into the final report the majority of the commenter's suggestions regarding the description of the Black Warrior Basin.

C. Piceance Basin

Summary of Comments: One commenter provided a brief description of the activities and progress of the pilot program in the White River Dome field.

EPA Response: The final report contains the information provided by the commenter.

D. Uinta Basin

Summary of Comments: One commenter indicated that the information on the Castlegate Field is out of date. The commenter clarified that the field is currently in production, and explained why he believes that cross-contamination from the Blackhawk to the Castlegate Sandstone and Star Point Sandstone (as indicated in the report) is unlikely.

EPA Response: EPA has made revisions to the basin description based on this information.

E. Powder River Basin

Summary of Comments: *No substantive comments were submitted on this section.*

F. Central Appalachian Basin

Summary of Comments: One commenter provided clarifications and corrections regarding CBM activity, regulations, and drinking water sources in Virginia.

EPA Response: EPA has incorporated many of the commenter's clarifications into the basin description.

G. Northern Appalachian Basin

Summary of Comments: One commenter provided information on the square mileage and number of CBM wells in this basin, with associated references. This commenter, who is the individual that was interviewed for some of the information provided in this attachment, provided edits to the interview summary. Another commenter suggested several editorial corrections pertaining to the location of specific coal groups, the use of the term "group," and the use of the term "separated laterally" vs. "vertical separation."

EPA Response: EPA has incorporated all appropriate information into the basin description.

H. Western Interior Basin

Summary of Comments: This commenter questioned the accuracy of the statement that "coal seams could be coincident with a USDW" within the Cherokee Basin. The commenter discussed the aerial extent to which various coal seams in the Cherokee Basin coincide with USDWs, and recommended that EPA also review a 1997 paper entitled "Kansas coal resources and their potential for coalbed methane."

EPA Response: EPA has modified the report to indicate that "all or part of targeted coal seams could be coincident with a USDW," thereby clarifying the summary of the data provided in Table A8-2, which presents the relative depths of coal seams and USDWs.

I. Raton Basin

Summary of Comments: *No comments were submitted on this section.*

J. Sand Wash Basin

Summary of Comments: One commenter pointed out that in the Sand Wash Basin, the pilot at Craig Dome was abandoned "due to excessive water production." This commenter also believed that EPA's findings that hydraulic fracturing poses very little potential threat to USDWs does not account for proximity or overlap with natural fault lines. The commenter stated that: "if a fracture propagates into and along a fault plane, it may contaminate a USDW."

EPA Response: EPA has incorporated the commenter's information into Attachment 10 of the final report.

K. Washington Coal Regions (Pacific and Central)

Summary of Comments: *No comments were submitted on this section.*

Appendix A
Department of Energy - Hydraulic Fracturing White Paper

1.0 Introduction

The first hydraulic fracturing treatment was pumped in 1947 on a gas well operated by Pan American Petroleum Corporation in the Hugoton field.[1] The Kelpper Well No. 1, located in Grant County, Kansas was a low productivity well, even though it had been acidized. The well was chosen for the first hydraulic fracture stimulation treatment so that hydraulic fracturing could be compared directly to acidizing. Since that first treatment in 1947, hydraulic fracturing has become a standard treatment for stimulating the productivity of oil and gas wells.

Hydraulic fracturing is the process of pumping a fluid into a wellbore at an injection rate that is too high for the formation to accept in a radial flow pattern. As the resistance to flow in the formation increases, the pressure in the wellbore increases to a value that exceeds the breakdown pressure of the formation that is open to the wellbore. Once the formation "breaks-down", a crack or fracture is formed, and the injected fluid begins moving down the fracture. In most formations, a single, vertical fracture is created that propagates in two directions from the wellbore. These fracture "wings" are 180^o apart, and are normally assumed to be identical in shape and size at any point in time. In naturally fractured or cleated formations, such as gas shales or coal seams, it is possible that multiple fractures can be created and propagated during a hydraulic fracture treatment.

Fluid that does not contain any propping agent, often called "pad", is injected to create a fracture that grows up, out and down, and creates a fracture that is wide enough to accept a propping agent. The purpose of the propping agent is to "prop open" the fracture once the pumping operation ceases, the pressure in the fracture decreases, and the fracture closes. In deep reservoirs, we use man-made ceramic beads to prop open the fracture. In shallow reservoirs, sand is normally used as the propping agent. The sand used as a propping agent in shallow reservoirs, such as coal seams, is mined from certain quarries in the United States. The silica sand is a natural product and will not lead to any environmental concerns that would affect the United States Drinking Water (USDW).

The purposes of this paper are (1) to discuss the processes an engineer uses to design and pump a hydraulic fracture treatment, and (2) to provide an overview of the theories, design methods and materials used in a hydraulic fracture treatment. Currently, a discussion is taking place on the effects of hydraulic fracturing in coal seams on the USDW. Gas production from coal seams is increasing in importance in the United States. In 2000, over 6% of the natural gas production in the US was produced from coal seams, and that percentage will increase in the future. Because of the ever-increasing importance of natural gas production from coal seams, coal seam examples have been included in this technical paper.

Objectives of Hydraulic Fracturing

In general, hydraulic fracture treatments are used to increase the productivity index of a producing well, or the injectivity index of an injection well. The productivity index defines the volumes of oil or gas that can be produced at a given pressure differential between the reservoir and the well bore. The injectivity index refers to how much fluid can be injected into an injection well at a given pressure differential.

There are many different applications for hydraulic fracturing, such as:

- Increase the flow rate of oil and/or gas from low permeability reservoirs,
- Increase the flow rate of oil and/or gas from wells that have been damaged,
- Connect the natural fractures and/or cleats in a formation to the wellbore,
- Decrease the pressure drop around the well to minimize sand production,
- Decrease the pressure drop around the well to minimize problems with asphaltine and/or paraffin deposition,
- Increase the area of drainage or the amount of formation in contact with the wellbore, and
- Connect the full vertical extent of a reservoir to a slanted or horizontal well.

Obviously, there could be other uses of hydraulic fracturing, but the majority of the treatments are pumped for these seven reasons.

A low permeability reservoir is one that has a high resistance to fluid flow. In many formations, chemical and/or physical processes alter a reservoir rock over geologic time. Sometimes, these diagenetic processes restrict the openings in the rock and reduce the ability of fluids to flow through the rock. Low permeability rocks are normally excellent candidates for stimulation by hydraulic fracturing.

Regardless of the permeability, a reservoir rock can be damaged when a well is drilled through the reservoir and when casing is set and cemented in place. Damage occurs because drilling and/or completion fluids leak into the reservoir and plug up the pores and pore throats. When the pores are plugged, the permeability is reduced, and the fluid flow in this damaged portion of the reservoir may be substantially reduced. Damage can be severe in naturally fractured reservoirs, like coal seams. To stimulate damaged reservoirs, a short, conductive hydraulic fracture is often the desired solution. As such, hydraulic fracturing works very well in many damaged, coal seam reservoirs.

In many cases, especially for low permeability formations, damaged reservoirs and horizontal wells in a layered reservoir, the well would be "uneconomic" unless a successful hydraulic fracture treatment is designed and pumped. Thus, the engineer in charge of the economic success of such a well, must (1) design the optimal fracture treatment, and then (2) go to the field to be certain the optimal treatment is pumped successfully.

Candidate Selection

The success or failure of a hydraulic fracture treatment often depends on the quality of the candidate well selected for the treatment. Choosing an excellent candidate for stimulation often ensures success, while choosing a poor candidate will normally result in economic failure. To select the best candidate for stimulation, the design engineer must consider many variables. The most critical parameters for hydraulic fracturing are formation permeability, the *in-situ* stress distribution, reservoir fluid viscosity, skin factor, reservoir pressure, reservoir depth and the condition of the wellbore. The skin factor refers to whether the reservoir is already stimulated or, perhaps is damaged. If the skin factor is positive, the reservoir is damaged and could possibly be an excellent candidate for stimulation.

The best candidate wells for hydraulic fracturing treatments will have a substantial volume of oil and gas in place, and will have a need to increase the productivity index. Such reservoirs will have (1) a thick pay zone, (2) medium to high pressure, (3) *in-situ* stress barriers to minimize vertical height growth, and (4) either be a low permeability zone or a zone that has been damaged (high skin factor). For coalbed methane reservoirs, the ideal candidate, in addition to the 4 factors listed above, will be a thick coal seam containing both (1) a large volume of sorbed gas and (2) abundant coal cleats to provide permeability.

Reservoirs that are not good candidates for hydraulic fracturing are those with little oil or gas in place due to thin reservoirs, low reservoir pressure, or small aerial extent. Reservoirs with extremely low permeability may not produce enough hydrocarbons to pay all the drilling and completion costs even if successfully stimulated; thus, such reservoirs would not be good candidates for stimulation. In coal seam reservoirs, the number, thickness and location of the coal seams must be considered when deciding if the coals can be completed and stimulated economically. If the coal seams are too thin or too scattered up and down the hole, the coals may not be ideal candidates for stimulation by hydraulic fracturing.

Developing Data Sets

For most petroleum engineering problems, developing a complete and accurate data set is often the most time consuming part of solving the problem. For hydraulic fracture treatment design, the data required to run both the fracture design model and the reservoir simulation model can be divided into two groups. One group lists the data that can be "controlled" by the engineer. The second group reflects data that must be measured or estimated, but cannot be controlled.

The primary data that can be controlled by the engineer are the well completion details, treatment volume, pad volume, injection rate, fracture fluid viscosity, fracture fluid density, fluid loss additives, propping agent type, and propping agent volume. The data that must be measured or estimated by the design engineer are formation depth, formation permeability, *in-situ* stresses in the pay zone, *in-situ* stresses in the surrounding layers, formation modulus, reservoir pressure, formation porosity, formation compressibility, and the thickness of the reservoir. There are actually three (3) thickness that are important to the design engineer: the gross thickness of the reservoir; the net thickness of the oil or gas producing interval; and the permeable thickness that will accept fluid loss during the hydraulic fracture treatment.

The most critical data for the design of a fracture treatment are, roughly in order of importance, (1) the *in-situ* stress profile, (2) formation permeability, (3) fluid loss characteristics, (4) total fluid volume pumped, (5) propping agent type and amount, (6) pad volume, (7) fracture fluid viscosity, (8) injection rate, and (9) formation modulus. Since most engineers have more work to do than time to do the work, the design engineer should focus most of his/her time on the most important parameters. In hydraulic fracture treatment design, by far, the two most important parameters are the *in-situ* stress profile and the permeability profile of the zone to be stimulated and the layers of rock above and below the target zone.

In new fields or reservoirs, most operating companies are normally willing to spend money to run logs, cut cores and run well tests to determine important factors such as the *in-situ* stress and the permeability of the major reservoir layers. By using such data, along with fracture treatment records and production records, accurate data sets for a given reservoir in a given field can normally be compiled. These data sets can be used on subsequent wells to optimize the fracture treatment designs. It is normally not practical to cut cores and run well tests on every well. Thus, the data obtained from cores and well tests must be correlated to log parameters so the logs on subsequent wells can be used to compile accurate data sets.

To design a fracture treatment, most engineers use pseudo 3-dimensional (P3D) models. Full 3-D models exist; however, the use of full 3-D models is currently limited to supercomputers and research organizations. To use a P3D model, the data must be input by reservoir layer. Fig. 1 illustrates the profiles of important input data required by a P3D model. For the situation in

Fig. 1, the fracture treatment would be initiated in the sandstone reservoir. The fracture would typically grow up and down until a barrier is reached to prevent vertical fracture growth. In many cases, thick marine shale will be a barrier to vertical fracture growth. In some cases, coal seams will prevent fractures from growing vertically. Many coal seams are highly cleated, and when the fracture fluid enters the coal seam, it remains contained within the coal seam. In thick, highly cleated coal seams, the growth of the hydraulic fracture will normally be limited to the coal seam.

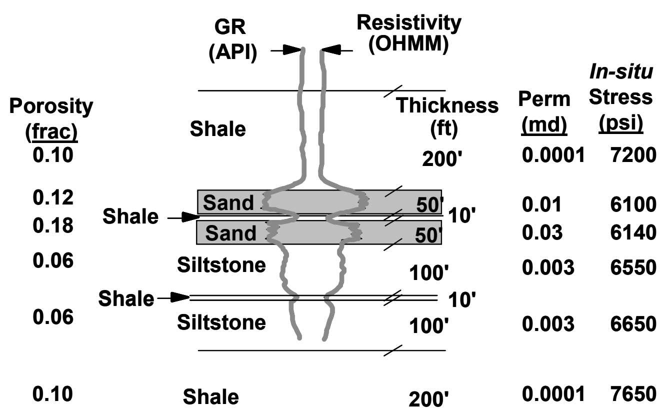

Fig. 1 – Typical input data for a P3D model.

The data used to design a fracture treatment can be obtained from a number of sources, such as drilling records, completion records, well files, open hole geophysical logs, cores and core analyses, well tests, production data, geologic records, and other public records, such as publications. In addition, service companies provide data on their fluids, additives and propping agents. Table 1 illustrates typical data needed to design a fracture treatment and possible sources for the data.

Table 1 – Sources of Data

Data	Units	Sources
Formation Permeability	md	Cores, Well Tests, Correlations, Production Data
Formation Porosity	%	Cores, Logs
Reservoir Pressure	psi	Well Tests, Well Files, Regional Data
Formation Modulus	psi	Cores, Logs, Correlations
Formation Compressibility	psi	Cores, Logs, Correlations
Poisson's Ratio		Cores, Logs, Correlations
Formation Depth	ft	Logs, Drilling Records
In-situ Stress	psi	Well Tests, Logs, Correlations
Formation Temperature	°F	Logs, Well Tests, Correlations
Fracture Toughness	psi - $\sqrt{\text{in}}$	Cores, Correlations
Water Saturation	%	Logs, Cores
Net Pay Thickness	Ft	Logs, Cores
Gross Pay Thickness	Ft	Logs, Cores, Drilling Records
Formation Lithology		Cores, Drilling Records, Logs, Geologic Records
Wellbore Completion		Well Files, Completion Prognosis
Fracture Fluids		Service Company Information
Fracture Proppants		Service Company Information

<u>Fracture Treatment Optimization</u>

The goal of every design engineer should be to design the optimum fracture treatment for each and every well. In 1978, Holditch *et al.*[2] wrote a paper concerning the optimization of both the propped fracture length and the drainage area (well spacing) for low permeability gas reservoirs. Fig. 2 illustrates the methodology used to optimize the size of a fracture treatment [3,4]. Fig. 2 clearly shows the following:

- As the propped length of a fracture increases, the cumulative production will increase, and the revenue from hydrocarbon sales will increase,
- As the fracture length increases, the incremental benefit ($ of revenue per foot of additional propped fracture length) decreases,
- As the treatment volume increases, the propped fracture length increases,
- As the fracture length increases, the incremental cost of each foot of fracture ($ of cost per foot of additional propped fracture length) increases, and

- When the incremental cost of the treatment is compared to the incremental benefit of increasing the treatment volume, an optimum propped fracture length can be found for every situation.

Additional economic calculations can be made to determine the optimum fracture treatment design. However, in all cases, the design engineer must consider the effect of the fracture upon flow rates and recovery, the cost of the treatment, and the investment guidelines of the operator of the well.

Field Considerations

After the optimum fracture treatment has been designed, it must be pumped into the well successfully. A successful field operations requires planning, coordination and cooperation of all parties. Treatment supervision and the use of quality control measures will improve the successful application of hydraulic fracturing. Safety is always the primary concern in the field. Safety begins with a thorough understanding by all parties on their duties in the field. A safety meeting is always held to review the treatment procedure, establish a chain of command, be sure everyone knows his/her job responsibilities for the day, and to establish a plan for emergencies. The safety meeting should also be used to discuss the well completion details and the maximum allowing injection rate and pressures, as well as the maximum pressures to be held as backup to an annulus. All casing, tubing, wellheads, valves, and weak links, such as liner tops, should be thoroughly tested prior to rigging up the fracturing equipment. Mechanical failures during a treatment can be costly and dangerous. All mechanical problems should be repaired prior to pumping the fracture treatment.

Prior to pumping the treatment, the engineer-in-charge should conduct a detailed inventory of all the equipment and materials on location. The inventory should be compared to the design and the prognosis. After the treatment has concluded, the engineer should conduct another inventory of all the materials left on location. In most cases, the difference in the two inventories can be used to verify what was mixed and pumped into the wellbore and the hydrocarbon bearing formation.

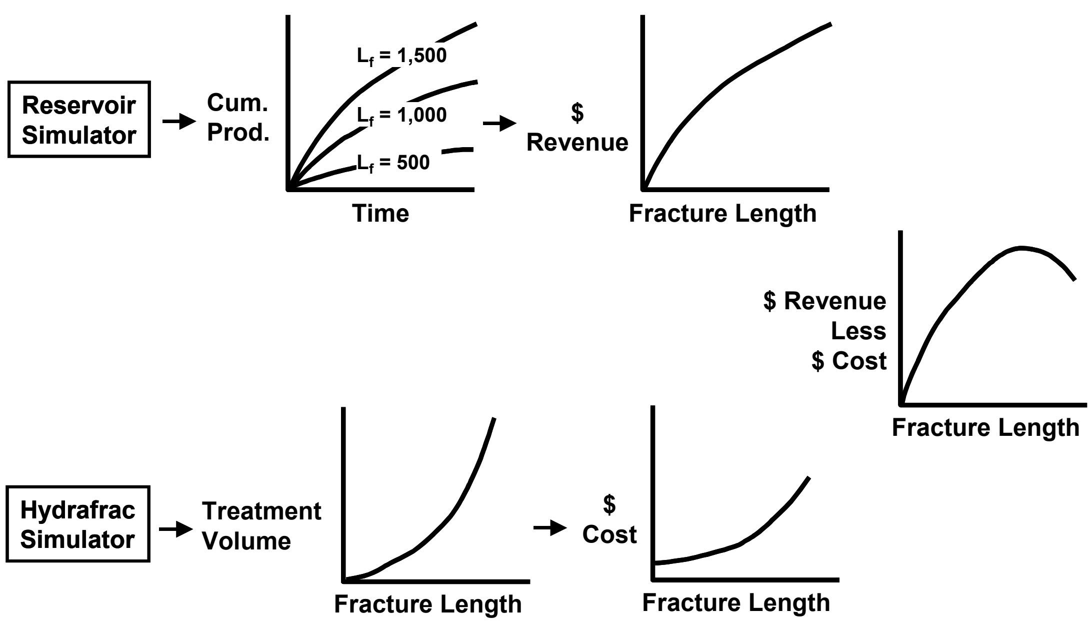

Fig. 2 – Fracture treatment optimization process.

In addition to an inventory, samples of the base fracturing fluid (usually water) should be taken and analyzed. Typically, a water analysis is done on the base fluid to determine the minerals present and the type of bacteria in the water. The data from the water analysis can be used to select the additives required to mix the viscous fracture fluid required to create a wide fracture and to transport the propping agent into the fracture. Table 2 shows the typical compositions for mix waters used in different fracturing situations. In addition to testing the water, samples of the additives used during a treatment and the fracture fluid after all additives have been added should be taken during the job and saved for future analyses, if required.

Table 2 – Fracturing Fluids and Conditions for Their Use

Base Fluid	Fluid Type	Main Composition	Used For
Water Based	Linear Fluids	Gelled Water, GUAR< HPG, HEC, CMHPG	Short Fractures, Low Temperatures
	Crosslinked Fluids	Crosslinker + GUAR, HPG, CMHPG, CMHEC	Long Fractures, High Temperatures
Foam Based	Water Based Foam	Water and Foamer + N_2 or CO_2	Low Pressure Formations
	Acid Based Foam	Acid and Foamer + N_2	Low Pressures, Water Sensitive Formations
	Alcohol Based Foam	Methanol and Foamer + N_2	Low Pressure Formations With Water Blocking Problems
Oil Based	Linear Fluids	Oil, Gelled Oil	Water Sensitive Formations, Short Fractures
	Crosslinked Fluids	Phosphate Ester Gels	Water Sensitive Formations, Long Fractures
	Water External Emulsions	Water + Oil + Emulsifier	Good For Fluid Loss Control

Formation temperature is one of the main factors concerning the type of additives required to mix the optimum fracturing fluid. In deep, hot reservoirs (>250°F), more additives are required than in shallow, low temperature reservoirs. Since most coal seams are very shallow, fewer additives are normally required to mix the optimum fracture fluid.

2.0 Fracture Mechanics

Fracture mechanics has been part of mining engineering and mechanical engineering for hundreds of years. No one is more interested in underground rock fractures than a miner working in an underground mine. In petroleum engineering, we have only used fracture mechanics theories in our work for about 50 years. Much of what we use in hydraulic fracturing theory and design has been developed by other engineering disciplines many years ago. However, certain aspects, such as poroelastic theory, are unique to porous, permeable underground formations. The most important parameters are *in-situ* stress, Poisson's ration, and Young's modulus.

In-situ Stresses

Underground formations are confined and under stress. Fig. 3 illustrates the local stress state at depth for an element of formation. The stresses can be divided into 3 principal stresses. In Fig. 3, σ_1 is the vertical stress, σ_2 is the maximum horizontal stress, while σ_3 is the minimum horizontal stress, where $\sigma_1 > \sigma_2 > \sigma_3$. This is a typical configuration for coalbed methane reservoirs. However, depending on geologic conditions, the vertical stress could also be the intermediate (σ_2) or minimum stress (σ_3). These stresses are normally compressive and vary in magnitude throughout the reservoir, particularly in the vertical direction (from layer to layer). The magnitude and direction of the principal stresses are important because they control the pressure required to create and propagate a fracture, the shape and vertical extent of the fracture, the direction of the fracture, and the stresses trying to crush and/or embed the propping agent during production.

A hydraulic fracture will propagate perpendicular to the minimum principal stress (σ_3). If the minimum horizontal stress is σ_3, the fracture will be vertical and, we can compute the minimum horizontal stress profile with depth using Eq. 1.

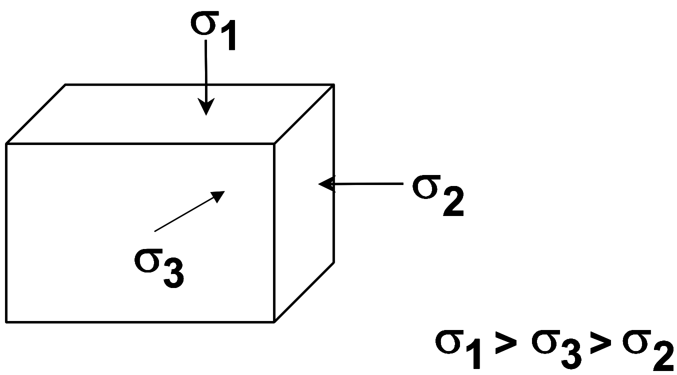

Fig. 3 – Local in-situ stress at depth.

$$\sigma_{min} \cong \frac{\nu}{1-\nu}\left(\sigma_{ob} - \alpha\,\sigma_p\right) + \alpha\,\sigma_p + \sigma_{ext} \qquad \text{Eq. 1}$$

Where:

σ_{min}	=	the minimum horizontal stress (*in-situ* stress)
ν	=	Poissons' ratio
σ_{ob}	=	overburden stress
α	=	Biot's constant
σ_p	=	reservoir fluid pressure or pore pressure
σ_{ext}	=	tectonic stress

Poisson's ratio can be estimated from acoustic log data or from correlations based upon lithology. For coal seams, the value of Poisson's ratio will range from 0.2 – 0.4. The overburden stress can be computed using density log data. Normally, the value for overburden pressure is about 1.1 psi per foot of depth. The reservoir pressure must be measured or estimated. Biot's constant must be less than or equal to 1.0 and typically ranges from 0.5 to 1.0. The first two (2) terms on the right hand side of Eq.1 represent the horizontal stress resulting from the vertical stress and the poroelastic behavior of the formation. The tectonic stress term is important in many areas where plate tectonics or other forces increase the horizontal stresses.

Poroelastic theory can be used to determine the minimum horizontal stress in tectonically relaxed areas.[8,9] Poroelastic theory combines the equations of linear elastic stress-strain theory for solids with a term that includes the effects of fluid pressure in the pore space of the reservoir rocks. The fluid pressure acts equally in all directions as a stress on the formation material. The "effective stress" on the rock grains is computed using linear elastic stress-strain theory. Combining the two sources of stress results in the total stress on the formation, which is the stress that must be exceeded to initiate fracturing.

In many areas, however, the effects of tectonic activity must be included in the analyses of the total stresses. To measure the tectonic stresses, injection tests are conducted to measure the minimum horizontal stress. The measured stress is then compared to the stress calculated by the poroelastic equation to determine the value of the tectonic contribution.

<u>Basic Rock Mechanics</u>

In addition to the *in-situ* or minimum horizontal stress, other rock mechanical properties are important when designing a hydraulic fracture. Poisson's ratio is defined as "the ratio of lateral expansion to longitudinal contraction for a rock under a uniaxial stress condition".[10] The value of Poisson's ratio is used in Eq. 1 to convert the effective vertical stress component into an effective horizontal stress component. The effective stress is defined as the total stress minus the pore pressure.

The theory used to compute fracture dimensions is based upon linear elasticity. To apply this theory, the modulus of the formation is an important parameter. Young's modulus is defined as "the ratio of stress to strain for uniaxial stress".[10] The modulus of a material is a measure of the stiffness of the material. If the modulus is large, the material is stiff. In hydraulic fracturing, a stiff rock will result in more narrow fractures. If the modulus is low, the fractures will be wider. The modulus of a rock will be a function of the lithology, porosity, fluid type, and other variables. Table 3 illustrates typical ranges for modulus as a function of lithology.

Table 3. Typical Ranges of Young's Modulus for Various Lithologies

Lithology	Young's Modulus
Soft Sandstone	2-5 x 10^6 psi
Hard Sandstone	6-10 x 10^6 psi
Limestone	8-12 x 10^6 psi
Coal	0.1-1 x 10^6 psi
Shale	1-10 x 10^6 psi

Because coal is highly cleated, the modulus of the coal seam *in-situ* may be very low. In very low modulus, highly cleated coal seams, it is likely that most fractures will be wide and short, that is, not penetrating far into the formation from the well bore.

Fracture Orientation

A hydraulic fracture will propagate perpendicular to the least principle stress (Fig. 3). In some shallow formations the least principal stress is the overburden stress; thus, the hydraulic fracture will be horizontal. Nielsen and Hansen published a paper where horizontal fractures in coal seam reservoirs were documented [11]. In reservoirs deeper than 1000 ft or so, the least principal stress will likely be horizontal; thus, the hydraulic fracture will be vertical. The azimuth orientation of the vertical fracture will depend upon the azimuth of the minimum and maximum horizontal stresses. Lacy and Smith provided a detailed discussion of fracture azimuth in SPE Monograph 12.[12]

Injection Tests

The only reliable technique for measuring *in-situ* stress is by pumping into a reservoir, creating a fracture, and measuring the pressure at which the fracture closes [13]. The well tests used to measure the minimum principal stress are as follows: *in-situ* stress tests; step-rate/flow back tests; mini-fracture tests; and step-down tests. For most fracture treatments, mini-fracture tests and step-down tests are pumped ahead of the main fracture treatment. As such, accurate data are normally available to calibrate and interpret the pressures measured during a fracture treatment. *In-situ* stress tests and step-rate/flow back tests are not run on every well. However, it is common to run such tests in new fields or new reservoirs to help develop the correlations required to optimize fracture treatments for subsequent wells.

An *in-situ* stress test (or micro-frac) can be either an injection-falloff test or an injection-flow back test. The *in-situ* stress test is conducted using small volumes of fluid (a few barrels), injected at low injection rates (gals/min), normally using straddle packers to minimize well bore storage effects, into a small number of perforations (1-2 ft). The objective is to pump a thin fluid (water or nitrogen) at a rate barely sufficient to create a small fracture. Once the fracture is open, then the pumps are shut down, and the pressure is recorded and analyzed to determine when the fracture closes. Thus, fracture closure pressure is synonymous with *in-situ* stress and with minimum horizontal stress. When the pressure in the fracture is greater than the fracture closure pressure, the fracture is open. When the pressure in the fracture decreases below the fracture closure pressure, the fracture is closed. Fig. 4 illustrates a typical wellbore configuration for conducting an *in-situ* stress test. Fig. 5 shows typical data that are measured. Multiple tests are conducted to ensure repeatability. The data from any one of the injection-falloff tests can be analyzed to determine when the fracture closes.

Fig. 6 illustrates how one such test can be analyzed to determine *in-situ* stress.

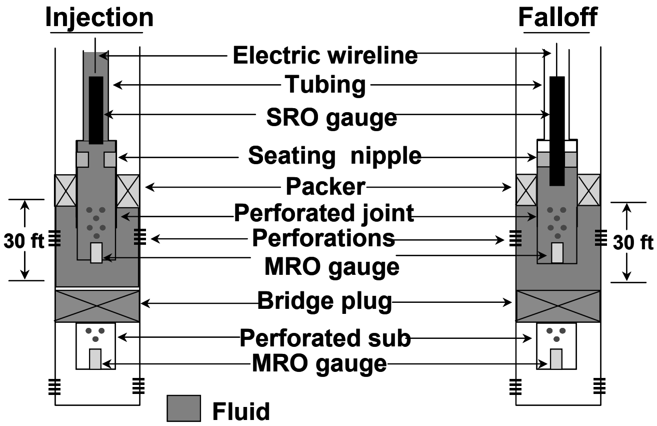

Fig. 4 – Cased hole test configuration.

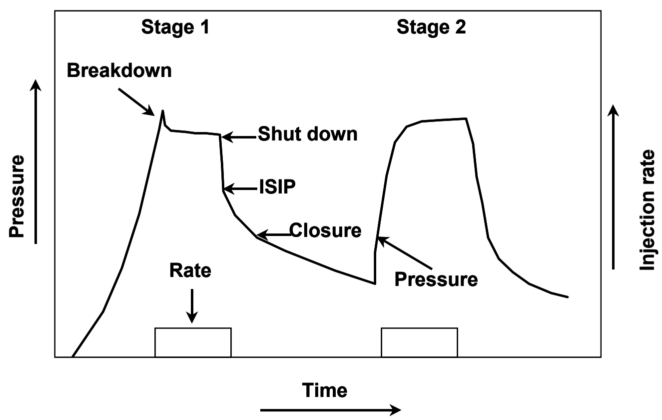

Fig. 5 – Typical stress test pump-in/shut-in.

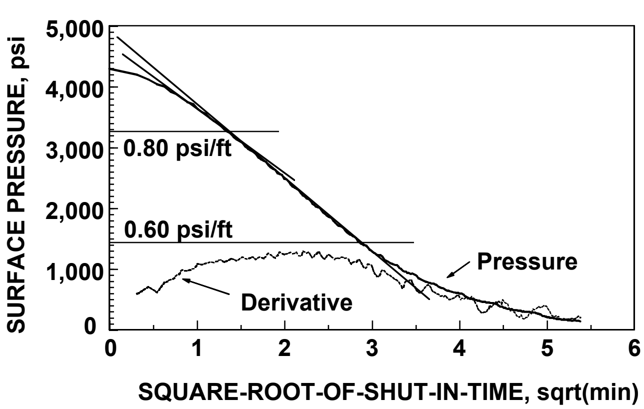

Fig. 6 – Closure pressure analysis.

Mini-fracture tests are run to reconfirm the value of *in-situ* stress in the pay zone and to estimate the fluid loss properties of the fracture fluid. A mini-fracture test is run using fluid similar to the fracture fluid that will be used in the main treatment. Several hundred barrels of fracturing fluid are normally pumped at fracturing rates. In coal seams, because the fracture height will usually be small, the mini-fracture test will often be eliminated or pumped with only a small volume of fracturing fluid. The purpose of the injection is to create a fracture that will be of similar height to the one created in the main fracture treatment. After the mini-fracture has been created, the pumps are shut down and the pressure decline is monitored. The pressure decline can be used to estimate the fracture closure pressure and the total fluid leak-off coefficient. Data from mini-fracture treatments can be used to alter the design of the main fracture treatment if the data determined during the mini-fracture test is substantially different that the data used to design the main fracture treatment.

For an injection-falloff test to be conducted successfully, it is necessary to have a clean connection between the wellbore and the created fracture. The purpose of *in-situ* stress tests and mini-fracture tests are to determine the pressure in the fracture when the fracture is open, and the pressure when the fracture is closed. If there is excess pressure drop near the wellbore, due to poor connectivity between the wellbore and the fracture, the interpretation of *in-situ* stress test data can be difficult. In coal seam reservoirs, due to the highly cleated nature of the coal, multiple fractures that follow tortuous paths are often created during injection tests.[14] When these tortuous paths are created, the pressure drop in the "near-wellbore" region can be very high, which complicates the analyses of the pressure falloff data. As such, *in-situ* stress test data and data from mini-fracture tests in coal seams are very difficult to measure and interpret.

The design engineer needs data from well tests to design the optimum fracture treatment. It is common for an operator to spend a lot of money and time running injection tests to determine values of *in-situ* stress, formation permeability, and leak-off coefficient. Fracture treatment theory is well grounded in science and engineering and, in most cases, data are collected from logs, cores and well tests to assure that designs are as accurate as possible.

3. Fracture Propagation Models

The first fracture treatments were pumped just to see if a fracture could be created and if sand could be pumped into the fracture. In 1955, Howard and Fast[15] published the first mathematical model that an engineer could use to design a fracture treatment. The Howard and Fast model assumed the fracture width was constant everywhere, allowing the engineer to compute fracture area based upon fracture fluid leakoff characteristics of the formation and the fracturing fluid.

2D Fracture Propagation Models

The Howard and Fast model was a two-dimensional (2D) model. In the following years, other 2D models were published.[16-19] When using a 2D model, the engineer fixes one of the dimensions (normally the fracture height), then calculates the width and length of the fracture. With experience and accurate data sets, 2D models can be used with confidence because the design engineer can accurately estimate the created fracture height beforehand.

Figs. 7 and 8 illustrate two of the most common 2D models used in fracture treatment design. The PKN geometry (Fig. 7) is normally used when the fracture length is much greater than the fracture height, while the KGD geometry (Fig. 8) is used if fracture height and length are similar [20]. Either of these two models can be used successfully to design hydraulic fractures. The key is to use models to make decisions. The design engineer must always compare actual results with the predictions from model calculations. By "calibrating" the 2D model with field results, the 2D models can be used to make design changes and improve the success of stimulation treatments.

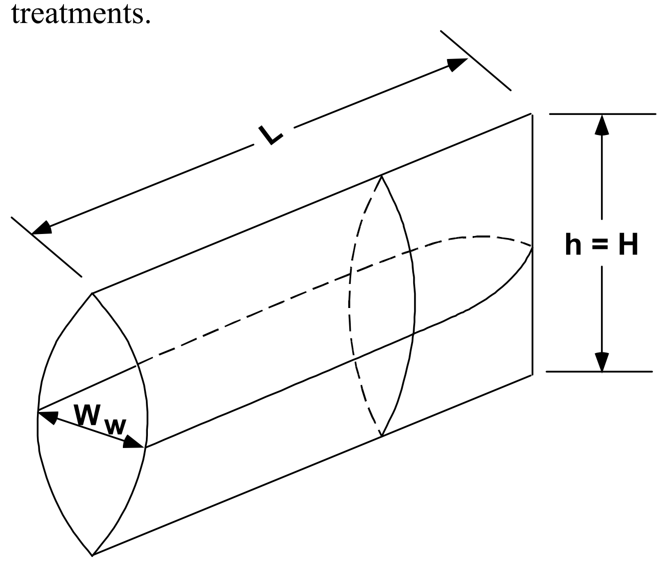

Fig. 7 – PKN geometry.

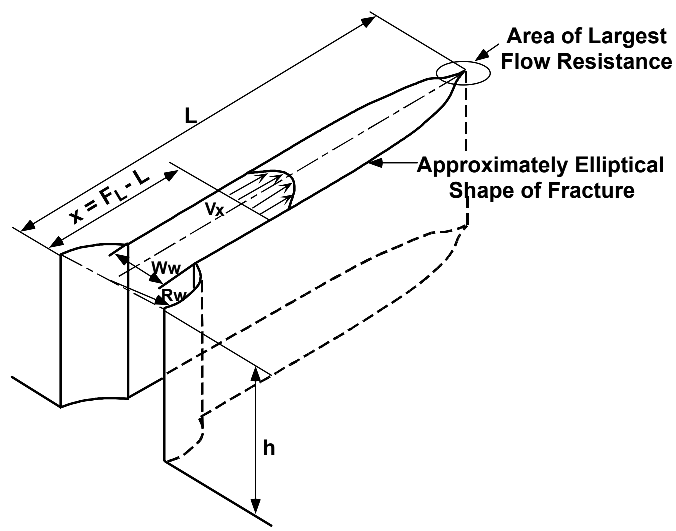

Fig. 8 – KGD geometry.

If the correct value of fracture height is used in a 2D model, the model will give reasonable estimates of created fracture length and width, provided, of course, that other parameters, such as *in-situ* stress, Young's modulus, formation permeability and total leakoff coefficient are also entered correctly. Engineers had to use 2D models for years due to the lack of computing power. Today, with high-powered computers available to most engineers, Pseudo 3-Dimensional (P3D) models are used by most fracture design engineers. P3D models are better than 2D models for most situations because the P3D model computes the fracture height, width and length distribution using the data for the pay zone and all the rock layers above and below the perforated interval.

<u>*3D Fracture Propagation Models*</u>

Clifton[21] provides a detailed explanation of how 3-Dimensional fracture propagation theory is used to derive equations for programming 3D models, as well as P3D models. Figs. 9 and 10 illustrate typical results from a P3D model. P3D models give more realistic estimates of fracture geometry and dimensions, which can lead to better designs and better wells. P3D models are used to compute the shape of the hydraulic fracture as well as the dimensions.

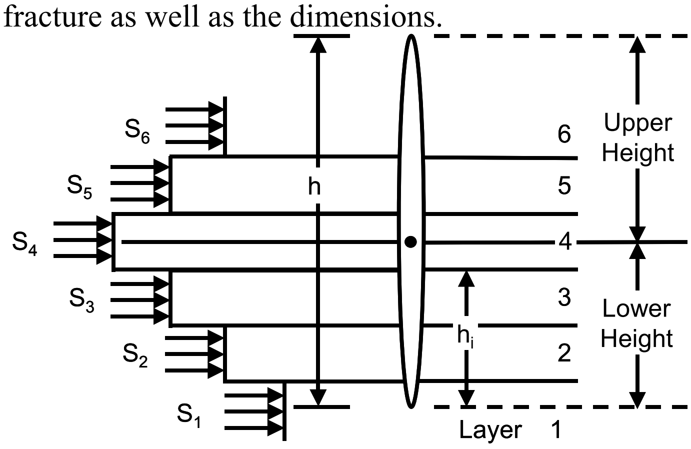

Fig. 9 – Width from a P3D model.

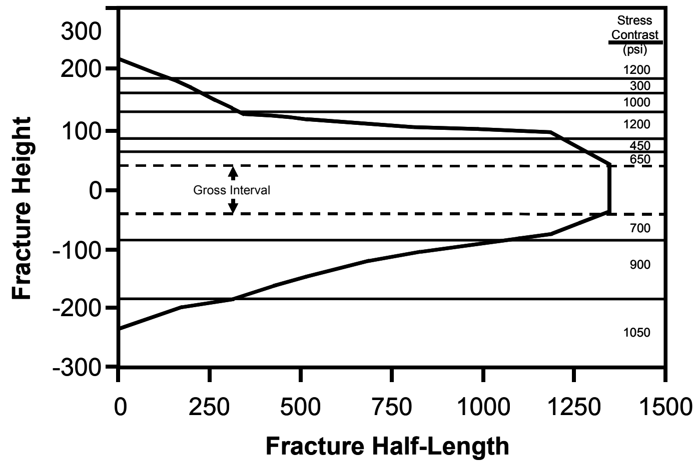

Fig. 10 – Width and height from P3D model.

4. Fracturing Fluids and Additives

To create the fracture, a fluid is pumped into the wellbore at high rate to increase the pressure in the wellbore at the perforations to a value greater than the breakdown pressure of the formation. The breakdown pressure is generally believed to be the sum of the *in-situ* stress and the tensile strength of the rock. Once the formation is broken down, and the fracture is created, then the fracture can be propagated at a pressure called the fracture propagation pressure. The fracture propagation pressure is equal to the sum of the *in-situ* stress, plus the net pressure drop, plus the near wellbore pressure drop. The net pressure drop is equal to the pressure drop down the fracture due to viscous fluid flow in the fracture. The near wellbore pressure drop can be a combination of the pressure drop of the viscous fluid flowing through the perforations and/or the pressure drop due to tortuosity between the wellbore and the propagating fracture. Thus, the fracturing fluid properties are very important in the creation and propagation of the fracture.

<u>Properties of a Fracturing Fluid</u>

The ideal fracturing fluid should be compatible with the formation rock, compatible with the formation fluid, generate enough pressure drop down the fracture to create a wide fracture, be able to transport the propping agent in the fracture, break back to a low viscosity fluid for clean up after the treatment, and be cost effective. The family of fracture fluids available consist of water base fluids, oil base fluids, acid base fluids and foam fluids. Table 2 lists the types of fracturing fluids that are available and the general use of each type of fluid. For most reservoirs, water base fluids with appropriate additives will be the best fluid. In some cases, foam generated using N_2 or CO_2 can be used to successfully stimulate shallow, low-pressure zones. When water is used as the base fluid, the water should be tested for quality. Table 4 presents generally accepted levels of water quality for use in hydraulic fracturing.

Table 4 - Acceptable Levels for Mix Water

pH	6-8
Iron	< 10 ppm
Oxidizing Agents	None
Reducing Agents	None
Carbonate*	< 300 ppm
Bicarbonate*	< 300 ppm
Bacteria	None
Cleanliness	Reasonable
*Higher Carbonate/Bicarbonate Content Will Require Further Pilot Testing on Gel Break, and Crosslinking	

The viscosity of the fracture fluid is important. The fluid should be viscous enough (normally 50–1000 cp) to create a wide fracture (normally 0.2–1.0 in) and transport the propping agent into the fracture (normally 10s to 100s of feet). The density of the fluid is also important. Water based fluids have densities near 8.4 ppg. Oil base fluids, although never used to fracture treat coal seam reservoirs, will have densities that are 70-80% of the water based fluids. Foam fluids can have densities that are 50% or less those of water based fluids. The density affects the surface injection pressure and the ability of the fluid to flow back after the treatment. In low pressure reservoirs, low density fluids, like foam, can be used to assist in the fluid clean up.

A fundamental equation used in all fracture models is that the fracture volume is equal to the total volume of fluid injected minus the volume of fluid that leaks off into the reservoir. The fluid efficiency is the percentage of fluid that is still in the fracture at any point in time, when compared to the total volume injected at the same point in time. The concept of fluid loss was used by Howard and Fast to determine fracture area [15]. If too much fluid leaks off, the fluid has a low efficiency (say 10-20%) and the created fracture volume will be only a fraction of the total volume injected. However, if the fluid efficiency is too high (say 80-90%), the fracture will not close rapidly after the treatment. Ideally, a fluid efficiency between 40-60% will provide an optimum balance between creating the fracture and having the fracture close down after the treatment.

In most low permeability reservoirs, fracture fluid loss and efficiency is controlled by the formation permeability. In high permeability formations, a fluid-loss additive must be added to the fracture fluid to reduce leak-off and improve fluid efficiency. In highly cleated coal seams, the leak-off can be extremely high, with efficiencies down in the 10-20% range. To fracture treat these highly cleated coal seams, the treatment must often be pumped at high injection rates using fluid loss additives. In general, the objective of most fracture treatments in coal seams is to create a short, wide fracture to connect the coal cleat system to the well bore vs. creating long hydraulic fractures that penetrate deeply into the coal seam. Therefore, water with very few additives, pumped at medium to high injection rates is commonly used to stimulate coal seam reservoirs.

Fracture Fluid Additives

Typical additives for a fracture fluid have been described in detail by Ely [22]. Typical additives for a water based fluid are briefly described below.

- Polymers – used to viscosify the fluid
- Crosslinkers – used to change the viscous fluid to a pseudo-plastic fluid
- Biocides – used to kill bacteria in the mix water
- Buffers – used to control the pH of the fracture fluid
- Surfactants – used to lower the surface tension
- Fluid loss additives – used to minimize fluid leak-off into the formation
- Stabilizers – used to keep the fluid viscous at high temperature
- Breakers – used to break the polymers and crosslink sites at low temperature

Additional information on additives is presented in Table 5.

Table 5 – Summary of Chemical Additives

Type of Additive	Function Performed	Typical Products
Biocide	Kills bacteria	Gluteridehyde carbonate
Breaker	Reduces fluid viscosity	Acid, oxidizer, enzyme breaker
Buffer	Controls the pH	Sodium bicarb., fumaric acid
Clay stabilizer	Prevents clay swelling	KCl, NH CL, KCl substitutes
Diverting agent	Diverts flow of fluid	Ball sealers, rock salt, flake boric-acid
Fluid loss additive	Improves fluid efficiently	Diesel, particulates, fine sand
Friction reducer	Reduces the friction	Anionic copolymer
Iron Controller	Keeps iron in solution	Acetic & citric acid
Surfactant	Lowers surface tension	Fluorocarbon, Nonionic
Gel stabilizer	Reduces thermal degradation	MEOH, sodium thiosulphate

The owner of the oil or gas well normally does not own the equipment or the additives required to pump a fracture treatment. The operator will hire a service company to pump the fracture treatment. Each service company has their own research department for developing fracture fluids and additives. Each service company obtains their additives from various suppliers. As such, there is no set of rules one can use to select the proper additives for a fracture fluid, without first consulting with the service company that will mix and pump the fluid into the well. Many times, pilot tests of the fracture fluids must be conducted to be certain all the additives will work properly at the temperature in the reservoir and for the duration of the treatment.

All operating and service companies are concerned with protecting the environment and the USDW. As such, research is being conducted in developing "green additives" to use in hydraulic fracturing, especially in shallow formations like coal seam reservoirs. It costs a lot of money to handle additives and dispose of fracturing fluids that are either left over after the treatment or produced back from the well bore. The development of new, green additives will be a new technology that will benefit all parties.

5. Propping Agents and Fracture Conductivity

Propping agents are required to "prop-open" the fracture once the pumps are shut down and the fracture begins to close. The ideal propping agent will be strong, resistant to crushing, resistant to corrosion, have a low density, and readily available at low cost.[23] The products that best meet these desired traits are silica sand, resin-coated sand, and ceramic proppants.

Types of Propping Agents

Silica sand is obtained from sand mining operations. There are several sources in the

United States and a few outside the US. The sand must be tested to be sure it has the necessary compressive strength to be used in any specific situation. Generally, sand is used to prop open fractures in shallow formations. For coal seam reservoirs, sand is usually the best choice for a propping agent and virtually every fracture treatment in a coal seam reservoir uses sand. Sand is much less expensive per pound than the resin-coated sand or the ceramic proppants.

Resin-coated (epoxy) sand is stronger than sand and is used where more compressive strength is required to minimize proppant crushing. Some resins can be used to form a consolidated sand pack in the fracture, which will help to eliminate proppant flow back into the wellbore. Resin coated sand is more expensive than sand.

Ceramic proppants consist of sintered bauxite, intermediate strength proppant (ISP), and light weight proppant (LWP). The strength of the proppant is proportional to its density. Also, the higher strength proppants, like sintered bauxite, cost more than ISP and LWP. Ceramic proppants are used to stimulate deep (>8,000 ft) wells where large values of *in-situ* stresses will apply large forces on the propping agent.

Factors Affecting Fracture Conductivity

The fracture conductivity is the product of propped fracture width and the permeability of the propping agent, as illustrated in Fig. 11. The permeability of all the propping agents, sand, resin-coated sand, and the ceramic proppants, will be 200+ darcies when no stress has been applied to the propping agent. However, the conductivity of the fracture will be reduced during the life of the well because of increasing stress on the fracture, stress corrosion affecting the proppant strength, proppant crushing, proppant embedment into the formation, and damage due to gel residue or fluid loss additives.

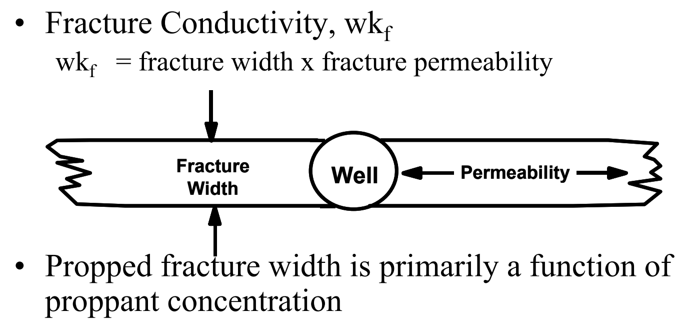

Fig. 11 – Definition of fracture conductivity.

The effective stress on the propping agent is the difference between the *in-situ* stress and the flowing pressure in the fracture, as illustrated in Fig. 12. As the well is produced, the effective stress on the propping agent will normally increase because the value of the flowing bottom hole pressure will be decreasing. However, as can be seen by examining Eq. 1, the *in-situ* stress will decrease with time as the reservoir pressure declines. This phenomenon of decreasing *in*-situ stress as the reservoir pressure declines was proven conclusively by Salz.[8] In shallow coal seam reservoirs, the effective stress on the propping agent is always low and does not normally affect the fracture conductivity.

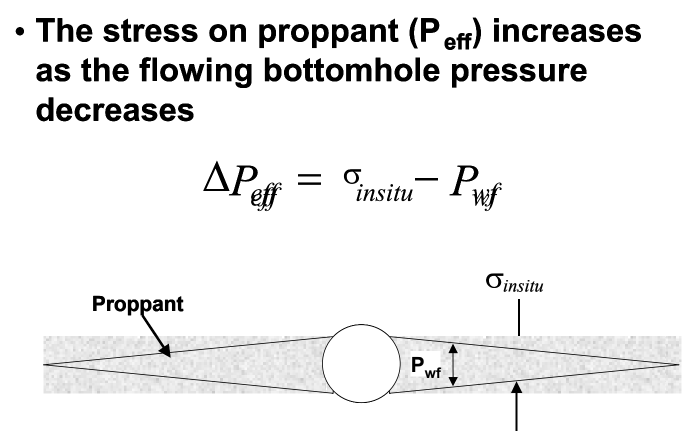

Fig. 12 – Effective stress on proppant.

Fig. 13 illustrates the differences is fracture conductivity vs. increasing effective stress on the propping agent for a variety of commonly used propping agents. The data in Fig. 13 clearly show that for shallow wells, where the effective stress is less than 4000 psi, sand can be used to create high conductivity fractures. As the effective stress increases to larger and larger values, then the higher strength, more expensive propping agents must be used to create a high conductivity fracture.

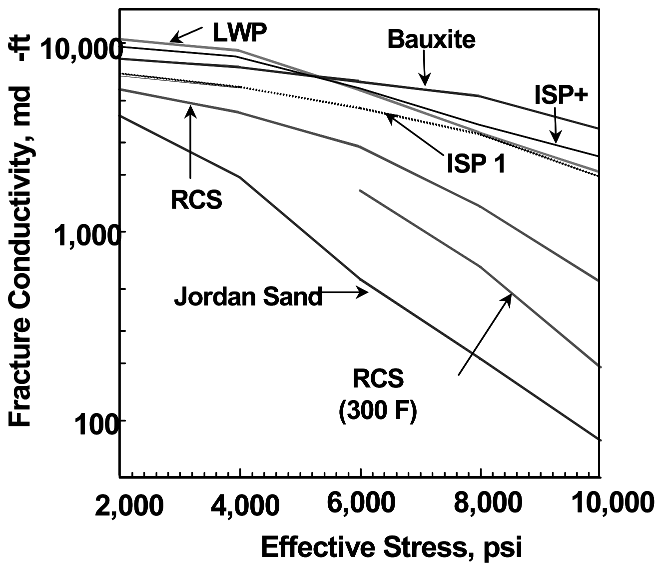

Fig. 13 – Effect of stress on conductivity.

6. Fracture Treatment Design

Data Requirements

In **Section 1** of this paper, the data required by the engineer to design a hydraulic fracture treatment was discussed. The data were divided into two groups: (1) data that must be measured or estimated and (2) data that can be controlled by the design engineer. The primary data that can be controlled by the engineer are the well completion details, treatment volume, pad volume, injection rate, fracture fluid viscosity, fracture fluid density, fluid loss additives, propping agent type, and propping agent volume.

As stated earlier, the most important data are (1) the *in-situ* stress profile, (2) formation permeability, (3) fluid loss characteristics, (4) total fluid volume pumped, (5) propping agent type and amount, (6) pad volume, (7) fracture fluid viscosity, (8) injection rate, and (9) formation modulus. The two most important parameters are the *in-situ* stress profile and the permeability profile of the zone to be stimulated and the layers of rock above and below the target zone.

There is a structured methodology followed by the engineer to design, optimize, execute, evaluate and re-optimize the fracture treatments in any reservoir. The first step is always the construction of a complete and accurate data set. Table 1 lists the sources for the data required to run fracture propagation and reservoir models. Notice that the design engineer must be capable of analyzing logs, cores, production data, well test data, and digging through well files to obtain all the information needed to design and evaluate a well that is hydraulically fracture treated.

Design Procedures

To design the optimum treatment, the engineer must determine the effect of fracture length and fracture conductivity upon the productivity and the ultimate recovery from the well. As in all engineering problems, sensitivity runs need to be made to evaluate uncertainties, such as formation permeability and drainage area. In coal seam reservoirs, uncertainties can also exist in variables such as the gas content and the desorption rate. The production data obtained from the reservoir model should be used in an economics model to determine the optimum fracture length and conductivity. Then a fracture treatment must be designed using a P3D fracture propagation model to achieve the desired length and conductivity at minimum cost. The most important concept is to design a fracture using all data and appropriate models that will result in the optimum economic benefit to the operator of the well.

A P3D hydraulic fracture propagation model should be run to determine what needs to be mixed and pumped into the well to achieve the optimum values of propped fracture length and fracture conductivity. The base data set should be used to make a base case run. Then, the engineer determines which variables are the most uncertain. Many times, the values of *in-situ* stress, modulus, permeability, fluid loss coefficient, for example, are not known with certainty and have to be estimated. The design engineer acknowledges these uncertainties and makes sensitivity runs with the P3D model to determine the effect of these uncertainties on the design process. As databases are developed, the number and magnitude of the uncertainties will diminish.

In effect, the design engineer should fracture treat the well many times on his or her computer screen. Making these sensitivity runs will (1) lead to a better design and (2) educate the design engineer on how certain variables affect the ultimate values of both the created and the propped fracture dimensions. Such designs will be comprehensive, will consider uncertainties, and will be developed using professional processes.

Fracturing Fluid Selection

A critical decision by the design engineer is the selection of the fracture fluid for the treatment. Economides *et al.* [24] developed a flow chart that can be used to select the category of fracture fluid on the basis of factors such as reservoir temperature, reservoir pressure, the expected value of fracture half-length, and a determination if the reservoir is water sensitive. Their fluid selection flow chart for a gas well is presented in Fig. 14.

Most productive coal seam reservoirs are less than 5000 ft deep. The permeability in highly cleated coal seams decreases with increasing depth and overburden stress. At depths greater than about 5000 ft, in most cases, the coal seam does not have enough permeability to be economically developed.

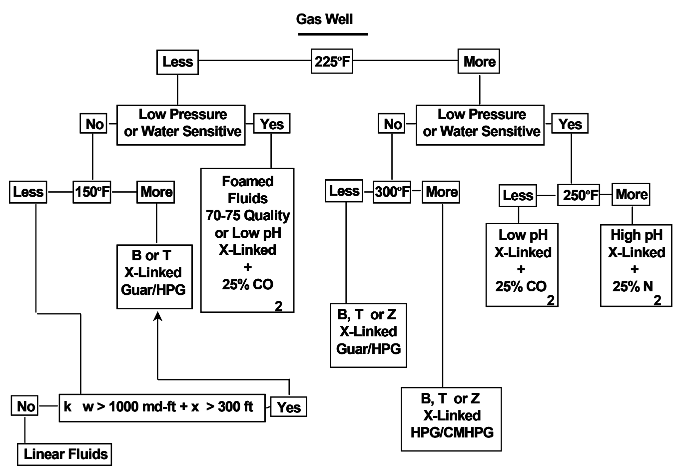

Fig. 14 – Selecting a fracture fluid.

Because most productive coal seams are shallow, low temperature reservoirs, then the choice of fracturing fluid (according to Fig. 14) will be (1) N_2 foam for low pressure reservoirs, (2) linear water based fluids if all you need is a short, low conductivity fracture, or (3) cross-linked gel if you need a wide or long fracture. Holditch *et al.*[14] discussed the criteria for selecting a fracturing fluid in the Gas Research Institute's Coal Seam Stimulation Manual.

For thick highly cleated coals, a crosslinked fluid should be used to create wide fractures and place as much proppant as possible in the fractures close to the wellbore. The purpose of the treatment is to link up the cleats to the wellbore using the hydraulic fracture and the proppant. The fluid should use the minimum amount of gel possible and breaker should be used to minimize damage to the fracture, and to assist in cleanup.

If the fracture is intended to connect up several thin coal seams that are vertically scattered up and down the wellbore, then coil tubing can be used to selectively stimulate each coal seam. Fig. 15 illustrates how coil tubing can be used to stimulated multiple intervals, one at a time.

- Single or multiple fracturing stimulation using coiled tubing as a conduit for both the isolation and the treatment.

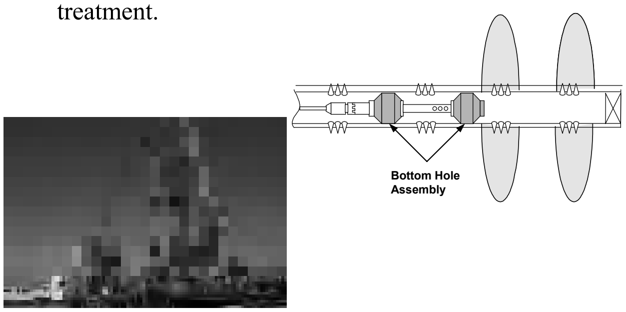

Fig. 15 – Fracturing using coil tubing.

In low-pressure coal seams, N_2 foam can be used as the fracture fluid. Foamed fracture fluids will create wide fractures, can transport the propping agent, and are easier to clean up than fluids that do not contain N_2.

Propping Agent Selection

Economides *et al.* [24] also produced a flow chart for selecting propping agents. Their chart is included as Fig. 16. Because most productive coal seams are shallow, sand is always used as the propping agent. In certain cases, where proppant flow back becomes a problem, then resin-coated sand is sometimes used. Special care must be used to design such treatments, because at low temperature, it may be difficult to get the resin to set and to create the consolidated sand pack needed to prevent proppant flow back.

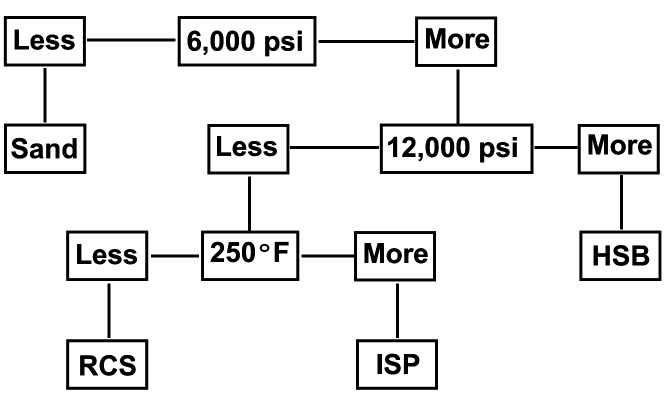

Fig. 16 - Proppant selection based on closure pressure.

To determine the optimum fracture conductivity, the design engineer should use the dimensionless conductivity (Cr) concept published by Cinco-Ley [25].

$$C_r \quad \frac{P_i \; K \; L_f}{wk_f} \qquad \text{Eq. 2}$$

where w is the fracture width (ft), k_f is the proppant permeability (md), k is the formation permeability (md), and L_f is the fracture half-length. To minimize the pressure drop down the fracture, the value of Cr should be approximately equal to ten (10).

For example, in a coal seam, if the formation permeability is 25 md, and the optimum fracture half-length is 50 ft, then the optimum fracture conductivity would be 3,927 md-ft. The engineer needs to design the treatment to create a fracture wide enough, and pump proppants at concentrations high enough to achieve the high conductivity required to optimize the treatment.

Some engineers tend to compromise fracture length and conductivity in an often-unsuccessful attempt to prevent damage to the formation around the fracture. Holditch[26] showed that substantial damage to the formation around the fracture can be tolerated as long as the optimum fracture length and conductivity are achieved. Ideally, the design engineer can create the optimum fracture length and conductivity while minimizing damage to the formation. If the opposite occurs, that is, the formation is not damaged, but the fracture is not long enough or conductive enough, then the well performance will be disappointing.

The operator of the well should always evaluate the risks such as mechanical risks, product price risks and geologic risks. Uncertainties in the input data can be evaluated by making sensitivity runs using both the reservoir models and the fracture propagation models. One of the main risks in hydraulic fracturing is that the entire treatment will be pumped and/or paid for (i.e. the money is spent), but for whatever reason, the well does not produce at the desired flow rates nor recovers the expected cumulative recovery. Many times, mechanical problems with the well or the surface equipment cause the treatment to fail. Other times, the reservoir does not respond as expected.

To evaluate the risk of mechanical or reservoir problems, the design engineer can use 100% of the costs on only a fraction of the revenue in the economic analyses. For example, say one (1) in every five (5) fracture treatments in a certain formation is not successful. Then one can use 80% of the expected revenue and 100% of the expected costs to determine the optimum fracture length. An illustration of how such an analyses can alter the desired fracture length is presented in Fig. 17.

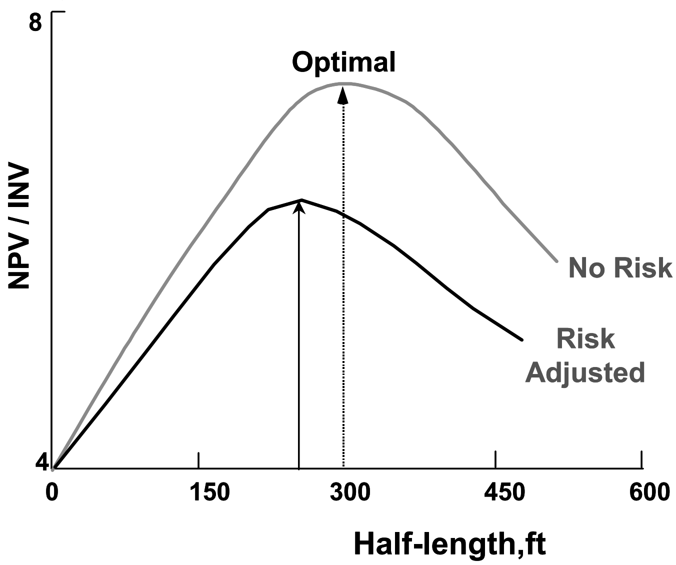

Fig. 17 – Economic analysis.

Finally, after the optimum, risk adjusted fracture treatment has been designed, it is extremely important to be certain the optimum design is pumped correctly into the well. For this to occur, the design engineer and the service company should work together to provide quality control before, during and after the treatment is pumped. The best engineers tend to spend sufficient time in the office to design the treatment correctly, then go to the field to help supervise the field operations (or provide on-site advice to the supervisor).

7. Post-Fracture Well Behavior

The original fracture treatments in the 1950's were designed to increase well productivity. These treatments were normally pumped to remove damage in moderate to high permeability wells. McGuire and Sikora[27] and Prats[28] published equations that were used for many years to design fracture treatments that resulted in desired folds of increase in the productivity index of a well. The productivity index of an oil well is

$$J = \frac{q_o}{\left(p_e - p_{wf}\right)} \qquad \text{Eq. 3}$$

and for a gas well is

$$J = \frac{q_g \quad \mu\, z}{\left(p_e^2 - p_{wf}^2\right)} \qquad \text{Eq. 4}$$

J is the productivity index in terms of barrels per psi per day or mcf per psi squared per day. The viscosity and compressibility are included in the equation for productivity index of a gas well, because they are pressure dependent.

Assuming J is the productivity index for a fractured well at steady state flow, and Jo is the productivity index of the same well under radial flow conditions, Prats[28] found that

$$\frac{J}{J_o} = \frac{\ln\left(\frac{r_e}{r_w}\right)}{\ln\left(\frac{r_e}{0.5\,L_f}\right)} \qquad \text{Eq. 5}$$

for a well containing an infinite conductivity fracture whose fracture half-length is L_f. Prats found that a well with a fracture half-length of 100 ft will produce as if the well had been drilled with a 100 ft diameter drill bit. In other words, the hydraulic fracture, if conductive enough, acts to extend the wellbore and stimulate flow rate from the well. If the dimensionless fracture conductivity, Cr (Eq. 2), is equal to 10 or greater, the hydraulic fracture will essentially act as if it is an infinately conductive fracture.

In coal seam reservoirs, the gas diffuses through the coal into the cleat system. If the cleat system is poorly developed and the permeability of the coal is low (<<1md), then the coal reservoir will probably not be economic to produce because it is almost impossible to create long, conductive fractures in thin coal seams. Thus, most commercial coal seam reservoirs are highly cleated, moderate permeability (5md<k<100md) reservoirs. As such, short, conductive fractures are required and large volumes of fluids are not needed to stimulate highly cleated coal seam reservoirs. The object of a hydraulic fracture in a highly cleated coal seam is to connect the cleat system with the well bore using the hydraulic fracture fluids and proppants.

8.0 Fracture Diagnostics

Fracture diagnostics involves analyzing the data before, during and after a hydraulic fracture treatment to determine the shape and dimensions of both the created and propped fracture. Fracture diagnostic techniques have been divided into several groups.[29]

Group 1 – Direct far field techniques

Direct far field methods are comprised of tiltmeter fracture mapping and microseismic fracture mapping techniques. These techniques require delicate instrumentation that has to be emplaced in boreholes surrounding and near the well to be fracture treated. When a hydraulic fracture is created, the expansion of the fracture will cause the earth around the fracture to deform. Tiltmeters can be used to measure the deformation and to compute the approximate direction and size of the created fracture. Surface tiltmeters are placed in shallow holes surrounding the well to be fracture treated and are best for determining fracture orientation and approximate size. Downhole tiltmeters are placed in vertical wells at depths near the location of the zone to be fracture treated. As with surface tiltmeters, downhole tiltmeter data can be analyzed to determine the orientation and dimensions of the created fracture, but are most useful for determining fracture height. Tiltmeters have been used on an experimental basis to map hydraulic fractures in coal seams.[11]

Microseismic fracture mapping relies on using a downhole receiver array of accelerometers or geophones to locate microseisms or micro-earthquakes that are triggered by shear slippage in natural fractures surrounding the hydraulic fracture. The principle of microseismic fracture mapping[29] is illustrated in Fig. 18. In essence, noise is created in a zone surrounding the hydraulic fracture. Using sensitive arrays of instruments, the noise can be monitored, recorded, analyzed and mapped.

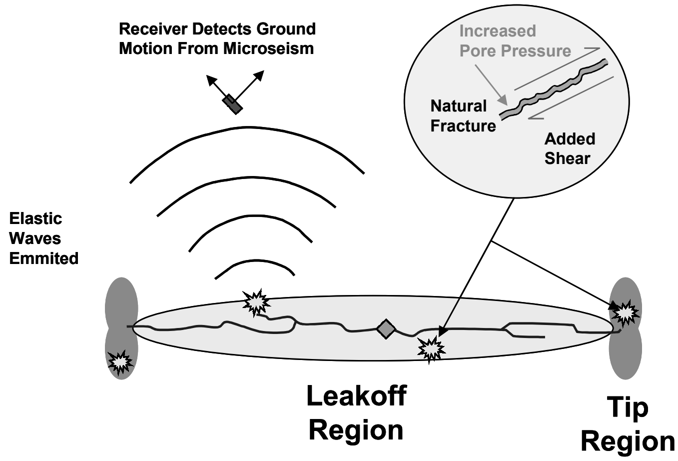

Fig. 18 – Principle of microseismic fracture mapping.

Tiltmeters have been used extensively in the oil and gas industry for more than 10 years, although it has only been recent that the technology has been available to look at fractures at depths greater than 4,000ft. Current surface tiltmeter technology can see below 10,000ft. Microseismic monitoring has traditionally been too expensive to be used on anything but research wells, but its cost has dropped dramatically in the past few years, so although still expensive (on the order of $50,000 to $100,000), it is being used more commonly throughout the industry. As with all monitoring and data collection techniques, however, the economics of marginal wells makes it difficult to justify any extra expense. If the technology is used at the beginning of the development of a field, however, the data and knowledge gained are often used on subsequent wells, effectively spreading out the costs.

Group 2 – Direct near-wellbore techniques

Direct near-wellbore techniques are run in the well that is being fracture treated to locate or image the portion of fracture that is very near (inches) the wellbore. Direct near-wellbore techniques consist of tracer logs, temperature logging, production logging, borehole image logging, downhole video logging, and caliper logging. If a hydraulic fracture intersects the wellbore, these direct near-wellbore techniques can be of some benefit in locating the hydraulic fracture.

However, these near-wellbore techniques are not unique and can not supply information on the size or shape of the fracture once the fracture is 2-3 wellbore diameters in distance from the wellbore. In coal seams, where multiple fractures are likely to exist, the reliability of these direct near-wellbore techniques are even more speculative. As such, very few of these direct near-wellbore techniques are used on a routine basis to look for a hydraulic fracture.

Group 3 – Indirect fracture techniques

The indirect fracture techniques consist of hydraulic fracture modeling of net pressures, pressure transient test analyses, and production data analyses. Because the fracture treatment data and the post-fracture production data are normally available on every well, the indirect fracture diagnostic techniques are the most widely used methods to determine the shape and dimensions of both the created and the propped hydraulic fracture.

The fracture treatment data can be analyzed with a P3D fracture propagation model to determine the shape and dimensions of the created fracture. The P3D model is used to history match the fracturing data, such as injection rates and injection pressures. Input data, such as the *in-situ* stress and permeability in key layers of rock can be varied (within reason) to achieve a history match of the field data.

Post-fracture production and pressure data can be analyzed using a 3D reservoir simulator to estimate the shape and dimensions of the propped fracture. Values of formation permeability, fracture length and fracture conductivity can be varied in the reservoir model to achieve a history match of the field data.

The main limitation of these indirect techniques is that the solutions are not very unique and require as much fixed data as possible. For example, if the engineer has determined the formation permeability from a well test or production test prior to the fracture treatment, so that the value of formation permeability is known and can be fixed in the models, the solution concerning values of fracture length become more unique. Most of the information in the literature concerning post-fracture analyses of hydraulic fractures has been derived from these indirect fracture diagnostic techniques.

Limitations of fracture diagnostic techniques

Warpinski discussed many of these same fracture diagnostic techniques.[30] Table 6, from Warpinski's paper, lists certain diagnostic techniques and their limitations. In general, fracture diagnostics is expensive and only used in research wells. Fracture diagnostic techniques do work and can provide important data when entering a new area or a new formation. However, in coal seam wells, where costs must be minimized to maintain profitability, fracture diagnostic techniques are rarely used and are generally cost prohibitive.

Table 6 – Limitations of Fracture Diagnostic Techniques

Parameter	Technique	Limitation
Fracture Height	Tracer logs	Shallow depth of investigation; shows height only near the wellbore
Fracture Height	Temperature logs	Difficult to interpret; shallow depth of investigation; shows height only near wellbore
Fracture Height	Stress profiling	Does not measure fracture directly; must be calibrated with *in-situ* stress tests
Fracture Height	P3D models	Does not measure fracture directly; estimates vary depending on which model is used
Fracture Height	Microseismic	Optimally requires nearby offset well; difficult to interpret; expensive
Fracture Height	Tiltmeters	Difficult to interpret; expensive and difficult to conduct in the field
Fracture Length	P3D models	Length inferred, not measured; estimates vary greatly depending on which model is used
Fracture Length	Well testing	Large uncertainties depending upon assumptions and lack of prefracture welltest data
Fracture Length	Microseismic	Optimally requires nearby offset well; difficult to interpret; expensive
Fracture Length	Tiltmeters	Difficult to interpret; expensive and difficult to conduct in the field
Fracture Azimuth	Core techniques	Expensive to cut core and run tests; multiple tests must be run to assure accuracy
Fracture Azimuth	Log techniques	Requires open hole logs to be run; does not work if natural fractures are not present
Fracture Azimuth	Microseismic	Analysis intensive; expensive for determination of azimuth
Fracture Azimuth	Tiltmeters	Useful only to a depth of 5000 ft; requires access to large area; expensive

9.0 Nomenclature

CMHPG	=	Carboxymethylhydroxypropyl-guar
HEC	=	Hydroxyelthycellulose
HPG	=	Hydroxypropylguar
ISIP	=	Instantaneous shut-in pressure
ISP	=	Intermediate strength proppant
k	=	Formation permeability, md
KCL	=	Potassium chloride
KGD	=	Kristonovich, Geertsma, Daneshy
L_f	=	Fracture half-length, ft
LWP	=	Light weight proppant
MEOH	=	Methanol
MRO	=	Memory readout gauge
NH_4CL	=	Ammonium chloride
PKN	=	Perkins, Kern, Nordgren
RSC	=	Resin coated sand
SRO	=	Surface Readout gauge
wk_f	=	Fracture conductivity, md-ft
α	=	Biot's constant
ν	=	Poissons' ratio
σ_{ext}	=	Tectonic stress
σ_{min}	=	Minimum horizontal stress (*in-situ* stress)
σ_{ob}	=	Overburden stress
σ_p	=	Reservoir fluid pressure or pore pressure
σ_1	=	Vertical (overburden) stress
σ_2	=	Minimum horizontal stress
σ_3	=	Maximum horizontal stress

Quality Assurance Plan: Evaluation of Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reservoirs

The U.S. Environmental Protection Agency (EPA), bases environmental protection efforts on the best available scientific information and sound science. The credibility of the resulting policy decision depends, to a large extent, on the strength of the scientific evidence on which it is based. Sound science can be described as organized investigations and observations conducted by qualified personnel using documented methods and leading to verifiable results and conclusions (SETAC, 1999).

This Quality Assurance Plan for data collection and evaluation describes the procedures the Agency used for a systematic and well-documented, graded approach to realizing the goal for the "Evaluation of Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reservoirs." The goal of Phase I of EPA's hydraulic fracturing study was to assess the potential for contamination of USDWs due to the injection of hydraulic fracturing fluids into CBM wells and to determine based on these findings, whether further study is warranted. This Quality Assurance Plan (developed following the guidelines of EPA publication 240/B-01/003) guides the production of a set of data and scientific findings that are sound, with conclusions supported by the data.

1.0 Project Management

This section of the Quality Assurance Plan addresses the basic area of project management, including the project history and objectives, and roles and responsibilities of the participants.

1.1 Project and Task Organization

Overall project management was provided by the EPA's Office of Water, Groundwater and Drinking Water (OGWDW), Groundwater Protection Division. Data was gathered by an EPA OGWDW contractor.

The contractor compiled the gathered data into a draft summary report, reviewed the draft report, and submitted the draft report to EPA and other federal agencies for review. After the contractor addressed comments from EPA and other federal agencies, EPA submitted the draft report to a Peer Review Panel for their comments (see Table B-1 for a list of the members of the Peer Review Panel). Following receipt of comments from the Peer Review Panel, EPA and its contractors responded to those comments. The availability of the report for stakeholder review and comment was announced in the *Federal Register* on August 28, 2002.

Table B-1: Peer Review Panel

Name	Affiliation	Education	Experience
Morris Bell	Engineer, Colorado Oil and Conservation Commission	Engineering Degree, University of Oklahoma	Closely involved with coalbed methane development in the San Juan and Raton Basins. Has investigated water well complaints and directed projects to test water wells. Worked for Amoco as a production engineer, drilling and completing tight gas wells. Also worked as a consultant, specializing in the completion and evaluation of coalbed methane wells.
Peter E. Clark	Associate Professor, Dept. of Chemical Engineering and Material Science, University of Alabama	Ph.D., University of Oklahoma State University	Specializes in complex fluid flows and hydraulic fracturing. Has taught several courses in the Chemical Engineering, Mineral Engineering, Engineering Mechanics, and Civil Engineering Departments. These courses included fluid mechanics, petroleum rock and fluids, well completion, drilling, and natural gas engineering.
David Hill	Manager, Engineering Resources, Gas Technology Institute (GTI)	MBA, Northwestern University; BS, Marietta College, Petroleum Engineering	Expertise includes unconventional reservoirs (e.g., coalbed methane, gas shales, tight sands); hydraulic fracturing; and reservoir evaluation in technical, managerial, and marketing aspects of technology development, deployment, and commercialization. Has authored and co-authored over 40 articles about oil- and gas-related research and development, and field-based operations.

Table B-1: Peer Review Panel

Name	Affiliation	Education	Experience
Buddy McDaniel	Technical Advisor for Production Enhancement Technology, Halliburton	B.S., Chemical Engineering, University of Oklahoma	Specializes in applications for highly deviated and horizontal wellbores and understanding of reservoir response to fracturing applications. Conducted research related to laboratory measurement of fracture conductivity of proppants under simulated reservoir conditions. Was actively involved in design and application of hydraulic fracturing treatments in soft chalks, deviated and horizontal wellbores, gas storage wells, geothermal wells, and conventional hydrocarbon reservoirs.
Jon Olson	Asst. Professor, Dept. of Petroleum and Geosystems Engineering, University of Texas at Austin	Ph.D., Stanford University, Applied Earth Sciences	Worked in the areas of fracture mechanics and coal geology and has published several papers on these subjects. Was employed by Mobil Exploration for several years as research engineer in the areas of rock mechanics, structural geology, and well performance.
Ian Palmer	Senior Petroleum Engineer, BP Amoco	Ph.D., University of Adelaide in Australia	Has worked extensively in coalbed methane extraction, including fracture design and prediction, rock mechanisms of coal, and openhole cavity completions. Also developed hydraulic fracturing models.
Norm Warpinski	Distinguished Member of Technical Staff, Sandia Laboratories	Ph.D., University of Illinois, Mechanical Engineering	Authority on hydraulic fracturing, geomechanics, poroelasticity, in situ stresses, and production mechanisms. Has expertise ranging from theoretical modeling and laboratory testing to field and in situ mineback experiments. Serves as project manager and lead scientist for a program to develop hydraulic fracture diagnostic technology for use in industry fracturing applications. Has published extensively on subject of hydraulic fracturing.

1.2 Problem Definition and Background

Hydraulic fracturing is a half century-old technology used in oil and natural gas production. The hydraulic fracturing process uses very high hydraulic pressures to initiate a fracture. A hydraulically induced fracture acts as a conduit in the rock or coal formation that allows the oil or coalbed methane to travel more freely from the rock pores (where the oil or methane is trapped) to the production well that can bring it to the surface.

After a well is drilled into a reservoir rock that contains oil, natural gas, and water, every effort is made to maximize the production of oil and gas. One way to improve or maximize the flow of fluids to the well is to connect many pre-existing fractures and flow pathways in the reservoir rock with a larger fracture. This larger, man-made fracture starts at the well and extends out into the reservoir rock for as much as several hundred feet. To create or enlarge fractures, a thick fluid, typically water-based, is pumped into the coal seam at a gradually increasing rate and pressure. Eventually the coal seam is unable to accommodate the fracturing fluid as quickly as it is injected. When this occurs, the pressure is high enough that the coal fractures along existing weaknesses within the coal. Along with the fracturing fluids, sand (or some other propping agent or "proppant") is pumped into the fracture so that the fracture remains "propped" open even after the high fracturing pressures have been released. The resulting proppant-containing fracture serves as a conduit through which fracturing fluids and groundwater can more easily be pumped from the coal seam.

To initiate coalbed methane production, groundwater and some of the injected fracturing fluids are pumped out (or "produced" in the industry terminology) from the fracture system in the coal seam. As pumping continues, the pressure eventually decreases enough so that methane desorbs from the coal, flows toward, and is extracted through the production well.

EPA is conducting a study to assess the potential for contamination of underground sources of drinking water (USDWs) due hydraulic fracturing fluid injection into coalbed methane wells. The study focuses on hydraulic fracturing used specifically for enhancing coalbed methane production. EPA, through its contractors and subcontractors, gathered information on the hydraulic fracturing process and requested comment from the public on contamination allegedly due to hydraulic fracturing practices. In this Phase I effort, EPA did not incorporate new, scientific fact finding, but used existing sources of information, and consolidated pertinent data in a summary report to serve as the basis for the study. EPA decided if additional research was required based on the findings from this effort.

1.3 Project and Task Description

The purpose of this project is to assist EPA in assessing the potential for contamination of USDWs from the injection of hydraulic fracturing fluids into coalbed methane wells, and to determine based on these findings if further study is warranted. EPA will use the information from this study in any regulatory or policy decisions regarding hydraulic fracturing. The first step in investigating the potential for hydraulic fracturing to affect the quality of USDWs was to define mechanisms by which contamination could occur.

EPA defined two hypothetical mechanisms by which hydraulic fracturing of coalbed methane wells could potentially impact USDWs:

1. Direct injection of fracturing fluids into a USDW in which the coal is located, or injection of fracturing fluids into a coal seam that is already in hydraulic communication with a USDW (e.g., through a natural fracture system).

2. Creation of a hydraulic connection between the coalbed formation and an adjacent USDW.

The objective of the project is to consider these two mechanisms, based on existing literature and data, when evaluating whether hydraulic fracturing fluid injection into coalbed methane wells could contaminate USDWs.

Information was collected regarding the geology and hydrogeology of the coalbed methane production regions, the processes used to hydraulically fracture coalbed methane production wells, and the fluids used in the fracturing process. EPA also evaluated water supply incidents possibly related to hydraulic fracturing of coalbed methane production wells. EPA relied on currently available literature and data as the primary source of information for project efforts.

1.4 Quality Objectives and Criteria

To ensure that findings are valid, the following quality assurance questions will be addressed for all sources of data:

- What was the purpose of the study?
- Whose data are they?
- What is their source?
- Are the data reliable?
- Is the interpretation biased?

This Quality Assurance Plan establishes a set of guidelines and general approaches to assess available data and information in a clear, consistent, and explicit manner. Data collection and review according to this process will make conclusions more transparent, and thus more readily understood and communicable to stakeholders.

The objectives of the systematic expert review of data and information are transparency, avoidance of bias, validity, replicability, and comprehensiveness. Following a data and information review protocol can ensure a common understanding of the task and adherence to a systematic approach. The components of this Quality Assurance Plan are as follows:

- Specification of the hypotheses to be addressed;
- Justification of the expertise represented in the expert investigators team;
- Specification of the methods to be used for identification of relevant studies, assessment of evidence of the individual studies, and interpretation of the entire body of available evidence (WHO, 2000);
- Review process; and
- Communication of findings.

Revisions to the Quality Assurance Plan may be necessary as new aspects of the task emerge during the study development process.

1.5 Special Training and Certification

To provide authoritative assessments of data and information, it is important to rely on expert investigators to evaluate the evidence, draw conclusions on the existence of actual and/or potential hazard, and estimate the magnitude of the associated risk. The team of expert investigators, that evaluated the evidence associated with this study, possesses the following qualifications:

- Formal training in basic scientific principles applicable to the project;
- Basic knowledge of the subject or the body of technical information pertaining to it;
- Experience in scientific review of technical data and information;
- Ability to use descriptive and analytical tools appropriately;
- Ability to design studies to test hypotheses;
- Ability to communicate results accurately to decision-makers and stakeholders; and
- Experience coordinating multiple tasks and disciplines to ensure timely and accurate delivery of study components.

The above-listed qualifications ensure that the project team was able to fulfill the objectives of this project.

1.6 Documents and Records

Documents produced for the project and submitted to EPA included the draft and final summary reports (hard copy and digital format). Information and records included in the data report package following completion of the project included:

- Maps (hard copies);
- Scientific literature (hard copies);
- Books (hard copies);
- Database search results (hard copies);
- Logbooks (hard copies); and
- Site visit notes and photographs (hard copies).

All the above-listed materials are maintained by the EPA OGWDW.

2.0 Data Generation and Acquisition

Processes and methods used to collect the data and information must be clear, explicit, and based on valid practice. It is important to adhere to a rigorous and thorough approach to the processes of data collection and data logging.

In Phase I, EPA did not incorporate new, scientific fact finding, but instead used existing sources of information, and consolidated pertinent data in a summary report to serve as the basis for the study. EPA decided if additional research is required based on the findings from this effort. As such, this Quality Assurance Plan does not cover areas of sampling process design, sampling methods, sample handling and custody, analytical methods, quality control, instrument/equipment testing, inspection, and maintenance, instrument/equipment calibration and frequency, and inspection/acceptance of supplies and consumables.

2.1 Non-Direct Measurements

All information summaries and conclusions developed during the course of this project were based on non-direct measurements. Available literature and data were used as the primary source of information for the summary report. An extensive literature search was conducted using the Engineering Index and GeoRef on-line reference databases. Searches will be guided by subject topics and key words within the following areas:

- Hydrogeology of the coalbed methane basins;
- Hydraulic fracturing practices;
- Fracture behavior;
- Hydraulic fracturing fluids and additives; and
- Information regarding water quality incidents.

All search results were printed, catalogued, and surveyed for pertinent journal articles, books and conference proceedings that may contain information meeting the specific data needs of the summary report. Most pertinent articles were acquired from the University of Texas Library in Austin, Texas, as this library's holdings include an extensive collection of oil and gas-related publications. References from the articles were researched and documents relevant to the study were acquired. All papers collected for the study were archived by topic for future reference.

To verify facts extracted from the literature, state regulatory agencies, geological surveys, gas companies, service companies and other relevant organizations were contacted by telephone. Dated telephone logs were used to document all communications. Personal conversations with the employees of the various organizations yielded additional information in the form of literature, figures and maps. These were collected and referenced in conjunction with literature identified in the literature searches.

Internet-based searches were used to locate additional information. Relevant web sites were located using various search engines such as Google™, Yahoo®, and Alta Vista®. More specialized search engines, such as those provided on state geological survey web sites, also were searched. All relevant web sites were logged and referenced appropriately. Efforts were made to acquire the most recent literature. EPA offered state drinking water agencies and the public an opportunity to provide information to EPA on any impacts to groundwater believed to be associated with hydraulic fracturing by a request for public comment. Submissions were reviewed by EPA staff for information pertinent to this report. In addition, a request to provide information and comments regarding incidents of public and private well impacts that could potentially be associated with hydraulic fracturing was published in the July 30, 2001 *Federal Register* (*Federal Register*: July 30, 2001; Volume 66; Number 146; Page 39395-39397).

Details on specific methods used to collect information for each of the major report chapters is included in Chapter 2 of this report.

2.2 Data Management

Gathered information and data was managed to facilitate finding any one piece of gathered data. To achieve this goal, the following data management procedures were used:

- All telephone interviews were recorded in labeled log books;
- All scientific literature, published maps, existing water quality data, conference proceedings, and trade journal articles were filed by coal basin;
- Material safety data sheets and product literature were filed separately;
- Trip folders (to contain notes and photographs) were generated for each site visit;
- Computer database searches were filed separately; and
- Internet websites were referenced in the summary report.

Most data was stored in hard copy format. Wherever possible, data was stored digitally on compact disc.

3.0 Assessment and Oversight

The quality assurance review process provides a means to examine if the results and conclusions are verifiable. The review process results in a determination of whether the conclusions are directly supported by the data or evidence gathered and can be independently validated by others. This quality assurance review process is hierarchical and includes four review levels:

- Weighted emphasis on data based on source;
- Cross referencing of data sources when possible;
- EPA and other federal agencies review; and
- Review by a Peer Review Panel.

EPA's review was accomplished by the Work Assignment Manager in conjunction with other EPA headquarter offices and with other EPA Underground Injection Control regional offices involved with coalbed methane or hydraulic fracturing. Other federal agencies asked to review work products produced by this project, included the United States Geological Survey and the Department of Energy.

EPA assembled a peer review panel consisting of experts in hydraulic fracturing or associated subjects. The panelists provided comments to EPA regarding the sources of data used in the study, the data themselves, and the conclusions drawn from those data.

Comments were requested to assist the investigators in making the study as sound as possible and to ensure that the study met EPA standards for objectivity, evidence, and responsiveness to the study charge. Reviewer comments and objections were preserved and made a part of the record for the study. Issue papers were written containing detailed explanations of responses to comments and objections. Reasons for proceeding or not proceeding with the study were clearly explained.

4.0 Data Validation and Usability

This section describes activities that occurred after the initial collection of data. These activities determined whether or not the gathered data were useful and helpful to the project.

4.1 Data Review, Verification, and Validation

Subsequent to the data logging process, those reports potentially providing useful information underwent a selection process to evaluate quality of the information and usefulness to the study. Systematic evaluation of the validity of individual studies, data, and information included assessment of the following:

- Source of the data and information;
- Qualitative review of the literature;
- Qualitative review of data and information collected;
- Scientific strength of the data and information;
- Geographical, geological, geochemical, spatial, and temporal relevance;
- Relevance to determining baseline conditions;
- Validity of extrapolation to the scope of the study;
- Characteristics of associations, plausibility, alternative explanations;
- Consistency and specificity of the results;
- Scientific uncertainties, limitations, and confounding variables; and

- Other evaluation parameters, as appropriate.

A scale or rating of the data and information with respect to a level of proof required to support conclusions is specifically not proposed as part of this quality assurance process. Establishing a specific level of scientific evidence required to justify a subsequent conclusion would generate significant controversy. Instead, expert judgment was used to evaluate and weigh available data and information.

A variety of technical methods and tools were utilized to sort through the pertinent information and decipher the meaning of the data. These data analysis methods may include:

- Quantitative review of selected data and information collected;
- Tabulating valid data and information;
- Constructing geologic cross sections;
- Evaluating current and historical site operations;
- Review of consistencies between studies;
- Review of sources of discrepancies between studies and information; and
- Other methods/tools as appropriate.

All assumptions were explicitly documented, the basis for the use of any models explained, lack of evidence noted, and scientific uncertainties described as precisely as possible.

4.2 Reconciliation with User Requirements

This sub-section describes how the gathered and validated data and information were used to meet the requirements of this project and EPA.

4.2.1 Drawing Conclusions

Drawing conclusions from evaluated, analyzed, and summarized data and information involve judgment as to whether observations are consistent with the study hypotheses/objectives, or, whether some alternative is suggested. The expert investigators drew upon all evaluated and appropriately summarized data and information; however, no checklist or formula was applied to arrive at conclusions. Instead, critical scientific reasoning and judgment was used to draw conclusions. The process of scientific reasoning and judgment was made explicit by describing and documenting how investigators:

- Assessed completeness of data and information;
- Accounted for lack of evidence and limitations, and impacts on the conclusions;
- Assessed and accounted for bias in original data and/or information;
- Used applicable guidelines and rationales;
- Used any ranges of estimates to arrive at conclusions, where appropriate and;
- Incorporated assumptions into assessments and accounted for the implications of those assumptions in their conclusions.

Conclusions were drawn within the boundaries of the data and the scope of the study. Lack or absence of evidence was addressed. The relative strength or weakness of available information to support conclusions, limitations on where a conclusion may apply, and alternative interpretations of data, was recognized. Any qualification on the use of the data and factors that contribute to uncertainty was conveyed.

Much of the information obtained from public response to the *Federal Register* Notice or from other sources cannot be confirmed through review of peer-reviewed publications or other data sources. However, the information was reviewed and contrasted to evaluate the extent of complaints received and any trends in the complaints within and between individual coalbed methane production basins.

4.2.2 Communication of Findings

This Quality Assurance Plan is reflected in the communication of scientific findings in a clear, accurate, and complete manner to interested parties. Investigators communicated:

- The body of technical information that was considered;

- The manner for evaluating, and drawing conclusions from, collected data and information; and

- Conclusions that address the hypotheses/objectives, supported by the results of data evaluation and analysis.

The use of presentation tools such as charts, diagrams, and computer-generated displays was based on sufficient, valid, and defensible data.

Attachment 1
The San Juan Basin

The San Juan Basin covers an area of about 7,500 square miles across the Colorado/New Mexico line in the Four Corners region (Figure A1-1). It measures roughly 100 miles long in the north-south direction and 90 miles wide. The Continental Divide trends north-south along the east side of the basin, and land surface elevations within the basin range from 5,100 feet on the western side to over 8,000 feet in the northern part.

The San Juan Basin is the most productive coalbed methane basin in North America. Coalbed methane production in the San Juan Basin totaled over 800 billion cubic feet (Bcf) in 1996 (Stevens et al., 1996). This number rose to 925 Bcf in 2000 (GTI, 2002). The coals of the Upper Cretaceous Fruitland Formation range from 20 to over 40 feet thick. Total net thickness of all coalbeds ranges from 20 to over 80 feet throughout the San Juan Basin. Coalbed methane production occurs primarily in coals of the Fruitland Formation, but some coalbed methane is trapped within the underlying and adjacent Pictured Cliffs Sandstone, and many wells are completed in both zones. Coalbed methane wells in the San Juan Basin range from 550 to 4,000 feet in depth, and about 2,550 wells were operating in 2001 (CO Oil and Gas Conservation Commission and NM Oil Conservation Division, 2001).

1.1 Basin Geology

The San Juan Basin is a typical asymmetrical, Rocky Mountain basin, with a gently dipping southern flank and a steeply dipping northern flank (Figure A1-2) (Stone et al., 1983). The Fruitland Formation is the primary coal-bearing unit of the San Juan Basin and the target of most coalbed methane production. Geologic cross sections showing generalized relationships between the Fruitland Formation and adjacent are shown in A1-4 through A1-6. The Fruitland coals are thick, with individual beds up to 80 feet thick. The Fruitland Formation is composed of interbedded sandstone, siltstone, shale, and coal. The stratigraphy of the Fruitland Formation is predictable throughout the basin, as follows:

- The thickest coalbeds are always found in the lower third of the formation;
- Pictured Cliffs Sandstone occurs immediately below the formation;
- Sandstone content is greater in the lower half; and
- Siltstone and shale predominate in the upper half (Choate et al., 1993).

The San Juan Basin may be subdivided into three unique regions, based on similar geologic, hydrologic, and production characteristics (Figure A1-7). These regions are denoted as Area 1, Area 2, and Area 3, and are described in more detail below (Kaiser and Ayers, 1994).

Area 1 consists of the northwestern quarter of the basin. Area 1 is characterized by the thickest (>20 feet) and highest-rank coal deposits in the San Juan Basin (Ayers et al., 1994). Most wells produce more than 1,000 cubic feet per day and several wells produce more than 15,000 cubic feet per day. Almost 90 percent of total methane production from the Fruitland Formation comes from three fields in a region of Area 1 known as the "Fairway" (Young et al., 1991; Ayers et al., 1994). Area 1 is an area of active recharge and in most places is hydrostatically over-pressured (greater than 0.50 pounds per square inch per foot). Wells in Area 1 usually produce moderate to large volumes of water, some of which meet the quality criteria of less than 10,000 milligrams per liter (mg/L) total dissolved solids (TDS) for an underground source of drinking water (USDW) (Kaiser et al., 1994).

Area 2 (the west-central region of the San Juan Basin) is hydrostatically under-pressured (0.30 to 0.50 pounds per square inch per foot) and is an area of regional groundwater discharge. Coalbeds are usually 7 to 15 feet thick, and occur primarily in northwest-trending belts that extend to the southwestern margin of the basin. Methane production from wells can be more than 100 thousand cubic feet per day, and a few wells produce 200 to 500 thousand cubic feet per day. Methane gas is produced water-free in this area as a consequence of the hydrostratigraphy and trapping mechanisms (Kaiser and Ayers, 1994). Additionally, Kaiser and Ayers (1994) suggest that water may be less mobile in the hydrophilic and low permeability coals. The Fruitland Formation in this area where it is under-pressured generally shows the presence of saline-type waters (Kaiser et al., 1994) that most likely have TDS concentrations greater than 10,000 mg/L, which does not meet the criteria for a USDW.

Area 3, the eastern region of the San Juan Basin, is hydrostatically under-pressured, and features low permeability and low hydraulic gradient, which suggests slow water movement within most of the aquifer. Only a few coalbed gas wells are located in this part of the basin, and they produce up to 8,000 cubic feet of methane per day, with little or no water content (Kaiser and Ayers, 1994). Produced waters from the Fruitland Formation in most of Area 3 have a high-salinity, resembling seawater (Kaiser and Ayers, 1994) in which TDS are too high to meet the water quality criteria of a USDW. However, along the southern margin of Area 3, TDS concentrations are less than 10,000 mg/L (Kaiser et al., 1994).

1.2 Basin Hydrology and USDW Identification

Tertiary sandstones and Quaternary alluvial deposits are present at the surface over much of the basin interior. These serve as the primary drinking water aquifers in the basin (Figure A1-2), and produced 55 million gallons per day in 1985 (Wilson, 1986). Cretaceous sandstones are an important source of water on the basin's periphery (Choate et al., 1993). The Paleocene Ojo Alamo Sandstone yields as much as 30 gallons per minute of potable water (Hale et al., 1965) and is mentioned as one of the primary drinking water aquifers of the region (Brown and Stone, 1979). Cleats and larger fractures in the Fruitland coals and the presence of interbedded permeable sandstones make the Fruitland Formation an aquifer and source of drinking water along the northern margin of the basin where TDS in the groundwater are less than 10,000. In most of Area 1, both the Fruitland Formation and the underlying upper Pictured Cliffs Sandstone act as a single hydrologic unit (Kaiser et al., 1994). The Fruitland and upper Pictured Cliffs Sandstone aquifer is underlain and confined by the low-permeability main Pictured Cliffs Formation and is overlain and partly confined by the Kirtland shale, which is up to 1,000 feet thick in the central basin. Overlying the Kirtland Formation is the Ojo Alamo Sandstone, (Figures A1-4, A1-5 and A1-6) which has been suggested as a possible source of groundwater for the municipality of Bloomfield (Stone et al., 1983). At Bloomfield, the coal and gas bearing Fruitland is separated from the Ojo Alamo aquifer by the Kirtland shale.

In the northern part of the basin, the Fruitland Formation and the underlying upper Pictured Cliffs Sandstone can be considered a single hydrogeologic unit on a regional scale because they exhibit the same hydraulic head and water quality characteristics and are the source of both the water and gas in the Pictured Cliffs sand tongues (Ayers and Zellers, 1994; Ayers et al., 1994). At the local scale, however, the two formations appear to exhibit poor hydraulic continuity, as evidenced by areas of over-pressuring (greater than 0.5 pounds per square inch per foot), abrupt changes in potentiometric surface (Figure A1-8), and upward flow (Kaiser et al., 1994). Discrete flow within individual units here is likely due to pinch out of thick, laterally extensive coal seams and truncation and offset of the beds by faults.

In general, groundwater is recharged along the Fruitland outcrops at the elevated, west, northern, and northwestern margins of the basin, and lateral flow converges primarily from the northeast and southeast toward upward discharge to the San Juan River valley (Kaiser et al., 1994). In the north, the Fruitland and upper Pictured Cliffs Sandstone aquifer system is confined by the overlying Kirtland shale, but it is poorly confined by the Kirtland in the central and southern portions of the basin. Water from the Fruitland discharges in the western part of the basin and migrates upward across the Kirtland shale into the Animas and San Juan Rivers (Stone et al., 1983). Generalized groundwater movement in the Fruitland system is shown in cross-section and plan view in Figures A1-9 and A1-10 (Kaiser and Swartz, 1988). The results of groundwater flow modeling for the entire basin (Kaiser et al., 1994) are shown in Figure A1-11.

In most of Area 1, the Fruitland system produces water containing less than 10,000 mg/L TDS, the water quality criteria for a USDW. Groundwater is usually freshest at the outcrop in recharge areas. The water dissolves salts and mixes with formation water as it flows, and the groundwater becomes increasingly saline as distance from the recharge source increases. The presence of low-salinity water at given locations in the San Juan Basin usually marks close proximity to the recharge source or the most permeable flow paths and implies a dynamic, active aquifer system (Kaiser et al., 1994). Figure A1-12 shows the chloride concentration of groundwater in the Fruitland Formation, and indicates that water nearest the northern recharge areas has a low dissolved solids and chloride content. Kaiser et al. (1994) reported that wells in the northern part of Area 1 produced water containing from 180 to 3,015 mg/L TDS. This was found to be the case over large portions of Area 1, especially within freshwater plumes resulting from areas of high permeability or fracture trends (Kaiser and Swartz, 1990; Oldaker, 1991).

Kaiser et al. (1994) conducted a water-quality sampling program in the San Juan Basin. Analyses taken from Fruitland coal wells in Area 1 show that the majority of wells (16 of 27 wells) produce water containing less than 10,000 mg/L TDS, (Figures A1-13a and A1-13b), although some nearby wells thought to be in less permeable zones produce water with higher TDS concentrations up to 23,000 mg/L (Kaiser et al., 1994). The boundary between waters with more and less than 10,000 TDS has not been published. Another group of wells throughout the same area was also sampled, but these wells were completed (constructed) in the adjacent and underlying Pictured Cliffs Sandstone bodies, which are in hydrologic communication with the Fruitland system (Kaiser et al., 1994).

Although from the above information it would seem that the Fruitland would be classified a USDW, the following additional information about disposal of brackish water produced along with the methane would seem to indicate that most of the water in the Fruitland would not meet the TDS criteria for USDW. Coalbed methane wells in the San Juan Basin produced from 0 to over 10,500 gallons of water per day, which contain from less than 300 mg/L TDS to over 25,000 mg/L (Kaiser et al., 1994; Kaiser and Ayers, 1994). Brackish water of various TDS concentrations and brine are produced in the over-pressured Area 1 of the basin while virtually no water is produced from coalbed methane wells in Areas 2 and 3 of the basin. Cox (1993) reported "Water disposal in the San Juan basin is a significant, long-term issue." In 1992, coalbed methane wells produced over 5 million gallons of water per day, and production was expected to increase to over 7.5 million gallons per day by 1995 (Cox, 1993). Produced water is disposed of by means of evaporation ponds, or, more commonly, by Class II injection into deeper zones such as the Entrada and Bluff sandstones, Morrison Formation, and Mesa Verde sandstone (Kaiser and Ayers, 1994). The authors estimated that injection wells cost up to $2 million each and Cox (1993) reported that 51 of them had been constructed in the basin by 1993.

Area 2 is primarily an area of groundwater discharge. The Fruitland coals and Pictured Cliffs Sandstone in Area 2 are in hydraulic communication and behave as a single aquifer. The aquifer is under-pressured (less than 0.50 pounds per square inch per foot), transmits groundwater from the northeast and southeast, and eventually discharges to the

Animas and San Juan rivers. The TDS of most samples from Area 2 ranges from 10,000 to 16,000 mg/L (Kaiser et al., 1994).

The Fruitland system in most of Area 3 contains slow-moving water with salinity approximately equal to that of seawater, greater than 25,000 mg/L TDS, (Kaiser and Ayers, 1994). In Area 3, the Fruitland and Pictured Cliffs are separate, confined aquifers. In the southeastern one-third of Area 3, the Kirtland shale is absent because of Tertiary-age erosion, and the Fruitland and Ojo Alamo Sandstone could be in hydraulic communication with one another (Figure A1-6). In this area Tertiary rocks, including the Ojo Alamo, are mapped by the United States Geological Survey (Figure A1-14) as an aquifer having water with TDSs ranging from 500 to 1,000 mg/L (Lyford, 1979).

At the basin's southern margin in Area 3, downward flow occurs from the Ojo Alamo through the Kirtland shale to the poorly confined Fruitland aquifer through which it then moves southward to outcrops at a lower elevation and northward to the San Juan River Valley (Kaiser et al., 1994) (Figure A1-11). Twenty-four of 26 water samples from the Fruitland/Pictured Cliffs aquifer system in the south margin of the basin reported by Kaiser and Swartz (1994) had less than 9,000 mg/L TDS (Figure A1-13e & A1-13f). Groundwater in the Fruitland Formation at the southern margin of the basin has less than 10,000 mg/L TDS because most recharge there comes from above the Kirtland formation, rather than from southward throughput from the Fruitland Formation.

1.3 Coalbed Methane Production Activity

Coalbed methane production occurs primarily in coals of the Fruitland Formation. However, some methane is absorbed in the underlying and adjacent Pictured Cliffs Sandstone, therefore many wells are completed in both zones. About 2,550 wells were operating in the San Juan Basin in 2001 (CO Oil and Gas Conservation Commission and NM Oil Conservation Division, 2001). All wells are vertical wells that range from about 500 to 4,000 feet in depth, and were drilled using water or water-based muds. Almost every well has been fracture-stimulated, using either conventional hydraulic fracturing in perforated casing or cavitation cycling in open holes (Palmer et al., 1993b). Total gas production was 925 Bcf in 2000 (GTI, 2002).

Cavitation cycling is a fracturing method unique to a small area of the north-central San Juan Basin called the "Sweet Spot," or Fairway, of Area 1 (Figure A1-15). Almost half of all San Juan wells are located within the Fairway area and utilize open-hole completions (no casing across the production interval) and cavitation cycling. Cavitation cycling is used in this area because coals are: 1) very thick (individual coals over 40 feet thick); 2) hydrostatically over-pressured (0.5 to 0.7 pounds per square inch per foot); and 3) relatively more permeable than the rest of the basin (and coals in other basins) (Palmer et al., 1993b). This method uses several mechanisms to link the wellbore to the coal fracture system. Cavitation cycling:

- Creates a physical cavity in the coals of the open-hole section (up to 10 feet in diameter);

- Propagates a self-propping, vertical, tensile fracture that extends up to 200 feet away from the wellbore (parallel to the direction of least stress); and

- Creates a zone of shear stress-failure that enhances permeability in a direction perpendicular to the direction of least stress (Palmer et al., 1993a; Khodaverian and McLennan, 1993) (Figure A1-16).

Cavitation is accomplished by applying pressure to the well using compressed air or foam, and then abruptly releasing the pressure. The over-pressured coal zones provide a pressure surge into the wellbore (a “controlled blowout”), and the resulting stress causes dislodgement of coal chips and carries the chips up the well. These cycles of pressure and blowdown are repeated many times over a period of hours or days, and the repeated, alternating stress-shear failure in the coal formation creates effects that extend laterally from the wellbore (Kahil and Masszi, 1984). The resulting vertical fracture is tensile in origin, that is, it results from a “pulling” force rather than the compressive forces that create conventional hydraulic fractures. Because the fracture is tensile in origin, the height of the fracture does not usually extend out of the target coal seam (Logan et al., 1989).

Wells outside the Fairway area utilize cased-hole, perforated completions that employ conventional hydraulic fracturing (Holditch, 1990). Palmer et al. (1993a) reported that hydraulic fracturing in the San Juan Basin uses between 55,000 to 300,000 gallons of stimulation and fracturing fluids and between 100,000 to 220,000 pounds of sand proppant. In the San Juan Basin, geologic conditions in conjunction with fracturing techniques usually produce vertical fractures much longer than they are high, for example, up to 400 feet radially and less than 150 feet high (e.g., Colorado 32-7 No. 9 well, La Plata County, CO; Mavor et al., 1991). The primary reasons for the controlled height of San Juan coalbed fractures are the thickness and close spacing of coal seams (obviating the need for excessive height), and the presence and petro-physical properties of the overlying Kirtland shale (which prevents inadvertent fracture excursion out of the Fruitland) (Jeu et al., 1988; Logan et al., 1989; Palmer and Kutas, 1991). Holditch (1993) reports that where the coal seam is not overlain by shale, hydraulic fractures in the San Juan Basin can grow into overlying beds.

Fassett (1991) found that coalbed methane could migrate into overlying USDWs near the northern outcrop, in areas where confining shale layers are absent. Because of these factors, hydraulic fracturing in the San Juan Basin may indirectly impact overlying USDWs near the Fruitland outcrop at the basin margins, where USDWs are in closer proximity and the Kirtland shale may be eroded. Near the northern and northwestern recharge zones, groundwater usually contains less than 3,000 mg/L TDS (Kaiser et al., 1994; Cox et al., 1995).

Fracturing and stimulation fluids utilized in the northern San Juan Basin include (Figure A1-17 and Table A1-1):

- Hydrochloric acid (12% to 28% HCl);
- Plain water;
- Slick water (water mixed with solvent);
- Linear gels (water and a thickener such as guar-gum or a polymer);
- Cross-linked gels with breakers (gels with additives to prevent fluid leak-off from the fracture, and "breaker" chemicals to reduce viscosity so that the gel can be produced back from the well after treatment); and
- Nitrogen and CO_2 foam (75 percent gas, 25 percent water or slick water, plus a foaming agent) since about 1992 (Harper et al., 1985; Jeu et al., 1988; Holditch et al., 1989; Palmer et al., 1993a; Choate et al., 1993)

Oilfield service companies supply the stimulation fluid used to fracture the well as part of the service. The chemical composition of many fracturing fluids may be proprietary, and EPA was unable to find complete chemical analyses of any fracturing fluids in the literature. Table A1-1 presents some data from the literature concerning the general chemical makeup of common San Juan fracturing fluids (Economides and Nolte, 1989; Penny et al., 1991). In addition, most gel fluids utilize a breaker compound (usually borate or persulfate compounds or an enzyme, at 2 pounds/1,000 gallons) to allow post-treatment thinning and easier recovery of gels from the fracture (e.g., Jeu et al., 1988; Palmer et al., 1993a; Pashin and Hinkle, 1997).

Many of the compounds listed in Table A1-1 are quite hazardous in their undiluted form. However, these compounds are substantially diluted prior to injection. Coalbed methane development by fracturing, and stimulation in the San Juan Basin are regulated by the Colorado Oil and Gas Conservation Commission and the New Mexico Oil and Gas Board. Based on an analysis of current regulations, neither agency regulates the type or amount of fluids used for fracturing (Colorado State Oil and Gas Board Rules and Regulations 400-3, 2001; New Mexico Energy, Minerals and Natural Resources Department, Oil Conservation Division Regulations Title 19, Chapter 15, 2001).

About half of the coalbed methane wells in Area 1 are located in the Fairway zone and feature "cavitation-cycling" completions (Palmer et al., 1993a) (Figure A1-15). Therefore, about half of the wells in Area 1 have probably been stimulated using conventional fracture treatments. Based on the well density of Area 1 in 1990 (Figure A1-18) compared to the 2001 well population (2,550 wells), it is estimated that between 700 and 1,000 coalbed methane wells have been fracture-stimulated in the USDW of Area 1.

It has been shown that methane can migrate from gas wells into aquifers along the northern margin of the basin, but this condition was remediated with improved gas well construction (Cox et al., 1995). In addition, wells completed in other aquifers in the outcrop area have been shown to produce water chemically and isotopically similar to Fruitland wells, implying communication between the formations (Cox et al., 1995).

1.4 Summary

Coalbed methane development and hydraulic fracturing in some of the northern portions of the San Juan Basin take place within a USDW. The waters of the Fruitland-upper Picture Cliffs aquifer and producing zone in Area 1 usually contain less than 10,000 mg/L TDS. Most waters in the northern half of Area 1 contain less than 3,000 mg/L, and wells near the outcrop produce water that contains less than 500 mg/L.

Each fracture stimulation treatment may inject, on average, approximately 55,000 to 300,000 gallons of stimulation and fracturing fluid per treatment. There are no state controls on the type, composition, or volume of fracturing fluid employed in each well or treatment. In contrast to conventional gas formations, the anisotropic nature of fracture permeability, the volume of treatment fluids employed, and the height and proppant distribution in coalbed fractures may prevent the effective recovery of fracturing fluids during subsequent production.

The potential for fracturing to cause or allow degradation of water in aquifers adjacent to the producing zones seems relatively remote in the currently active gas producing fields, but the potential for such degradation varies in different parts of the basin. It has been shown that methane can migrate from gas wells into aquifers along the northern margin of the basin, but this condition was corrected with improved gas well construction. There is little potential for fracturing to create communication between the Fruitland-upper Picture Cliffs aquifer and the Ojo Alamo aquifer over much of the basin because the aquifers are separated by the poorly permeable Kirkland shale. However, the Kirkland varies greatly in thickness and forms a leaky hydrogeologic barrier when it is thinner. In the eastern part of the basin, the Kirkland Formation has been eroded and the Ojo Alamo lies disconformably and directly upon the Fruitland Formation, potentially allowing fracturing to cause hydraulic communication between the saline waters of the Fruitland and the fresh waters (500 to 1,000 mg/L) of the Ojo Alamo.

Table A1-1. Chemical Components of Typical Fracture/Stimulation Fluids Used for San Juan Coalbed Methane Wells

Type of Stimulation Fluid	Composition	pH
Hydrochloric acid	12% to 28% HCl water solution	<1-3
"Slick" water	miscible or immiscible solvent as viscosity reducer (% unknown)	NA
Diesel oil	NA	NA
Nitrogen and CO_2 foam	75 % gas, 25 % water or slick water, plus a foaming agent)	NA
Gels[1]		
R-F	3% resorcinol, 3% formaldehyde, 0.5% KCl, 0.4% $NaHCO_3$	6.5
Pfizer Flocon 4800	0.4% xanthan, 154 ppm Cr^{3+} (as $CrCl_3$), 0.5% KCl	4.0
Marathon MARCIT	1.4% polyacrylamide (HPAM), 636 ppm Cr^{3+} (as acetate), 1% NaCl	6.0
DuPont LuDox SM	10% colloidal silica, 0.7% NaCl	8.2
CPAM crosslinked with Pfizer Floperm 500	0.4% cationic polyacrylamide (CPAM), 1520 ppm glyoxal 2% KCl	7.3
Drilling Specialties HE-100 Crosslinked	0.3% HPAM-AMPS, 100 ppm Cr^{3+} (as acetate), 2% KCl	5.0
Dowell YF-230	Hydroxypropylguar (HPG) x-linked with borate, persulfate with amine	NA

[1] Gels are typically mixed at a ratio of 40 lbs. per 1000 gal. water; compositions shown are "as mixed".

The Sand Wash Basin

The Sand Wash Basin is in northwestern Colorado and southwestern Wyoming. It is part of the Greater Green River Basin, which includes the Washakie Basin, the Great Divide (Red Desert) Basin, and the Green River Basin (Figure A10-1). These sub-basins are separated by uplifts caused by deformation of the basement rock. The Cherokee Arch, an anticlinal ridge that runs east to west along the Colorado/Wyoming border, separates the Sand Wash Basin from the adjacent Washakie Basin. The Greater Green River Basin, in total, covers an area of approximately 21,000 square miles. The Sand Wash Basin covers approximately 5,600 square miles, primarily in Moffat and Routt Counties of Colorado.

Coalbed methane resources in the Sand Wash Basin have been estimated at 101 trillion cubic feet (Tcf). Approximately 90 percent of this resource is within the Williams Fork Formation (Kaiser et al., 1993). Despite this ample resource, economic viability of recovery of the gas is limited by the presence of large volumes of water in most coalbeds. Presently, there appears to be no commercial production (GTI, 2002); however, approximately 120 permits for drilling within Moffat County were issued between February 2000 and August 2001 (Colorado Oil and Gas Commission, 2001). It is not clear exactly how many of these permits were related to coalbed methane exploration and production.

10.1 Basin Geology

The geologic history of the Sand Wash Basin is relatively complex, characterized by periods of deposition followed by deformation related to tectonic activity. This activity has impacted depositional patterns, coal occurrence and maturity, and hydrology (Tyler and Tremain, 1994). A very thorough discussion of the geologic history of the Sand Wash Basin is available in Tyler and Tremain (1994).

The coal-bearing formations in the region include the Iles, Williams Fork, Fort Union, and the Wasatch Formations (Figure A10-2). These formations were deposited, from bottom to top, during the Upper Cretaceous, Paleocene and upper Paleocene periods. The total thickness of the coal seams in these formations can measure up to 150 feet (Quarterly Review, 1993). Basement rock formations in the Sand Wash Basin can be as deep as 17,000 feet (Tyler and Tremain, 1994). A map of the coal and geologic features is presented in Figure A10-3a and a conceptual cross-section is presented in Figure A10-3b.

The Sand Wash Basin was near the western edge of the Western Interior Seaway that spreads across what is now central North America during the Upper Cretaceous (Figure

A10-4). During the late Cretaceous the seaway retreated to the northeast. Intermontane basins developed during the Laramide, and coal-bearing fluvial-lacustrine sediments were deposited (Quarterly Review, 1993). The coal in the Sand Wash Basin was formed from peat deposited in swamps along a broad coastal plain. Sediments that eroded from nearby uplift formations covered the peat beds (Tyler and Tremain, 1994). The alternating deposition of organic material and sands was repeated many times creating layers of coal interbedded with layers of sandstone and other sedimentary rocks that filled the basin.

Cretaceous or Mesaverde Group coal in the Sand Wash Basin ranges in rank from sub-bituminous along the basin margins to high volatile A bituminous coal in the deeper parts of the basin. These ranks are indicative of moderately mature to well-developed mature coal formed under high pressure and high heat. Within the Mesaverde Group, the most important potential coalbed methane resource in the basin (Kaiser et al., 1993), the coal ranks from sub-bituminous along the basin margins to medium volatile bituminous in the basin center (Kaiser et al., 1993). The methane in these coals formed both biogenically (by bacterial action on organic matter), and thermogenically (under high temperature). The average gas content of 261 coal samples collected during two studies was 147 standard cubic feet of methane per ton of coal (Boreck et al., 1977; Tremain and Toomey, 1983). Some samples from the Sand Wash Basin have been found to contain as much as 540 standard cubic feet of methane feet per ton. Gas content has generally been found to increase somewhat with depth. At depths of less than 1,000 feet, gas content is typically less than 20 standard cubic feet per ton, which has been taken to indicate that gas probably leaked out of the shallow coalbeds into the atmosphere. Analysis of gas samples has indicated that the gas is typically 90 percent methane, the remainder being mostly nitrogen and carbon dioxide (Scott, 1994). Carbon dioxide content ranges from 1 to more than 25 percent (Scott, 1994).

Of all the coal-bearing formations, the Upper Cretaceous Williams Fork is the most significant unit because it contains the thickest and most extensive coalbeds. The Williams Fork Formation is within the Mesaverde Group that also includes the Almond Formation along the Wyoming state line (Tyler and Tremain, 1994). The Almond Formation is shown (Figure A10-2) as a separate formation overlying the Williams Fork (Tyler and Tremain, 1994), but is also reported (Kaiser et al., 1993) to be a lateral equivalent of the upper Williams Fork Formation found in the southern Sand Wash Basin. For more information relative to this apparent conflict see Kaiser et al. (1993, p. 29). The coal-bearing Williams Fork Formation outcrops along the southern and eastern margins of the basin, and may be deeper than 8,000 feet in the deepest part of the basin (Figure A10-3b). The coals are interbedded with sandstones and shale. The thickest total coal deposits in the Williams Fork Formation, up to 129 feet, are centered near Craig, CO. This total is made up of several separate coalbeds up to 25 feet thick interbedded with sedimentary rock.

Stratigraphically above the Williams Fork Formation, the Paleocene Fort Union Formation, which includes sandstone, siltstone, shale, and coal, is also a potentially productive zone for coalbed methane production. The Fort Union outcrops at the Elkhead Mountains east of the basin and along the southern and western parts of the basin. The bottom of the Fort Union Formation is about 7,000 feet below the surface. Net coal thickness can be up to 80 feet with as many as nine individual beds. Individual beds up to 50 feet thick have been identified.

The Wasatch Formation includes beds of shale and sandstone and minor amounts of coal. It can extend as deep as 2,000 feet below the surface. The Wasatch Formation has not been targeted for coalbed methane development because of the small quantity of coal.

10.2 Basin Hydrology and USDW Identification

Regional groundwater flow in the Sand Wash Basin is from east to west and to the northwest towards the center of the basin. Water enters the aquifers at the exposed outcrops along the southern and eastern margins of the basin and moves northwestward. Vertical movement of groundwater, including potential artesian conditions, is dependent on local geologic conditions. Kaiser and Scott (1994) summarized their extensive investigation of groundwater movement within the Fort Union and Mesaverde Group. The Mesaverde Group is a highly transmissive aquifer. The coalbeds along with associated sandstone beds within the group may be the most permeable part of the aquifer. The Williams Fork Formation contains sandstone beds that are reported to be excellent aquifers (Brownfield, 2002). Lateral flow within the Fort Union Formation is slower, in part, owing to less permeable fluvial sandstones in the unit.

Total dissolved solids (TDS) concentrations of groundwater in the Mesaverde Group were investigated by Kaiser and Scott (1994) (Figure A10-5). They found that chloride concentrations ranged from 290 milligrams per liter (mg/L) in the eastern area of the basin near the outcrops where water enters the aquifers, to more than 26,000 mg/L in the central part of the basin. Calcium showed a similar pattern of distribution with the lowest concentrations near the outcrops, increasing toward the basin center. Calcium concentrations ranged from 10 mg/L to over 2900 mg/L. Based on the chloride and calcium concentrations presented by Kaiser and Scott (1994), the water in the aquifers near the recharge areas at the basin margins meets the water quality criteria for an underground source of drinking water (USDW) of less than 10,000 mg/L, but the water in the deeper central part of the basin does not (Figure A10-5). The mapped outcrop area (Figure A10-3a) of the Mesaverde Group indicates that the coal seam lies within a USDW where it is relatively shallow and close to the eastern and southern margins of the basin.

10.3 Coalbed Methane Production Activity

Coalbed methane resources in the Sand Wash Basin have been estimated at 101 Tcf. Approximately 90 percent of this gas is in the Williams Fork Formation (Kaiser et al., 1993). Approximately 24 Tcf of coalbed methane are located at depths less than 6,000 feet below ground surface (Kaiser et al., 1994). Despite this ample resource, economic viability of recovery of the gas is limited by the presence of large volumes of water in most coalbeds. Exploration in the 1980s and 1990s led to limited commercial use of the resource. Records from the Colorado Oil and Gas Commission indicate that approximately 31 million cubic feet of coalbed methane was produced in Moffat County during 1995 (Colorado Oil and Gas Commission, 2001). From 1996 to 1999 (the last year that data are available), no further gas was produced in this County (Colorado Oil and Gas Commission, 2001). However, Colorado Oil and Gas Commission records indicate that approximately 120 permits for drilling within Moffat County were issued during the period from February 2000 through August 2001 (Colorado Oil and Gas Commission, 2001). It is not clear exactly how many of these permits were related to coalbed methane exploration and production, but a handful of the permits were issued to gas companies, and the permits are listed as targeting known coalbeds within specific methane producing formations (Colorado Oil and Gas Commission, 2001).

At Craig Dome in Moffat County, Cockrell Oil Corporation drilled a 16-well development for exploration in the Williams Fork Formation. According to the Colorado Geological Survey, Craig Dome is located along the Cedar Mountain fault system (Colorado Geological Survey, 2002). The wells were abandoned a short time later because of excessive water. The Colorado Geological Survey indicated that the fault system may act as a conduit for anomalously high water migration from the outcrop. An average total of 40 feet of high-volatile bituminous coal was encountered in beds up to 15 feet thick. Gas content was tested at 10 to 350 cubic feet per ton of coal. Wells were cased through the target coalbed, perforated, and hydraulically fractured using water and sand. The wells yielded large volumes of fresh water with TDS levels measuring less than 1,000 mg/L, but little gas (Colorado Oil and Gas Commission, 2001). Water was removed at an average of 21,756 gallons per day per well during testing. Based on records from the Colorado Oil and Gas Commission, Cockrell Oil Corp does not appear to be involved currently with coalbed methane production in this region (Colorado Oil and Gas Commission, 2001).

The Colorado Geological Survey also indicated that faults in Trout Creek Canyon southeast of Craig are on trend with (and thus are likely to be related to) the Cedar Mountain fault system (Colorado Geological Survey, 2002). In addition, KLT Gas Inc. has a pilot program southwest of Craig Dome on the Breeze lease which is on trend with the Cedar Mountain fault system. If a fracture propagates into and along a fault plane, it may contaminate a USDW (Colorado Geological Survey, 2002.)

Limited commercial success has been experienced in the basin. As of 1993, only one commercial operator, Fuelco, was working in the basin. Fuelco was operating 11 wells along Cherokee Arch at 40 to 80 acre spacing. Well depths were to 2,500 feet. A total of 40 feet of coal was found in the Almond Formation (Mesaverde Group) between 810 to 2,360 feet. All wells were cased through the coal, selectively perforated, and stimulated using water and sand. Gas production averaged a total of 50,000 cubic feet per day from four wells. The highest producing well peaked at 100,000 cubic feet per day (Quarterly Review, 1993). Total production of gas through 1993 from the Dixon Field, the only producing field in this region, was about 84 million cubic feet (Kaiser et al., 1993). Total water production for the four wells was high at 126,000 gallons per day due to the high permeability of the coal (Quarterly Review, 1993). Water pumped from the wells contained 1,800 mg/L of TDS and was discharged to the ground with a National Pollution Discharge Elimination System permit (Quarterly Review, 1993).

The Sand Wash Basin has been used by the University of Texas Bureau of Economic Geology in the development of its Coalbed Methane Producibility Model (Kaiser et al., 1994). The development of the model was based on a comparison of basins that included the Sand Wash Basin and the San Juan Basin of southwestern Colorado and northwestern New Mexico. The San Juan Basin has proven to be a very productive coalbed methane resource. The Sand Wash Basin was used as an example of a basin with low potential for productivity (Figure A10-6) (Kaiser et al., 1994).

Hydraulic fracturing has been used in the Sand Wash Basin to improve the flow of gas into the wells. Hydraulic fracturing fluids have typically consisted of water with sand used as a proppant. However, very little information was available regarding specific types and volumes of fluids and proppants used. No indication of the use of other materials was noted in the sources reviewed (Colorado Oil and Gas Commission, 2001).

10.4 Summary

Coalbeds containing methane gas are present within the Sand Wash Basin at accessible depths. Some investigation and very limited commercial development of this resource have occurred, mostly in the late 1980s and early 1990s. There appears to be no commercial production at present. Development of coalbed methane resources in the Sand Wash Basin has been slower than in many other areas due to limited economic viability. The need for extensive dewatering in most wells has been a limiting factor, compounded by relatively low gas recovery.

Between 1996 and 1999, no coalbed methane was produced in Moffat County. Permits for new gas wells have been issued indicating that there may be some continued interest in this area (Colorado GIS, 2001).

Groundwater quality in the basin varies greatly. Typically, chloride and calcium concentrations within the coal-bearing Mesaverde Group are low and potentially within potable ranges in the eastern and southern parts of the basin, implying the existence of a USDW, and therefore the potential for impacts. Concentrations increase as the water migrates toward the central and western margins of the basin. TDS concentrations significantly higher than the 10,000 mg/L USDW water quality standard have been detected in the western portion of the basin.

Compared to other potentially productive areas of the country, very little information has been published regarding current developments, groundwater location and conditions, drilling techniques, etc. The level of information available seems to be commensurate with the amount of commercial activity.

The use of fracturing fluids, specifically water and sand proppant, has been reported for this basin. No record of any other fluid types has been noted. Although variable, the water quality within the fractured coals indicates the presence of USDWs within the coalbeds.

Attachment 11
The Washington Coal Region (Pacific and Central)

The Pacific Coal Region (Figure A11-1) is approximately 6,500 square miles and lies along the western and eastern flanks of the Cascade Range from Canada into northern Oregon. The coals along the western flank lie within the Puget downwarp. Bellingham, Seattle, Tacoma, and Olympia in the State of Washington, and Portland, Oregon lie in or adjacent to the sub-basins. Choate et al. (1980) estimated coalbed methane resources for four target sub-basins (Figure A11- 1) representing 1,800 square miles of the 6,500 square mile Pacific Coal Region to be 0.3 trillion to 24 trillion cubic feet (Tcf). The Central Coal Region (Figure A11-2) is primarily the Columbia Plateau, between the Cascade Range to the west and the Rocky Mountains in Idaho, to the east. The Region extends from the Okanogan Highlands in the north to the Blue Mountains to the south, and encompasses approximately 63,320 square miles. Pappajohn and Mitchell (1991) estimated the coalbed methane potential of the Central Coal Region to be more than 18 billion cubic feet (Bcf) per square mile. According to the available literature, there were no producing fields in either the Pacific Coal Region or the Central Coal Region in Washington as of 2000 (GTI, 2001).

11.1 Basin Geology

A series of discontinuous coal fields lie along the western flank of the Cascade Range (Figure A11-3). The Roslyn and Taneum-Manastash fields are located on the eastern flank of the Cascade Range (Figure A11-3). The coal-bearing sediments were formed in a swampy fluvial-deltaic coastal plain depositional environment in the Paleocene to late Eocene Eras. In the Columbia Plateau Region, the Cretaceous to Eocene coal-bearing rocks are buried beneath a thick sequence of extrusive basalts.

The coal-bearing deposits of the Pacific and the Central Coal Regions are Cretaceous to Eocene Age and formed within fluvial and deltaic depositional environments prior to the uplift of the Cascade Mountain Range. The coalbeds of the Pacific and Central Basins are thought to result from peat accumulations in poorly drained swamps of the lower deltas while the thinner coalbeds probably formed in the better drained upper deltas (Buckovic, 1979 as cited in Choate et al., 1980). During the Oligocene, Cascade volcanic activity buried the deltaic sediments and compression caused some deformation of the sediments. During the Miocene, extensive volumes of basalt poured out in central Washington and covered the coal-bearing fluvial deposits. During the late Pliocene, the Coast Range and the Cascades continued to be uplifted, separating the Pacific Coal Region from the Central Coal Region, and causing extensive tectonic deformation, folding and faulting, of the coal-bearing sediments.

Deformation of the coal-bearing rocks increases toward the Cascade front. Fracturing may enhance porosity and permeability of the coalbeds, allowing greater methane storage and production (Pappajohn and Mitchell, 1991). On the other hand, however, fracturing may also increase the porosity and permeability of confining beds, allowing methane to escape up the stratigraphic section over time and dissipate in the atmosphere. Continuing deformation, primarily faulting, may be a limiting factor controlling methane production in the Pacific Coal Region as well.

11.1.1 Pacific Coal Region Geology

In the Pacific Coal Region, deformation has increased geologic complexity making it difficult to follow or correlate coalbeds, especially across faults. Geothermal heating along the western flank of the Cascades created a thermally altered zone of increased coal rank ranging into the bituminous and anthracite ranks. The maturation to bituminous rank increases potential methane yields (Walsh and Lingley, 1991; Pappajohn and Mitchell, 1991).

The major coal-bearing areas are in, from north to south, Whatcom, Skagit, King, Pierce, Kittitas, Thurston, Lewis, and Cowlitz Counties in Washington (Figure A11-3). The discussion of regional geology presented here illustrates the geologic conditions in the Green River district in King County, the Wilkerson-Carbonado coalfield in Pierce County, and the Centralia-Chehalis district in northern Lewis and southern Thurston Counties, and does not attempt to provide a detailed description of every coalfield. For more detailed information on the Bellingham area, Whatcom County, the reader is referred to Beikman et al. (1961), for Whatcom and Skagit Counties to Jenkins (1923 and 1924), and for the Roslyn coal area to Walker (1980). Other areas not discussed but important within the Pacific Region are the Toledo-Castle Rock District, and the Roslyn-Cle Elum and Teneum-Manastash fields. The stratigraphy for three sub-basins (Green River, Wilkerson-Carbonado, and Centralia-Chehalis) of the Pacific Coal Region is presented in Figure A11-4. The general setting and geology of each sub-basin is unique and complex.

The coal deposits of King County are located southeast of Seattle (Figure A11-3). The Green River district is the largest and most extensively mined coal-bearing area in King County. The King County coals occur in the Puget Group of Eocene Age (Figure A11-4). Evans (1912) divided the Puget Group into 3 coal zones, which, from oldest to youngest, are the Bayne, Franklin, and Kummer. Deformation has been moderate and most of the coalbeds dip less than 35 degrees. In parts of the Green River district the deformation has been more intense, and dips of 50 degrees or more are common. The King County coals range in rank from subbituminous to high-volatile bituminous. Within the Green River District, the Puget Group is estimated to be at least 6,500 feet thick and contains at least 15 coalbeds up to 40 feet thick (Beikman et al., 1961). The principal coalbeds are located in the Franklin and Kummer zones in the Puget Group (Vine, 1969). Coal has been mined in the Green River District since about 1883, and it has produced more than 25 million tons of coal. Currently there is no coal production in the district.

The Wilkerson-Carbonado coalfield is located in Pierce County, southeast of Seattle (Figure A11- 3). The Pierce County coals occur in the Eocene Carbonado Formation (Beikman et al., 1961). The Carbonado consists of more than 5,000 feet of interbedded, layered lenses of sandstone, siltstone, mudstone, and shale with carbonaceous shale and coal (Figure A11-4). At least 10 coalbeds have been identified in the area. Coalbeds range in thickness from 1 to 5 feet with the maximum thickness of 15 feet. The coals range in rank from high-volatile bituminous to low-volatile bituminous. The Wilkerson-Carbonado coals have the highest rank of any major coal-bearing area in Washington State. Throughout the field, deformation has been intense. Dips of 60 degrees or more are common, and fault displacements range from a few feet to more than 1,500 feet. Although these areas have recently been targets of coalbed methane exploration, there is currently no production.

The coal deposits of Lewis and Thurston Counties occur in the Skookumchuck Formation (Figure A11-3) of late Eocene Age (Snavely et al., 1958). The Centralia-Chehalis district is located in northern Lewis and southern Thurston Counties (Figure A11-3). Deformation of the Skookumchuck is moderate resulting in tightly folded anticlines and broad open synclines. The coal deposits have been cut by a series of high angle reverse faults roughly paralleling the fold axes. The faults dip to the northeast, with the southwest block downthrown, and have displacements ranging from 200 to 500 feet. The coal rank ranges from lignite to anthracite. The central part of the Centralia-Chehalis district contains as many as 14 subbituminous coalbeds ranging from a few inches to over 40 feet in thickness. The district contains more than half of the calculated coal reserves of the State. The TransAlta Centralia Mining Company continues to operate a major strip mine centered about 5 miles northeast of Centralia, where it is anticipated that 9,400 acres will be stripped over 35 years. Within the Centralia mine, the Big Dirty bed is more than 40 feet thick. To the west of Centralia, the Vader coal area contains several lignite beds with thickness up to 20 feet, which may correlate in part with the coals in the Centralia-Chehalis area.

In Whatcom and Skagit counties (Figure A11-3), the Chuckanut Formation contains as many as 15 coalbeds, ranging from 1 to 15 feet thick and ranking from lignite to anthracite, but generally bituminous. The rank of the coal increases eastward towards the crest of the Cascades Range.

The rank of Pacific Region coals varies greatly from place to place, ranging from lignite to anthracite, but generally rank increases toward the crest of the Cascade Range. The coal rank is used to identify bituminous coal-target areas where gas yields may be greatest. While the structural geology is very complex, the thermally-altered metamorphic zone is rather predictable. Both of these factors will play a major role in the design of any exploration and development plans for coalbed methane in the Pacific Coal Region.

The complex stratigraphy and structural deformation of the lenticular coals in the Pacific Coal Region are major obstacles to the exploration and development of coalbed methane fields. Predicting the location of coalbeds is a complex and difficult process because the geology in the area has been modified by intense deformation. Additionally, the faulting that commonly occurs along the axes of anticlines may form conduits for the escape of methane through overlying confining beds. Steeply dipping beds of coal have presented difficulties in controlling drill bit directions and in development and stimulation for coalbed methane production.

Choate et al. (1980) estimated coalbed methane resources for four target sub-basins (Figure A11-1), representing 1,800 square miles of the 6,500 square mile Pacific Coal Region, to be 0.3 trillion to 24 Tcf. Methane had been encountered in 67 oil and gas exploration wells drilled in this region by 1984. Methane gas was found at depths of less than 500 feet in 25 wells, less than 1,000 feet in 38 wells, and less than 2,000 feet in 50 wells. In western Whatcom County, methane has been found in unconsolidated glacial drift capped by impervious clay beds. East of Ferndale, methane gas reportedly has been produced commercially from unconsolidated deposits at depths ranging from 166 to 193 feet at flow rates ranging from 750,000 to 5,000,000 cubic feet per day (Choate et al., 1980).

11.1.2 Central Coal Region Geology

The Central Coal Region refers to the coal-bearing formations east of the Cascade Range. The Columbia River Basalt Group, primarily the Grande Ronde Basalt, Wanapum Basalt, and Saddle Mountains Basalt bury the Cretaceous to Eocene coal-bearing formations of the Central Coal Region. In this region, methane is entrained in groundwater from confined aquifers in the basalts. Interbedded with the flood basalts are epiclastic and volcaniclastic sediments. The less fractured zones of basalt appear to act as aquitards (Johnson et al., 1993). Johnson et al. (1993) have concluded that the greatest volume of methane is derived from upward migration from the underlying Eocene coals. They also suggest that faults through the underlying sediments and basalts provide conduits for the migration of gas-bearing groundwater into the confined zones.

The Yakima fold belt lies between the confluence of the Snake and Columbia Rivers and the Cascade Range, and is a series of broad asymmetric anticlines and synclines whose axes generally trend west northwest to east southeast (Figure A11-5). The anticlinal ridges are typically cut by thrust faults that are inclined and steepen with depth (Reidel et al., 1989). While the anticlines may form structural traps for methane in the source coalbeds, the thrust faults in the anticlines may form conduits for the upward migration of methane through overlying confining beds. The fold structures are very flat and broad and do not result in the steeply dipping strata that are characteristic of the Pacific Coal Region west of the Cascades.

11.2 Basin Hydrology and USDW Identification

Surficial deposits of Pleistocene glacial outwash locally form aquifers capable of sustaining public drinking water supplies in the Pacific and Central Washington Regions. In the Central Coal Region, aquifers in the basalts are extensively developed for irrigation. Public water supplies in Pierce County (Olympia area) and King County (Seattle area) of the Puget Sound Region (Pacific Coal Basin) are obtained from the glacial drift aquifer (Dion, 1984) that overlies Eocene sediments, which may contain coal and methane. Water quality information from four gas test wells indicates the presence of 1,330 to 1,660 milligrams per liter (mg/L) total dissolved solids (TDS) in water within the coalbeds of Pierce County (Dion, 1984). This meets the water quality requirements of an underground source of drinking water (USDW). The Washington Department of Ecology and the EPA deemed this water to be of sufficient quality to permit its discharge to surface waters of the Carbon River (Pappajohn and Mitchell, 1991).

The Columbia River Basalt Group is identified as a major regional multi-aquifer province (Lindholm and Vaccaro, 1988; Dion, 1984). The aquifer is used extensively for irrigation, but may also be used as a source of drinking water. Wells in the Basalts commonly yield 150 to 3,000 gallons per minute. TDSs in the water produced generally range from 250 to 500 mg/L (Dion, 1984).

The occurrence of methane in groundwater is one factor leading to the assessment of the coalbed methane production potential in Washington. Methane in groundwater occurs in the basalts, but only in confined aquifers (porous or fractured zones near the top or bottom of a basalt layer), and is thought to have migrated upward from underlying coalbeds. Water supply wells and irrigation wells in the Columbia River Basalts and water wells in numerous different lithologies in the Pacific Coal Region have been recognized as containing methane. Data demonstrating the co-location of a coal seam and a USDW were found for Pierce County, where methane gas test well results report TDS levels far lower than the 10,000 mg/L USDW water quality threshold (Dion, 1984).

11.3 Coalbed Methane Production Activity

Complex stratigraphy and structural deformation creates major obstacles to the development of gas from the Pacific Coal Region. The coals are known from active and inactive mines to be gassy, folded, faulted, and commonly steeply inclined. The difficulties and dangers involved with underground coal mining led to closure of the mines once the shallow deposits were exhausted. However, their characteristics have been well documented by the mining operations. Many of these same structural characteristics have impeded the development of coalbed methane gas. The available literature indicates that no significant production had been achieved by 1996 (GRI, 1999). According to the available literature, there were no producing fields in either the Pacific Coal Region or the Central Coal Region in Washington as of 2000 (GTI, 2001). However, in northwest Oregon, the Mist gas field was developed in the 1990s.

11.3.1 Pacific Coal Region Production Activity

Between 1986 and 1993, 19 coalbed methane wells were drilled in the northern Pacific Coal Region (Quarterly Review, 1993). Three tests were conducted near the town of Black Diamond in the Green River coal area of King County. One of the wells was hydraulically fractured and the others completed by open-hole cavitation. Steep dips of the strata led to wellbore deviation during drilling and to caving following the fracturing operations. One well produced 32,000 to 62,000 cubic feet per day of coalbed methane gas with no water in an open-hole test. Another was hydraulically fractured with 12/20 mesh sand and nitrogen foam in two zones at depths of 2,228 to 2,442 feet and 2,505 to 2,638 feet, but no test results were released. Caving was so prominent that it interfered with wellbore cleanup following the hydraulic fracturing operations. According to available publications, optimal fracturing and completion methods for use in the structurally difficult Pacific Coal Region are yet to be applied and proven.

11.3.2 Central Coal Region Production Activity

The one commercial gas field (Rattlesnake Hills) in the Central Coal Region was shut down in 1941. Production from the Cretaceous to Eocene coalbeds that lie below the basalts may have large potential. Pappajohn and Mitchell (1991) estimated the coalbed methane potential of the Central Coal Region to be more than 18 Bcf per square mile. It is unlikely that the whole 63,320 square miles of the region could yield that rate because the coals are only known to occur below the basalts in the western part of the basin. Much is not known about the potential coalbed methane production from these obscured deposits, and development depends on successful exploration.

Although the coals of the Central Coal Region may not be as greatly deformed and unpredictable as those in the Pacific Coal Region, they are overlain by the Columbia River Basalt Group, in which individual basalt flows up to 300 feet thick can cover thousands of square miles. The Rattlesnake Hills gas field operated between 1913 and 1941 in the western part of this region and indicates greater potential for development.

11.4 Summary

The geologic structure of the coal-bearing rocks is difficult to interpret in the Pacific and Central Coal Regions, and methane may be technically difficult to produce in these regions. A connection exists between the Washington coalbeds and a USDW. However, there were no producing coalbed methane wells in the Pacific and Central Coal Regions in Washington as of 2000 (GTI, 2001). In some areas, the Pacific and Central Regions' coals exist within a potential USDW. In other areas of the basin, there is evidence that the coalbeds are below a USDW. Hydraulic fracturing has been documented in this region. Data demonstrating the co-location of a coal seam and a USDW were found for Pierce County, where methane gas test well results report TDS levels of 1,330 to 1,660 mg/L, far less than the USDW classification limit of 10,000 mg/L (Dion, 1984).

In this region, methane occurs in groundwater flowing through fractured zones in basalts, although less fractured zone of the basalts appear to act as hydraulic confining layers. Johnson, et al. (1993) concluded that the greatest volume of this methane has migrated upward from underlying coalbeds. Water supply wells and irrigation wells in the Columbia River Basalts and water wells in numerous different lithologies in the Pacific Coal Region have been recognized as containing methane. Development of coalbed methane in the Washington Coal Region may have some impact on highly productive basalt aquifers that meet the requirements of a USDW and are already in use as large sources of irrigation water for agriculture.

Attachment 2
The Black Warrior Basin

The Black Warrior Basin covers an area of about 23,000 square miles in Alabama and Mississippi. The basin is approximately 230 miles long from west to east and approximately 188 miles long from north to south. Coalbed methane production in Alabama is limited to the bituminous coalfields of west-central Alabama, primarily in Jefferson and Tuscaloosa Counties.

Coalbed methane production in the Black Warrior Basin is among the highest in the United States. In 1996, approximately 5,000 coalbed methane wells were permitted in Alabama. In 2000, this number increased to over 5,800 wells (Alabama Oil and Gas Board, 2002). Coalbed methane well production rates range from less than 20 to more than one million cubic feet per day per well (Alabama Oil and Gas Board, 2002). Between 1980 and 2000, coalbed methane wells in Alabama produced roughly 1.2 trillion cubic feet of gas. According to the Gas Technology Institute (GTI), annual gas production was 112 billion cubic feet in 2000 (GTI, 2002).

2.1 Basin Geology

Coalbed methane production in the Black Warrior Basin (Figure A2-1) is contained within the Upper Pottsville Formation of Pennsylvanian age (300 million years). The depositional history along the ancient coastline of prehistoric Alabama was characterized by 8 to 10 "coal deposition cycles" of sea level rising and lowering. Each of these 10 geologic "coal deposition cycles" features mudstone at the base of the cycle (deeper water) and coalbeds at the top of the cycle (emergence) (Pashin and Hinkle, 1997).

The geologic structure of the Black Warrior Basin is complex. Due to erosion and structural uplift, not all of the coal zones are present at all locations (Pashin et al., 1991; Young et al., 1993). In general, however, most coalbed methane wells tap the Black Creek/Mary Lee/Pratt cycles, at depths that range from 350 to 2,500 feet deep (Holditch, 1990).

Alabama coalbeds are typically very thin, ranging from less than 1 inch in thickness to 4 feet (in rare cases they may be up to 8 feet thick in surface mines) (Horsey, 1981; Heckel, 1986; Eble et al., 1991; Carrol et al., 1993; Pashin, 1994) (Figure A2-2). In the area of coalbed methane development, the Pottsville Formation exists at or near the surface, and the depth to commercial coalbeds ranges from the surface outcrop to 3,500 feet, depending on location (Figure A2-3).

2.2 Basin Hydrology and USDW Identification

In the location where coalbed methane development is taking place in west-central Alabama, the Pottsville Formation is an unconfined aquifer. The matrix permeability of Pottsville rocks (e.g., mudstone, cemented sandstone) is low, but water is present and flows within an extensive system of faults, fractures, and joints. Flow patterns within the Pottsville Formation are strongly controlled by fault- and fold-related isotropic joints and fractures (Koenig, 1989). The close spacing and systematic pattern of cleats, however, make coalbeds the most productive aquifers within the Pottsville Formation (Koenig, 1989; Pashin et al., 1991; Pashin and Hinkle, 1997). In the early 1990s, several authors reported fresh water production from coalbed wells at rates up to 30 gallons per minute (Ellard et al., 1992; Pashin et al., 1991).

Most of the recharge to the Pottsville aquifer is precipitation that infiltrates from the surface, but some recharge occurs where streamflow enters the outcrop and moves laterally into the aquifer along folded anticlinal beds (Pashin and Hinkle, 1997) (Figure A2-4). Several researchers also propose upwelling of more saline waters from deeper zones, which takes place along vertical, fault-related, rubble zones (Pashin et al., 1991). Discharge from the Pottsville aquifer is primarily from the dewatering of coalbeds due to mining and coalbed methane production (Pashin et al., 1991).

Formation water produced from Alabama coalbed methane wells contains between less than 50 to over 10,000 milligrams per liter (mg/L) total dissolved solids (TDS) (Koenig, 1989; Pashin et al., 1991; Pashin and Hinkle, 1997). Some portions of the Pottsville Formation contain waters which meet the quality criterion of less than 10,000 mg/L TDS for an underground source of drinking water (USDW) (Figure A2-7). According to the Alabama Oil and Gas Board, some waters in the Pottsville Formation do not meet the definition of a USDW and have TDS levels which are considerably higher than 10,000 mg/L (Alabama Oil and Gas Board, 2002). Water quality generally decreases with increasing depth (Figures A2-7 and A2-8), and areally is related to the faulting pattern (Figure A2-9) (Pashin et al., 1991; Pashin and Hinkle, 1997). Waters exceeding 10,000 mg/L TDS can be found below 3,000 feet in areas near deep vertical faults, suggesting upwelling from deeper, more saline zones (Pashin and Hinkle, 1997).

2.3 Coalbed Methane Production Activities

Alabama coalbed methane wells are categorized into three distinct types. The first two types, "gob" wells and horizontal wells, are less common. Gob wells are associated with mines. The well is drilled to a depth above the mine roof, and when the mine is abandoned, the roof collapses. Gob wells produce coalbed methane from the fractured mine debris. A few horizontal wells are drilled from within mines to reduce coalbed methane concentration in advance of a working face. The third type, which includes 98 percent of all Alabama methane wells, includes vertically drilled wells that utilize mainstream oilfield technologies (Pashin and Hinkle, 1997). Because neither gob nor horizontal wells typically are hydraulically fractured, this discussion is limited to vertical wells.

According to literature, most coalbed methane wells are drilled using water or air rotary methods or water-based mud, due to lower cost and concerns that mud fluids will invade the coal. Wells in Alabama are completed with tubing. Water is pumped up the tubing for disposal, whereas gas is produced up the annulus. Wells are drilled to a depth 10 to 30 feet below the lowest coalbed to create a sump that collects coal fines and allows water to separate from the coalbed methane (Holditch, 1990).

About 95 percent of produced water is disposed by discharge into surface water, via Type II National Pollution Discharge Elimination System permits (O'Neil et al., 1989; O'Neil et al., 1993; Pashin and Hinkle, 1997). These permits require some water quality monitoring and limit instream water quality to 230 mg/L TDS (Pashin and Hinkle, 1997). Since 1991, about 5 percent of produced water has been injected for disposal into Class II injection wells (Pashin and Hinkle, 1997). Eight Class II wells are currently active (Alabama Oil and Gas Board, 2001), disposing coalbed waters into zones between 4,300 and 10,000 feet deep (Ortiz et al., 1993).

Most wells are completed in multiple coal zones using perforations. Some wells are completed in mudstones immediately below a coal zone, rather than within the coal ("limited entry" completions), and a few wells feature un-cased, open-hole completions. Each well is hydraulically fractured to allow communication with the thin coal seams outside of the casing, and most wells are fractured more than once as described below:

- In wells with multiple coal seams present, the hydraulic fracturing process may involve several or multiple stimulations, using 2 to 5 hydraulic fracture treatments per well (depending on the number of seams and spacing between seams); and,

- Many coalbed methane wells are re-fractured at some time after the initial treatment, in an effort to re-connect the wellbore to the production zones to overcome plugging or other well problems (remedial fracture-stimulation) (Holditch, 1990; Saulsberry et al., 1990; Palmer et al., 1991a and 1991b; Schraufnagel et al., 1991; Holditch, 1993; Palmer et al., 1993b; Spafford et al., 1993; Schraufnagel et al., 1993) (Figure A2-10).

The geometry of hydraulic fractures in coalbed methane zones usually differs from that observed in conventional oil and gas scenarios. In conventional hydrocarbon zones, the gas and/or oil are physically "trapped" by the presence of an impermeable confining layer, usually shale. Shale formations may present a barrier to upward fracture growth because of the stress contrast between the coalbed and the higher-stress shale (see Appendix A). Therefore, for conventional fracturing, the vertical growth of fractures out of the target zone may be limited by the presence (i.e., stress contrast) of overlying shales. In conventional gas-well fracture environments, fracture half-length (200-1,600 feet from the well bore) almost always exceeds fracture height (10-200 feet above the perforations). In the Black Warrior Basin, however, the lithologic properties and stress fields of the coal cycles typically produce fractures that are higher than they are long ("length" refers to horizontal distance from the well bore) (Morales et al., 1990; Zuber et al., 1990; Holditch et al., 1989; Palmer and Sparks, 1990; Jones and Schraufnagel, 1991; Steidl, 1991; Wright, 1992; Palmer et al., 1991b and 1993a).

In the Black Warrior Basin of Alabama, hydraulic fractures created in coalbed methane deposits are able to grow much higher than some fractures in "conventional" gas reservoirs. There are three primary reasons for this phenomenon:

- Due to coal's low modulus of elasticity (i.e., brittleness, stiffness) and complex fracture geometries, high pressures are required to fracture coal hydraulically (500 to 2,000 pounds per square inch (psi), or 0.7 to 2.0 psi/ft), and high treatment pressure often causes preferential extension of the fracture in the vertical dimension (Jones et al., 1987; Reeves et al., 1987; Morales et al., 1990; Palmer et al., 1991a);

- The economics of coalbed methane production in this basin requires tall fractures that penetrate several coal seams. The coal seams are typically thin (1 to 12 inches) and economically viable production requires the drainage of as many seams as possible. Because coal seams may be vertically separated by up to hundreds of feet of intervening rocks, operators usually design fracture treatments to enhance the vertical dimension and might perform several fracture treatments within a single well (Ely, et al., 1990; Holditch, 1990; Saulsberry et al., 1990; Spafford, 1991; Holditch, 1993); and,

- The other rocks within the Pottsville coal cycles (jointed mudstone and sandstone) fracture much more easily than coal (Teufel and Clark, 1981; Saulsberry et al., 1990; Jones and Scraufnagel, 1991; Spafford, 1991). Because there are no significant barriers to fracture height (Simonson et al., 1978; Ely et al., 1990; Palmer et al., 1991a), vertical fractures in the Black Warrior basin typically penetrate several thin coalbeds and hundreds of feet of intervening rocks (Teufel and Clark, 1981; Hanson et al., 1987; Holditch et al., 1989; Ely et al., 1990; Palmer et al., 1991c; Schraufnagel et al., 1991; Spafford, 1991; Palmer et al., 1993b) (Figure A2-11).

Mined-through studies in the Black Warrior Basin identified many instances where thin (less than 1-foot thick) shales overlying targeted coalbeds were fractured. Penetration into layers above the coal was observed in more than 80 percent of the fractures intercepted by mines underground in the Black Warrior Basin (Diamond, 1987b). Some fractures continued completely through very thin shales (Diamond, 1987a and b). These studies did not conduct a systematic assessment of the extent of the vertical fractures through and above the roof rock shales.

Several researchers conclude (based on pressure behavior during fracturing and several examples where mines penetrated hydraulic fractures) that shallow fractures have a horizontal component as described below:

- Fractures that are created at shallow depth typically have more of a horizontal component and less of a vertical component. The vertical component is most likely due to the presence of vertical natural fractures (cleats and joints) as pre-existing planes of weakness from which vertical fractures can initiate.

- Fractures created at a greater depth can propagate vertically to shallower depth, and develop a horizontal component. In these “T-fractures”, the fracture tip may fill with coal fines and/or intercept a zone of stress contrast, which causes the fracture to “turn” and to develop horizontally.

As noted above, penetration of the layers above the coal was observed in more than 80 percent of the fractures intercepted by mines underground in the Black Warrior Basin (Diamond, 1987b), but, as coals become shallower, the potential for fracture height growth decreases. In general, horizontal fractures are most likely to exist at shallow depths (less than 1,000 feet). As depths increase, it is more likely that a simple vertical fracture will occur (Gas Research Institute, 1995).

Sand is the most common proppant used in coalbed methane treatments in Alabama. The amount of sand injected per fracture treatment ranges from 10,000 to 120,000 pounds (Holditch et al., 1989; Palmer et al., 1991b and 1993a). Fracture widths in the formation vary from 0.5 inches to closed (i.e., no proppant emplaced), depending on distance from wellbore and efficiency of the proppant displacement into the length of the fracture (Palmer and Sparks, 1990; Palmer et al., 1993a; Steidl, 1993).

Fracturing fluid (30,000 to 200,000 gallons per treatment) is injected at a rate of 5 to 50 barrels per minute (which equals 210 to 2,100 gallons per minute) at injection pressures ranging from 500 to 2,300 psi (Palmer et al., 1989 and 1993b; Holditch et al., 1989; Pashin and Hinkle, 1997). The most common constituent of fracturing fluid is plain water. Several researchers conclude that approximately 75 percent of all coalbed methane wells in Alabama were fractured using cross-linked gel fluids (Palmer et al., 1993a; Pashin and Hinkle, 1997).

According to service companies, diesel fuel is no longer used as a component of fracturing fluids in Alabama. In addition, additives that could introduce chemicals exceeding maximum contaminant levels (MCLs) are no longer used in fracturing fluids in Alabama.

Table A2-1 presents some data concerning the general chemical makeup of common fracturing fluids used in Alabama from literature published prior to the Alabama hydraulic fracturing regulation (Economides and Nolte, 1989; Penny et al., 1991). In addition, most gel fluids utilize a breaker compound (usually a borate or persulfate compound or an enzyme, at 2 lb/1,000 gal) to allow post-treatment thinning and easier recovery of gels from the fracture. Several researchers conclude that approximately 75 percent of all coalbed methane wells in Alabama were fractured using cross-linked gel fluids (Palmer et al., 1993a; Pashin and Hinkle, 1997).

According to Hunt and Steele (1992), environmental regulations restrict local disposal of used fracturing fluids, and fracturing fluids are transported to regulated disposal sites. Robb and Spafford (1991) reported that acids were used to fracture production zones as shallow as 400 feet deep.

In fracture treatments of wells in homogeneous formations in conventional gas fields, injection is temporary and the majority of fracturing fluid is subsequently pumped back up through the well when production resumes.

There are limited data in the literature concerning the volume of fracturing fluids subsequently pumped back to the well after stimulation has ceased. Palmer et al. (1991b) found that only 61 percent of fracturing fluids were recovered during production sampling of a coalbed well in the Black Warrior Basin of Alabama, and projected that 20 to 30 percent would remain in the formation.

2.4 Summary

Coalbed methane development and hydraulic fracturing in the Black Warrior Basin of Alabama takes place within a USDW, the Pottsville formation. Some portions of the Pottsville Formation contain waters which meet the quality criteria of less than 10,000 mg/L TDS for a USDW. Some waters in the Pottsville Formation do not meet the definition of a USDW and have TDS levels that are considerably higher than 10,000 mg/L (Alabama Oil and Gas Board, 2002).

According to service companies, diesel fuel is no longer used as a component of fracturing fluids in Alabama. In addition, additives that could introduce chemicals exceeding MCLs are no longer used in fracturing fluids in Alabama.

In the Pottsville Formation, the lack of a significant vertical barrier can provide for extensive fracture height growth (Holditch et al., 1989; Lambert et al., 1989; Ely et al., 1990; Saulsberry et al., 1990; Palmer and Sparks, 1990; Spafford, 1991; Palmer et al., 1991a and 1993a; Spafford et al., 1993; Gas Research Institute, 1995). Mined-through studies in the Black Warrior Basin identified many instances where thin (less than 1-foot thick) shales overlying targeted coalbeds were fractured. Penetration into layers above the coal, which are typically shale, was observed in more than 80 percent of the fractures intercepted by mines underground in the Black Warrior Basin (Diamond, 1987b).

Table A2-1. Chemical Components Previously Used in Typical Fracturing/Stimulation Fluids for Alabama Coalbed Methane Wells

Type of Stimulation Fluid	Composition	pH
Fluids		
Hydrochloric acid	15% HCl water solution	<1-3
"Slick" water	water-soluble solvent as viscosity reducer (% unknown)	NA
Diesel oil	NA	NA
Gels[1]		
R-F	3% resorcinol, 3% formaldehyde, 0.5% KCl, 0.4% $NaHCO_3$	6.5
Pfizer Flocon 4800	0.4% xanthan, 154 ppm Cr^{3+} (as $CrCl_3$), 0.5% KCl	4.0
Marathon MARCIT	1.4% polyacrylamide (HPAM), 636 ppm Cr^{3+} (as acetate), 1% NaCl	6.0
DuPont LuDox SM	10% colloidal silica, 0.7% NaCl	8.2
CPAM crosslinked with Pfizer Floperm 500	0.4% cationic polyacrylamide (CPAM), 1520 ppm glyoxal, 2% KCl	7.3

Attachment 3
The Piceance Basin

The Piceance Coal Basin is entirely within the northwest corner of Colorado. (Figure A3-1). The coalbed methane reservoirs are found in the Upper Cretaceous Mesaverde Group, which covers about 7,225 square miles and ranges in thickness from about 2,000 feet on the west to about 6,500 feet on the east side of the basin (Johnson, 1989). It is estimated that 80 trillion to 136 trillion cubic feet (Tcf) of gas are contained in coalbeds within the basin (Tyler et al., 1998). Total coalbed methane production was 1.2 billion cubic feet in 2000 (GTI, 2002).

3.1 Basin Geology

The Piceance is a northwest trending asymmetrical, Laramide-age basin in the Rocky Mountain foreland with gently dipping western and southwestern flanks and a sharply upturned eastern flank (Figure A3-1) (Tremain and Tyler, 1997). The Douglas Creek Arch bounds the basin on the northwest, and separates it from the Uinta Coal Basin, which lies almost entirely in Utah. The Mesaverde Group is sharply upturned to near vertical along the Grand Hogback, which forms the eastern boundary of the basin and separates the basin from the White River uplift to the east. Most of the Piceance Basin's coal deposits are contained in the Iles and Williams Fork Formations of the Late Cretaceous Age Mesaverde Group, which are approximately 100 to 65 million years in age (McFall et al., 1986). These formations composed of sandstone and shale, were deposited in a series of regressive marine environments (McFall et al., 1986; Johnson, 1989). It is believed that the coals were deposited in marine transitional, brackish, interdistributary marshes and freshwater deltaic swamps (Collins, 1976 in McFall et al., 1986). Figure A3-2 presents a stratigraphic section shown with a gamma ray-induction log from the Barrett 1-27 Arco Deep well (Reinecke et al., 1991). The Mesaverde Group is underlain by the marine Mancos Shale and overlain by the lower Tertiary Age Fort Union and Wasatch Formations, which consist of fluvial sandstones and shales. The Mancos Shale, Fort Union, and Wasatch Formations are essentially barren of coals (McFall et al., 1986). Depths to the coal-bearing sediments vary from outcrops around the margins of the basin (Figure A3-1) to more than 12,000 feet in the deepest part of the basin (Tyler et al., 1996).

The major fold structure of the Piceance Basin is the Grand Hogback Monocline, formed as the White River Uplift was uplifted and thrust westward during the Laramide Orogeny in Late Cretaceous through Eocene time (McFall et al., 1986). Broad folds, such as the Crystal Creek and Rangley Syncline, trend northwest to southeast, and generally parallel to the axis of the basin (Figure A3-1). Intrusions occur throughout the southeast part of the basin, locally elevating coal ranks to as high as anthracite grade. A buried laccolith intrusion is thought to be present under a coal basin anticline along the southeast margin of the basin (Figure A3-1) where high quality coking coal was mined since the 1800s (Collins, 1976).

Coalbed methane reservoirs occur exclusively in the Upper Cretaceous Mesaverde Group (Figure A3-2), which covers an area of approximately 7,255 square miles (Tremain and Tyler, 1997). Depths to the Mesaverde Group range from outcrop to greater than 12,000 feet along the axis of the basin (Tyler et al., 1996; Tremain and Tyler, 1997). Two-thirds of the coalbed methane occurs in coals deeper than 5,000 feet, making the Piceance Basin one of the deepest coalbed methane areas in the United States (Quarterly Review, August 1993).

The major coalbed methane target, the Cameo-Wheeler-Fairfield coal zone (Figure A3-3), is contained within the Williams Fork Formation of the Mesaverde Group and holds approximately 80 to 136 Tcf of coalbed methane (Tyler et al., 1998). This coal zone ranges in thickness from 300 to 600 feet, and lies more than 6,000 feet below the ground surface over a large portion of the basin (Tyler et al., 1998). Individual coal seams of up to 20 to 35 feet thick can be found within the group, with net coal thickness of the Williams Fork Formation averaging 80 to 150 feet thick. In 1991, at the Grand Valley field (Figure A3-4), there were 23 coalbed methane wells and 18 conventional gas wells (Reinecke et al., 1991). However, in 1984, most wells at the Rulison field (Figure A3-4) were conventional gas wells.

Initially, it was anticipated that coalbed methane wells in the sandstones and coals of the Cameo Zone would have high production rates of water. However, testing later showed that they produced very little water (Reinecke et al., 1991). Both the sandstones and coalbeds are tight, poorly permeable, and are generally saturated with gas rather than water or a mixture of water and gas. The dynamic flow of a hydrologic system enhances the collection of gas in traps, but in much of the Piceance Basin that flow is not present because of the over-pressuring and saturation with gas.

Consequently, the conventional models for coalbed methane accumulation developed for other basins do not apply well for exploration and development in the Piceance Basin. Tyler et al. (1996) concluded, “very low permeability and extensive hydrocarbon overpressure indicate that meteoric recharge, and, hence, hydropressure, is limited to the basin margins and that long-distance migration of groundwater is controlled by fault systems.” Recharge is limited along the eastern and northeastern margins of the basin because of offsetting faults, but zones of transition between hydropressure and hydrocarbon overpressure in the western part of the basin and on the flanks of the Divide Creek Anticline in the southeastern part of the basin may possess better coalbed methane potential, as indicated by the exploration targets delineated in Tyler et al. (1998) (Figure A3-5).

3.2 Basin Hydrology and USDW Identification

The Piceance Basin contains both alluvial and bedrock aquifers. Unconsolidated alluvial aquifers are the most productive aquifers in the Piceance Basin. These alluvial deposits are narrow, and thin deposits of sand and gravel formed primarily along stream courses. The City of Meeker, Colorado is supplied by wells tapping these deposits where they are over 100 feet thick in the White River Valley (Taylor, 1987).

The most important bedrock aquifers are known as the upper and lower Piceance Basin aquifer systems. These consolidated rock aquifers are lower Tertiary Eocene in age and occur within and above the large oil shale reserves. The upper and lower aquifers are separated by the Mahogany Zone of the Parachute Creek Member (Figure A3-6). The Mahogany Zone is a poorly permeable oil shale, which retards water movement but does not stop it. Both bedrock aquifers overlie the older Cretaceous Mesaverde Group where the coal and coalbed methane are located.

The upper aquifer system is about 700 feet thick and consists of several permeable zones in the Eocene Uinta Formation and the upper part of the Parachute Creek Member of the Eocene Green River Formation. Sub-aquifers of the Uinta Formations are silty sandstone and siltstone, while those of the Parachute Creek Member of the Green River Formation are fractured dolomite marlstone. There is some primary porosity (i.e., the porosity preserved from during or shortly after sediment deposition, such as the spaces between grains) in the sandstone and the permeability of the sub-aquifers has been enhanced by natural fracturing that occurred during post-deposition deformation. Layers between the individual sub-aquifers are less permeable than the sub-aquifers themselves, but they do not prevent water movement between the sub-aquifers.

The lower aquifer system is about 900 feet thick and consists of a fractured dolomitic marlstone of part of the lower Parachute Creek Member of the Green River Formation. It is semi-confined below the Mahogany Zone and above the Garden Gulch Member of the Green River Formation and a high resistivity zone just above it (USGS, 1984 and Taylor, 1987) (Figure A3-6). Fracturing during deformation of the rocks and subsequent solution enlargement owing to dissolution of soluble evaporite minerals has increased permeability of this lower aquifer system.

Groundwater is recharged from snowmelt on high ground from where it travels down through the upper aquifer system, the Mahogany Zone, and into the lower aquifer system. The groundwater then moves laterally and/or upward discharging from both the upper and lower aquifer systems into streams (Figure A3-7). The minerals nahcolite ($NaHCO_3$), dawsonite ($NaAl(OH)_2CO_3$) and halite ($NaCl$) are present in the groundwater, and the circulation of the groundwater (with these minerals in solution) has caused enlargement of the natural fractures (Taylor, 1987). Water in the lower aquifer is reported to contain several hundred milligrams per liter (mg/L) of chloride (Taylor, 1987).

Wells in these two bedrock aquifer systems, the upper and lower Piceance Basin aquifers, typically range in depth from 500 to 2,000 feet and commonly produce between 2 to 500 gallons per minute of water (USGS, 1984). These Tertiary bedrock aquifers are stratigraphically separated from the base of the Cameo Coal Zone in the Cretaceous Mesaverde Group by from less than 1,500 feet of strata along the Douglas Creek Arch to more than 11,000 feet along the basin trough just west of the Grand Hogback (Johnson and Nuccio, 1986) (Figure A3-2).

Aquifer maps do not exist for the Piceance Basin, but water quality in the Piceance Basin is poor owing to nahcolite (sodium bicarbonate) deposits and salt beds within the basin (Graham, 2001). Only very shallow waters such as those from the surficial Green River Formation are used for drinking water (Graham, CDWR, 2001). In general, the potable water wells in the Piceance Basin extend no further than 200 feet in depth, based on well records maintained by the Colorado Division of Water Resources (CDWR). At least two wells in the area are approximately 1,000 feet in depth, but they are used for stock watering. A composite water quality sample taken from 4,637 to 5,430 feet deep within the Cameo Coal Group in the Williams Fork Formation exhibited a total dissolved solid (TDS) level of 15,500 mg/L, which is above the 10,000 TDS water quality criterion for a underground source of water (USDW) (Graham, CDWR, 2001). The produced water from coalbed methane extraction in the Piceance Basin is of such low quality that it must be disposed of in evaporation ponds or re-injected into the formation from which it came or at even greater depths (Tessin, 2001).

It is unlikely that any USDWs and coals targeted for methane production would coincide in this basin. These targeted coals are generally located at great depth, of at least 4,000 feet. The thousands of feet of stratigraphic separation between the coal gas bearing Cameo Zone and the lower aquifer system in the Green River Formation should prevent any of the effects from the hydrofracturing of gas-bearing strata from reaching either the upper or the lower bedrock aquifers.

Permeability of the coal and the surrounding sandstone and shale is generally quite low except near outcrop, creating little potential for these rocks to contain a USDW. Researchers (Reinecke et al., 1991) report that the permeability of gas-bearing coal and sandstone of the Cameo Zone is so low that the gas is over-pressured and has forced groundwater out of the zone, a condition that tends to disfavor the entrapment of methane. Tyler et al. (1998) state that high coalbed methane gas productivity requires geologic and hydrologic conditions, and that these conditions are not optimal throughout much of the Piceance Basin because of the absence of dynamic groundwater flow and the low permeability of the host rocks.

The above conditions prevail in the central part of the basin, previously favored as a coalbed methane development fairway, and heavily targeted for exploration (Nowak, 1991). However, analyses by Tyler et al. (1998) suggest that a transitional zone, between the deeply buried coal and the outcrops at the boundaries of the basin, where groundwater circulation may be sufficient to create more favorable trapping conditions (Figure A3-5), may be a better target area for coalbed methane production exploration. These exploration target zones could possibly have sufficient meteoric groundwater circulation to meet the water quality criterion of USDWs. However, Figure A3-3 shows that the depths to coals in the targeted methane producing zones (Figure A3-5) are greater than 4,000 feet below ground surface and therefore, are not likely to contain water that would meet the USDW quality criterion of less than 10,000 mg/L TDS. Currently, test-drilling information is insufficient to determine if this is the case. Nevertheless, due to the very low permeability, great depth, and expected poor water quality of the targeted coalbed methane producing zones, conflicts with USDWs are considered to be of very low probability.

3.3 Coalbed Methane Production Activity

Measurements of coal permeabilities in the Piceance Basin have shown that the deep coals typical of the basin are much less permeable than coals in top-producing coalbed methane basins such as the San Juan Basin in Colorado (Quarterly Review, 1993). Consequently, operators rely on large hydraulic fractures to produce coalbed methane from the deep, low permeability coals (Quarterly Review, 1993).

Exploration for coalbed methane began in the basin during the early 1980s, but viable commercial production did not begin until 1989 (Quarterly Review, 1993). The first well to commercially produce coalbed methane from the Piceance Basin, Exxon’s Vega No. 2 well in Mesa County, went off-line in 1983 (Quarterly Review, 1993). Amoco Production Company attempted multi-well coalbed methane development in the late 1980s, and finally ceased activity in 1989. Commercial production was finally achieved in 1989 in the Parachute fields operated by Barrett Resources. Barrett Resources drilled 68 wells in 1990 and had planned for 22 more in 1991 (Western Oil World, 1991). The wells targeted both coals and sandstone within the Cameo Coal Zone and the Mesaverde sandstones, just above the Cameo coals. Other operators soon followed suit, including Fuelco at White River Dome field in the northern part of the basin (Figure A3-1), Conquest Oil Company near Barretts Resource’s production in the central part of the basin, Chevron USA Inc., and many others. However, not all operators were successful in locating or producing coalbed gas. Ultimately, Barrett found the sandstones to be far more productive than the coalbeds, and attempts to complete wells in the coalbeds were largely abandoned.

According to the Colorado Geological Survey (2002), some operators are having success in their pilot coalbed methane production program in White River Dome Field northwest of Meeker. Their success is attributed to the extensive natural fracturing found in the coal seams at White River Dome. Fracturing may be particularly extensive as a result of the formation of the White River anticline and the proximity to the large Danforth Hills Mesaverde outcrop. As a result, operators are taking another look at coalbed methane development in the Piceance Basin. In addition, one of the operators is drilling (but not fracturing) horizontal wells in the coal seams to take advantage of the anomalous natural fracturing found at White River Dome field. In some areas of coalbed methane potential, horizontal well technology may replace hydraulic fracturing as a method to enhance coalbed methane well performance.

Within the Cameo Coal Zone, Barrett Resources typically used 3,000 to 3,500 barrels of gelled 2% potassium chloride water with 273,000 to 437,000 pounds of sand over a maximum 450 feet of the Cameo Coal Zone to stimulate coalbed methane wells (Quarterly Review, 1993). It was shown that these hydraulic stimulations created short (100-foot), multiple fractures around the wells (Quarterly Review, August 1993). Fuel Resources Development Company used 3,000 to 10,000 barrels of gelled water and 200,000 to 1,300,000 pounds of sand to fracture their wells in the White River Dome Field (Quarterly Review, 1993). All but one of Conquest Oil Company's wells was hydraulically fractured with 1,500 barrels of water or cross-linked gel and 31,000 to 230,000 pounds of regular or resin-coated sand (Quarterly Review, 1993).

3.4 Summary

The Piceance Basin shows promise as a source for coalbed methane production based on the estimated 80 to 136 Tcf of gas contained within the Cameo-Wheeler-Fairfield coal zone (Tyler et al., 1998). However, overall low permeabilities as well as great depths to coalbeds appear to have slowed coalbed methane development in the basin. Nevertheless, a pilot program in White River Dome Field has had success in coalbed methane production, attributable primarily to the extensive natural fracturing in the area. As a result, operators are taking another look at coalbed methane development in this basin.

Hydraulic fracturing is the common method used to extract coalbed methane. Drilling of horizontal wells in the coal seams is a method that is being evaluated in the White River Dome Field pilot project as an alternative to hydraulic fracturing. In some areas of coalbed methane potential, horizontal well technology may replace hydraulic fracturing as a method to enhance coalbed methane performance.

The fluids used for fracturing vary from water with sand proppant to gelled water and sand. Between 1,500 to more than 11,000 feet of strata separate the coals from the shallow USDWs, indicating that the potential for water quality contamination from hydraulic fracturing techniques is minimal. The only hydraulic fracturing fluid contamination pathway to the USDWs might be through faults or fractures extending between the deep coal layers and the shallow aquifers. The occurrence of these fractures and faults has not been substantiated in any of the literature examined for this investigation.

Research suggests that exploration may target areas where groundwater circulation may enhance gas accumulation in the coal and associated sandstones (Tyler et al., 1998). Under these exploration and development conditions, a USDW located in shallower Cretaceous rocks near the margins of the basin, could be affected by hydraulic fracturing. The depth to methane-bearing coals (about 6,000 feet) seems to indicate that, in the Piceance Basin, the chances of contaminating any overlying, shallower USDWs (no deeper than 1,000 feet) from injection of hydraulic fracturing fluids and subsequent subsurface fluid transport are minimal. Potable wells in the Piceance Basin generally extend no further than 200 feet in depth. The coalbed methane producing Cameo Zone and the deepest known aquifer, the lower bedrock aquifer, have a stratigraphic separation of over 6,000 feet.

The Uinta Basin

The Uinta Coal Basin is located mostly within eastern Utah; a very small portion of the basin is in northwestern Colorado (Figure A4-1). The basin covers approximately 14,450 square miles (Quarterly Review, 1993) and is structurally separated from the Piceance Basin by the Douglas Creek Arch (Figure A4-1), an up-warp near the Utah – Colorado state line. Coalbeds are present within Cretaceous strata throughout much of the Uinta Basin. However, coalbed methane exploration, to date, has targeted coalbeds in the Ferron Sandstone Member of the Mancos Shale and coalbeds in the Blackhawk Formation of the Mesaverde Group. The total, in-place, coalbed gas resources in the Wasatch Plateau, Emory, Book Cliffs and Sago coal fields have been estimated at 8 trillion cubic feet (Tcf) to more than 10 Tcf by the Utah Geological Survey (Gloyn and Sommer, 1993). This estimate is based on extrapolation of known coal resources to a depth of 9,000 feet and an average projected gas content of 330 cubic feet per ton and does not include the Tabby Mountain or Vernal coalfields, or the Sevier-Sanpete coal region. Total production stood at 75.7 billion cubic feet (Bcf) of coalbed methane in 2000 (GTI, 2002).

4.1 Basin Geology

Much of the Rocky Mountain region, including the Uinta Basin was covered by an epicontinental sea. Deposition in the sea lasted from the Albian (about 100 million years ago) through the Cenonmanian (about 83 million years ago), with the deposition of the upper part of the Mesaverde Group generally marking the end of marine deposition in the basin (Howells et al., 1987).

The Uinta Basin formed as a result of uplift and deformation that began in the Late Cretaceous. The Cretaceous sediments outcrop along the perimeter of the basin. The basin is asymmetrical in shape with strata on the northern flank of the basin dipping steeply toward the basin axis, while strata on the southern flank dip gently toward the basin axis. The stratigraphic units of the coal bearing Cretaceous rocks of the Uinta Basin are shown in Figure A4-2.

Two Cretaceous stratigraphic units have been targeted for coalbed methane exploration: the Ferron Sandstone Member of the Mancos Shale and the Blackhawk Formation of the Mesaverde Group (Figure A4-2). The Ferron Sandstone Member was deposited in the Last Chance delta, a fluvial-deltaic environment (Garrison et al., 1997). The coalbeds and interbedded sandstone units form a wedge of clastic sediment 150 to 750 feet thick stratigraphically above the Tunuck Shale Member of the Mancos Shale and below the Lower Blue Gate Shale Member of the Mancos Shale (Figure A4-2). Both of these shale units have a very low permeability and constitute confining units for water and gas in the Ferron Sandstone Member. The coal-bearing rocks are thickest to the west and south margins of the basin, nearer to the upland sources of sediment. Coalmines producing from the Ferron Sandstone Member are located along the eastern boundary of the Wasatch Plateau south of Castle Dale, Utah (Figure A4-1). Depths to coal in the Ferron Sandstone Member range from 1,000 to over 7,000 feet (Garrison et al., 1997). Primary coalbed methane activity from the Ferron Sandstone takes place in the Drunkard's Wash Unit. Total coal thickness in this area ranges from 4 to 48 feet (averaging 24 feet) from depths of 1,200 to 3,400 feet (Lamarre and Burns, 1996).

The Blackhawk Formation consists of coal interbedded with sandstone and a combination of shale and siltstone. The Blackhawk Formation is underlain by the Star Point Sandstone and overlain by the Castlegate Sandstone (Figure A4-2). The Castlegate Project in the Book Cliffs coalfield initially targeted coals in the Blackhawk Formation at depths ranging from 4,200 to 4,400 feet (Gloyn and Sommer, 1993).

4.2 Basin Hydrology and USDW Identification

Groundwater hydrology of the Uinta Basin is controlled primarily by the geologic structure of the region (Howells et al., 1987). Variations of aquifer and aquitard permeability owing to differences of lithology and facies changes also play an important role in the hydrology, as does widespread faulting and fracturing of the rocks (Howells et al., 1987). Because of the basin's structure, the area may be a groundwater basin with internal drainage. If there were a deep groundwater outlet for the basin, it would be along or near the axis of the Uinta Basin at its western edge. The general pattern of groundwater flow is centripetal, with water flowing inward from recharge areas at exposures of permeable strata at the margins of the basin. Recharge is greatest near the northern edge of the basin. Other recharge areas include Eocene and Oligocene Formations in the basin interior.

Most of the sandstone formations in the Mesozoic rocks in the Upper Colorado River Basin are identified as aquifers by the United States Geological Survey (Freethey and Cordy, 1991). Freethey and Cordy stated that in the Uinta Basin, the older and deeper aquifers in strata below the Ferron Sandstone Member, (for example, the Navajo-Nugget Aquifer, Entrada-Preuss Aquifer, Morrison Aquifer, and the Dakota Aquifer) generally contain very saline to briny water, with total dissolved solids (TDS) values greater than 10,000 milligrams per liter (mg/L). The water quality component of the underground source of drinking water (USDW) definition specifies that a USDW contain less than 10,000 mg/L of TDS. The Ferron Sandstone Member (Figure A4-3) is designated as a producing aquifer in east-central Utah (Freethey and Cordy, 1991). In regard to the Mesaverde Group Aquifer, which includes the Star Point Sandstone, the Blackhawk Formation, the Castlegate Sandstone and the Price River Formation, (Figure A4-3) Freethey and Cordy (1991), stated that, "water in these aquifers is more likely to be developed where the saturated thickness is large and the depth to the aquifer is less than 2,000 ft." They further stated that the margins of the Uinta Basin where these rocks are near the surface or outcrop is a possible location for development of groundwater with low enough TDS to be used for drinking water.

Wells in the Ferron Sandstone Member at the Drunkard's Wash coalbed methane field typically penetrate to depths ranging from 1,200 to 3,400 feet (Lamarre and Burns, 1996). An average water quality value of 13,120 mg/L TDS (Gwynn, 1998) for production waters that have been retained in catchment ponds suggests that these wells are not within a USDW. Gwynn (1998) however, does state that due to the ponding of the produced water in evaporation lagoons, the concentration of salts in these waters has probably increased from their original levels. This implies that these water quality data may not be useful in the confirmation of USDW qualifications. Quarterly Review (1993) reported that three wells producing gas and water from the Ferron Sandstone Member coalbeds in the Drunkard's Wash field yielded over 49,000 gallons of water per day with a TDS level of about 5,000 mg/L (sodium bicarbonate) during the first 2 to 3 months of operation. The Ferron Sandstone is hydrologically confined above and below by shale members of the Mancos Shale formation. Water produced from the Ferron Sandstone is thought to be connate water that was trapped in the sediment during coalification (Gloyn and Sommer, 1993). Hunt (Utah Division of Oil, Gas, and Mining, 2001) noted that there were no USDWs located immediately above the Ferron Sandstone Member due to the thick tongues of Mancos Shale that encapsulate the coal-bearing interval (Figure A4-2).

Beds targeted for methane gas exploration and production within the Blackhawk Formation are approximately 4,200 to 4,400 feet below the ground surface (Gloyn and Sommer, 1993). Coalbed gas production in the Castlegate Field accounted for less than 10 percent of the coalbed methane production in the Uinta Basin (Petzet, 1996). The average gas well producing from the coalbeds in the Blackhawk Formation (Castlegate field) yielded 318 barrels of water per day, and TDS levels of 5,489 mg/L have been measured in the produced waters (Gloyn and Sommer, 1993).

According to the State of Utah Department of Natural Resources (DNR), Division of Oil, Gas and Mining, the water quality in the Ferron and Blackhawk varies greatly with location, each having some TDS levels below and some above 10,000 mg/L (Utah DNR, 2002). In general, the quality of Blackhawk water is higher than that of Ferron water. The most recent Underground Injection Control application received for the Drunkard's Wash field (Ferron) showed a composite quality of input water to be about 31,000 mg/L TDS, and for the Castlegate field (Blackhawk) 9,286 mg/L TDS. At some locations, either formation member would not qualify as a USDW.

In the western part of the Uinta Basin, the Castlegate Sandstone, an aquifer, is separated from the Black Hawk Formation coalbeds by approximately 300 feet of alternating shale and sandstone (Utah DNR 2002). The Star Point Sandstone is located below approximately 400 feet of alternating sandstone and shale that underlies the bottom coal of the Black Hawk Formation. In some areas, the shale and sandstone underlying the Black Hawk coals are highly faulted. There is some potential that hydraulic fracturing fluids could be transported through natural fracture networks in these areas and reach the Star Point Sandstone. The relatively impermeable upper Blue Gate Shale Member of the Mancos Shale Further would prevent further downward migration.

In reference to the quality of water produced by the coalbed gas wells in both the Ferron Sandstone Member of the Mancos Shale and the Blackhawk Formation, Quarterly Review (1993) states: "Disposal of produced water does not appear to present a major environmental problem in the Uinta basin, unlike the San Juan and some other western basins. Rates are moderate, 200 to 300 barrels per day per well during early stages of production and TDS levels are not high (about 5,000 mg/L)." Because these TDS values are less than the 10,000 mg/L limit, both the Ferron Sandstone Member of the Mancos Shale and the Blackhawk Formation may qualify as USDWs.

Tabet (2001) suggests that coalbed methane extraction wells are not located in "producing" aquifers and that most of the potable water in the sparsely populated area is supplied by surface water and shallow alluvial aquifers.

4.3 Coalbed Methane Production Activity

Full-scale exploration in the Uinta Basin began in the 1990s (Quarterly Review, 1993). The most active operators at that time were PG&E Resources Company, the River Gas Corporation, Cockrell Oil Corporation, and Anadarko Petroleum Corporation. PG&E acquired the Castlegate Field, from Cockrell Oil (Gloyn and Sommer, 1993). Gas was produced from coalbeds in the Blackhawk Formation. The five wells initially drilled in the Castlegate Field were hydraulically fractured with 80,000 to 143,000 pounds of sand and unreported volumes of fluid. Other wells were to be fractured with a low-residue gel system to ensure breakdown within the reservoir (Quarterly Review, 1993).

The Castlegate field was off-line due to production water disposal problems (Tabet, 2001; and Hunt, Utah Division of Oil, Gas, and Mining, 2001). According, to the State of Utah DNR, Division of Oil, Gas and Mining, the field is now on production (Utah DNR, 2002).

The River Gas Corporation operates the Drunkard's Wash Unit, producing methane gas from coals within the Ferron Sandstone Member. The company reported that high fracture gradients hampered hydraulic fracturing stimulations using cross-linked borate gel with 250,000 pounds of proppant (Quarterly Review, 1993). Excessive proppant flowback resulted in one well where nitrogen foam was used for the fracturing. The Buzzard Bench Field, also producing gas from the Ferron Sandstone Member, was initially operated by Chandler & Associates, Inc. (Petzet, 1996) and is currently being managed by Texaco (Garrison et al., 1997).

A query of a database covering the Uinta Basin revealed that there are about 1,255 coalbed methane wells in production in the basin (Osborne, 2002). Gas Technology Institute (GTI) places the annual coalbed methane production in the Uinta Basin at 75.7 Bcf in 2000 (GTI, 2002).

4.4 Summary

Waters from coalbed methane production in the Ferron Sandstone Member of the Mancos Shale in the Drunkard's Wash Unit are conflictingly reported to have TDS values of about 13,000 mg/L according to one source of information or to have levels of TDS of about 5,000 mg/L from another. However, the higher values were derived from water samples taken from evaporation lagoons and these high values might represent elevated concentrations of salts owing to evaporation. Consequently, if the more moderate TDS levels were correct, then the Ferron Sandstone would qualify as a USDW.

According to the State of Utah DNR, Division of Oil, Gas and Mining, the water quality in the Ferron and Blackhawk varies greatly with location, each having TDS levels below and above 10,000 mg/L (Utah DNR, 2002). In general, the quality of Blackhawk water is fresher than Ferron water. The most recent Underground Injection Control application received for the Drunkard's Wash field (Ferron) showed a composite quality of input water to be about 31,000 mg/L TDS, and for the Castlegate field (Blackhawk) 9,286 mg/L TDS. At some locations, neither formation member would qualify as a USDW.

The Drunkard's Wash and Castlegate coalbed methane extraction fields are located in a sparsely populated section of Utah. Tabet (Utah Geological Survey, 2001) suggests that coalbed gas extraction wells are not located in "producing" aquifers and that most of the potable water in the sparsely populated area is supplied by surface water and shallow alluvial aquifers.

The Blackhawk Formation is underlain by 300 feet of shale and sandstone that separate it from the Castlegate Sandstone aquifer. It is underlain by similar geologic strata, which separate it for the Star Point Sandstone. Only in highly faulted areas is there a reasonable possibility that hydraulic fracturing fluids could migrate down to the Star Point Sandstone.

Attachment 5
The Powder River Basin

The Powder River Basin is located in northeastern Wyoming and southern Montana. The basin covers an area of approximately 25,800 square miles (Larsen, 1989), approximately 75 percent of which is within Wyoming (Figure A5-1). Fifty percent of the basin (Figure A5-2) is believed to have the potential for production of coalbed methane (Powder River Coalbed Methane Information Council, 2000). Much of the coalbed methane-related activity has been north and south of Gillette in northeastern Wyoming (Figure A5-2). The majority of the potentially productive coal zones range from about 450 feet to over 6,500 feet below ground surface (Montgomery, 1999). In addition to being an important resource for coalbed methane, the basin has also produced coal, petroleum, conventional natural gas, and uranium oxide (Law et al., 1991; Randall, 1991). Recent estimates of coalbed methane reserves in the Powder River Basin have been as much as 40 trillion cubic feet (Tcf) (PRCMIC, 2000) but more conservative estimates range from 7 to 12 Tcf (Montgomery, 1999). Annual production volume was estimated at 147 billion cubic feet (Bcf) in 2000 (GTI, 2002). In 2002, wells in the Powder River Basin produced about 823 million cubic feet (Mcf) per day of coalbed methane (DOE, 2002).

The information available indicates that hydraulic fracturing currently is not widely used in this region due to concerns about the potential for increased groundwater flow into the coalbed methane production wells and collapse of open hole wells in coal upon dewatering. According to the available literature, where hydraulic fracturing has been used in this basin, it has not been an effective method for extracting methane.

5.1 Basin Geology

The Powder River Basin is a thick sequence of sedimentary rock formed in a large downwarp within the Precambrian basement. The basin is bounded on the east by the Black Hills uplift, on the west by the Big Horn uplift and Casper Arch, on the south by the Laramie and Hartville uplifts and, on the north, it is separated from the Williston Basin by the Miles City Arch and the Cedar Creek Anticline (Larsen, 1989) (Figure A5-1). The long axis of the basin is aligned in a generally southeast to northwest direction, and it is as much as 18,000 feet deep (Randall, 1991) (Figures A5-1 and A5-3). Sediments range from Paleozoic at the bottom through Mesozoic to Tertiary at the top (DeBruin et al., 2000). The basin is a large asymmetrical syncline with its axis (deepest part) near the west side of the basin (Figure A5-3). From outcrops along the eastern edge of the basin, the sediments slope gently (1.5^{o}, about 100 feet per mile) downward to the southwest and then bend steeply upward (10 to 45^{o}) to outcrop in a monocline along the western edge of the basin.

Several periods of deposition by marine and fluvial-deltaic processes have occurred within the basin during the Cretaceous and Tertiary periods. These Cretaceous and lower

Tertiary rocks have a total thickness of up to 15,000 feet (Montgomery, 1999). Coal is found in the Paleocene Fort Union and Eocene Wasatch Formations (Figure A5-4). The Wasatch Formation occurs at land surface in the central part of the basin and is covered by alluvium or White River Formation in some places (Figure A5-4). Most of the coalbeds in the Wasatch Formation are continuous and thin (six feet or less) although, locally, thicker deposits have been found (DeBruin et al., 2000). The Fort Union Formation lies directly below the Wasatch Formation and can be as much as 6,200 feet thick (Law et al. 1991). The Fort Union Formation outcrops at the ground surface on the eastern side of the basin, east of the City of Gillette and on the western side of the basin, north and south of Buffalo. The coalbeds in this formation are typically most abundant in the upper Tongue River Member (Figure A5-4). This member is typically 1,500 to 1,800 feet thick, of which up to a composite total of 350 feet of coal can be found in various beds. The thickest of the individual coalbeds is over 200 feet (Flores and Bader, 1999). The coalbeds are interspersed with sandstone, conglomerate, siltstone, mudstone and limestone (Montgomery, 1999).

Most coalbed methane wells in the Powder River Basin are in the Tongue River Member of the Fort Union Formation, in the Wyodak-Anderson coal zone, which contains up to 32 different coalbeds according to some authors (Ayers, 1986), including the Big George in the central part of the basin (Flores and Bader, 1999). The Wyodak is one of the thick coalbeds that are targeted for coalbed methane development. This coalbed is also called the Wyodak-Anderson or the Anderson, and it can be subdivided further into several other coalbeds. These coalbeds are the Canyon, Monarch, and Cook. All of these coalbeds are coalbed methane targets. Most coalbeds are found within 2,500 feet of the ground surface.

The Wyodak or Wyodak-Anderson coalbed in the Wyodak-Anderson coal zone is prominent in the eastern portion of the Powder River Basin near the City of Gillette (Figures A5-3, A5-5 and A5-6). The Wyodak has been identified as the largest single coalbed in the country (Montgomery, 1999). The coal is close to the ground surface and mining of the coal is common. The Wyodak coalbed gets progressively deeper and thicker toward the west. This bed ranges from 42 to 184 feet thick. Most of the coalbed methane wells in the Powder River Basin are within the Wyodak coal zone near the City of Gillette.

The Big George Coalbed is located in the central and western portion of the Powder River Basin (Figure A5-7). Although the Big George is stratigraphically higher than the Wyodak, owing to the structure of the basin, the Big George, in the center portion of the basin, is deeper than the Wyodak at the eastern margin of the basin (Tyler, et al., 1995). To date, the Big George has not been developed for coalbed methane production to the same extent as the Wyodak-Anderson coal zone. This is due to a combination of factors including greater depth to coal, more groundwater, and longer distances to available transmission pipelines. However, as of December 2001, there were about 850 coalbed methane wells drilled into the Big George with a large number of wells planned for the future (Osborne, 2002).

A third significant coal zone, the Lake De Smet coal zone in the Wasatch Formation, is up to 200 feet thick and is located in the Lake De Smet area (Figure A5-8), 55 miles southwest of Recluse on the western side of the basin (Larsen, 1989). It has not yet been widely used for coalbed methane production.

Most of the coal in the Powder River Basin is subbituminous in rank, which is indicative of a low level of maturity. Some lignite, lower in rank, has also been identified. The thermal content of the coals found in the Powder River Basin is typically 8,300 British thermal units per pound (Randall, 1991). Coal in the Powder River Basin was formed at relatively shallow depths and relatively low temperatures. Most of the methane generated under these conditions is biogenic, which means that it was formed by bacterial decomposition of organic matter. Thermogenic formation (formed under high temperature) was not significant in most locations within the Powder River Basin. Consequently, coal in the Powder River Basin contains less methane per unit volume than many other coal deposits in other parts of the country. Coal in the Powder River Basin has been found to contain 30 to 40 standard cubic feet of methane per ton of coal compared to 350 standard cubic feet of methane per ton in other areas (DeBruin et al., 2000). The gas is typically more than 95 percent methane, the remainder being mostly nitrogen and carbon dioxide. This resource was overlooked for many years because it was thought to be too shallow for the production of significant amounts of methane (Petzet, 1997). However, the relatively low gas content of Powder River Basin coal is compensated by the thickness of the coal deposits. Because of the thickness of the deposits and their accessibility, commercial development of the coalbed methane has been found to be economical.

The Powder River Basin contains approximately 60 percent of the coalbed methane reserves in the State of Wyoming (DeBruin et al., 2000). Recent estimates of coalbed methane reserves in the Powder River Basin have been as much as 40 Tcf (PRCMIC, 2000) but more conservative estimates range from 7 to 12 Tcf (Montgomery, 1999). As of December 1999, monthly production exceeded 7 Bcf from 1,657 wells (DeBruin et al., 2000). Wells typically produce 160,000 cubic feet of gas per day (DeBruin et al., 2000). Annual production volume was estimated at 147 Bcf in 2000 (GTI, 2002). In 2002, wells in the Powder River Basin produced about 823 Mcf per day of coalbed methane (DOE, 2002). Coalbed methane has been developed along both the east and west flanks of the basin where the coalbeds are buried but relatively shallow. Many existing wells are awaiting connection to the distribution system and still more wells are being drilled. The estimated lifetime production from these wells is 300 to 400 Mcf per well (Petzet, 1997).

The amount of coalbed methane produced from each well is highly variable, and the volume of gas depends on the quality and thickness of the coal, the frequency of natural cleats in the coal, and the amount of water present. Other factors, such as well completion techniques and well stimulation techniques, also control the amount of gas produced from a well. Maximum coalbed methane flow from a well is typically achieved after one to six months of dewatering (Montgomery, 1999). Stable production is usually experienced for one to two years before production begins to decline (Montgomery, 1999). Production often declines at a rate of 20 percent per year until the well is no longer economically useful (Montgomery, 1999). Several options exist at that point, including re-fracturing the well, completing the well in a deeper coal formation, converting the well to a water supply well, or abandoning the well.

5.2 Basin Hydrology and USDW Identification

A report prepared by the United States Geological Survey (USGS) showed that samples of water co-produced from 47 coalbed methane wells in the Powder River Basin all had total dissolved solids (TDS) levels of less than 10,000 milligrams per liter (mg/L) (Rice et al., 2000). Based on the water quality component of the underground source of drinking water (USDW) definition, which specifies that a USDW contain less than 10,000 mg/L of TDS, the Fort Union Formation coalbeds are within a USDW. The water produced by coalbed methane wells in the Powder River Coal Field commonly meets drinking water standards, and production waters such as these have been proposed as a separate or supplemental source for municipal drinking water in some areas (DeBruin et al., 2000). Sandstones in the sediments both above and below the coalbeds are also aquifers.

In 1990, Wyoming withdrew an average of 384 million gallons per day of groundwater for a variety of purposes, the majority of which was agriculture. Approximately 13 percent was used for potable water supplies. Approximately 22 percent was withdrawn by industry and mining (Brooks, 2001). The proportion of this 22 percent attributable to coalbed methane production is increasing rapidly, and a concern exists that such good quality water in a semiarid region should be conserved (Quarterly Review, 1993). In 1990, before the rapid expansion of coalbed methane extraction in the region, Campbell County was identified by the USGS as an area of major groundwater withdrawal.

Approximately 80 percent of Wyoming residents rely on groundwater as their drinking water source (Powder River Basin Resource Council, 2001). Few public water supply systems exist in the Powder River Basin due to relatively low population densities. The City of Gillette, the largest in the major coalbed methane development area (Figure A5-2), uses groundwater from two sources identified as “in-town wells”, and the “Madison Well Field”. The city has experienced considerable drawdown and reduced production from their in-town wells that are completed in the Fort Union and Lance/Fox Hills aquifers (Brooks, 2001). It is unclear how much of the drawdown is attributable to withdrawals for water supply as a consequence of population growth and how much is attributable to nearby coalbed methane production. Between 1995 and 1998, the city restored and/or replaced several of its wells. The Madison Well Field produces water from the Madison Formation and is approximately 60 miles east of the city. There are no coalbed methane wells in the vicinity of the Madison Well Field (Brooks, 2001).

Regional groundwater flow in the basin is reported to be toward the northwest (Martin et al., 1988 in Law, 1991), with recharge occurring in the east along the Rochelle Hills.

Cleats and other fractures within the coalbeds create high hydraulic conductivities and facilitate the flow of groundwater and high water production within the coalbeds (Montgomery, 1999). The coalbeds are largely hydraulically confined by underlying shale and by basinward pinch-out. Surficial water and rainwater can enter the Fort Union coals from land surface at the eastern edge of the basin and at the Black Hills uplift. This flow inward from outcrop areas at higher elevations on the edge of the basin may have created artesian conditions in the deeper central portions of the basin. However, this view may not be entirely correct. For example, coalbed research (Law et al., 1991) hypothesizes that the sodium bicarbonate water in the Fort Union coal near the central part of the basin may not be derived from meteoric recharge, but rather from interstitial waters of the original peat deposits. Furthermore, Martin et al. (1988, as cited in Law et al., 1991) concluded on the basis of isotopic composition of water samples that only part of the water near outcrops was of meteoric origin. Although artesian pressure in the center of the basin has been thought to be evidence that the center of the basin is fed from meteoric recharge at the basin margins, the apparent artesian pressure (flowing wells) could be explained by the airlift effect of methane coming out of solution within the rising well water column.

Because the coalbeds are productive aquifers, they also require more dewatering of coalbed methane wells for methane production. Groundwater production, in terms of volume of water produced, was a major factor considered in the selection of sites for early coalbed methane wells and may still guide development of sites in some parts of the Powder River Basin. Wells in the eastern portion of the basin have been found to contain less water due to their location above the water table within the eastern anticlinal updip of the formation and, in some areas, due to the presence of nearby mines that dewater the aquifer. Drawdowns of up to 80 feet have been measured in wells near active mines; however, water levels have been reported to be unaffected at distances of more than three miles from mines (Randall, 1991). The Bureau of Land Management in conjunction with the State Engineer’s Office has been conducting ongoing research on the effects of coalbed methane production on drawdown (Wyoming Geological Association, 1999).

5.3 Coalbed Methane Production Activity

Coalbed methane activity in Wyoming occurs predominantly in Campbell, Sheridan and Johnson Counties (DeBruin, 2001). Wells are spaced from 40 to 80 acres per well, as determined by the State. Permits are required under both state water well regulations and state gas well regulations before drilling can commence. A discharge permit from the Wyoming Department of Environmental Quality is also required for the water that is removed from the well. Coalbed methane production wells in the Powder River Basin are typically 400 to 1,500 feet deep and can be as shallow as 150 feet (PRCMIC, 2000). By comparison, conventional gas and oil wells installed in the area are typically 4,000 to 12,000 feet deep (PRCMIC, 2000). Plans for construction of approximately 4,000 new coalbed methane production wells in the Montana portion of the Powder River Basin await completion of an in-depth environmental study (DeBruin, 2001).

Commercial development of methane directly from the coal seams began approximately in 1986. There were only 18 wells producing coalbed methane in the Powder River Basin by 1989. The number grew slowly through the early 1990s with 171 wells producing approximately 8 Bcf of gas per year. The rate of development of the resource accelerated greatly from 1997 to 1999. In 1999, there were 1,657 coalbed methane wells operating in the Powder River Basin, producing approximately 58 Bcf per year (Figure A5-9) of coalbed methane. As of November 2000, there were about 4,270 wells in Wyoming producing 15 Bcf of coalbed methane in that month alone (Osborne, 2002). By November 2001, monthly coalbed methane production had climbed to 23.5 Bcf from 7,870 producing wells in Wyoming (Osborne, 2002). In Montana, 246 active wells produced 872,008 Mcf of coalbed methane in December, 2001 (Osborne, 2002). The Powder River Basin has become the most active coalbed methane exploration and production area in the country (DeBruin et al., 2000). Despite all of the activity, less than 5 percent of the land underlain by coal in the Powder River Basin had been explored for the presence of coalbed methane as of the year 2000 (PRCMIC, 2000).

During the early years of coalbed methane development in the Powder River Basin (1980s to early 1990s), gas exploration and development companies completed wells with and without hydraulic fracture techniques. Larsen (1989) indicated that early wells were completed without fracturing treatments, particularly wells targeting gas reserves in coals interspersed between sandstone layers. However, the Quarterly Review (1989) reported that in one well, Rawhide 15-17, located north of Gillette, Wyoming, an “open frac” hydraulic fracturing was performed using 13,000 lbs of 12/20-mesh sand in 3,500 gallons of gelled water. Several wells installed in the early 1990s by Betop, Inc. were fractured using 4,000 to 15,000 gallons of a solution with 2 percent potassium chloride (KCl) in water. Sand was used to prop the fractures open in five of these wells (Quarterly Review, 1993). However, hydraulic fracturing experienced little success in this basin. Fractured wells produced poorly because the permeable, shallow subbituminous coals collapsed under the pressure of the overburden after they were dewatered (Lyman, 2001).

The Powder River Basin contains coals of high permeability. The permeability is so high in many areas that drilling fluid (typically water) is lost when drilling the coalbeds. Many times drilling mud is substituted to prevent loss of circulation (DeBruin, 2001). Because of this high permeability, most coalbed wells in the Fort Union Formation can be drilled and completed without the use of hydraulic fracturing (DeBruin, 2001; Quarterly Review, 1993). This has been confirmed by USGS officials in Wyoming (Brooks, 2001). Hydraulic fracturing is also avoided to prevent fracturing of impermeable formations adjacent to the coal, such as shales, that prevent the migration of groundwater. It is thought that fracturing the shale would increase the amount of water flowing into the wells. When fracturing has been done, it has been with water or sand/water mixtures. Unspecified “modest” improvements in coalbed methane gas flow have been observed (Quarterly Review, 1993).

In the Powder River Basin, two different coalbed methane sources are commonly developed: (1) gas extraction from methane-charged dry sand layers overlying or interbedded with the coals, and (2) conventional methane extraction from the water saturated coal seams. In the eastern (up dip) portion of the basin, the coals in the Wyodak-Anderson seam are relatively shallow and interbedded with sands (Montgomery, 1999) (Figure A5-6). In up dip areas above the water table, wells require minimal dewatering for coalbed methane production because there is little to no water in the sands (Quarterly Review, 1989; Montgomery, 1999). Coal mining operations near Gillette have lowered the water table in the vicinity of the mines, thereby dewatering nearby coalbeds and allowing desorption of methane gas from the coal. The sands are penetrated using open-hole techniques, generally without any fracture treatments (Quarterly Review, 1989). Further west, down dip (Figure A5-6), the coalbed methane producing sands and coals of the Fort Union Formation are separated from the overlying Wasatch Formation by a poorly permeable shale of limited areal extent (Quarterly Review, 1989; Quarterly Review, 1993). Further west, down dip (Figure A5-6) in this more water-saturated part of the basin, coalbed methane wells are also completed as open-hole wells.

The practice of open-hole drilling is commonly used in this region. In this practice, a portion of the borehole in the coal is drilled without any casing or well screen. Most other regions of the country where coalbed methane is recovered use a perforated casing throughout the target coal interval. The open coal zone is then cleaned out with water, and the surrounding coal formation is sometimes fractured to improve recovery of the methane. A submersible pump is set at the bottom of the target zone with tubing to the ground surface to remove groundwater from the well. The methane gas travels up the space between the water tubing and the casing. The well is capped to control the flow of methane gas. Wells are often dewatered for several months before producing optimal quantities of methane gas.

Side jetting has also been performed with some success; however, dynamic open-hole cavitation had not been attempted as of 1993. Side jetting is the process by which water and air are injected at high pressure to enlarge the boring in the coal seam. The cavitation process uses dynamic pressure changes to break apart the coal and to widen the boring within in the coal seam (Quarterly Review, 1993).

Production of coalbed methane from water-saturated coalbeds below the water table first requires partial dewatering of the coal to allow desorption of methane from the coal. Production from water-bearing coal seams can yield significant volumes of water; enough to make it difficult or infeasible to dewater the formation sufficiently to initiate coalbed methane flow (Montgomery, 1999). Tests on 11 wells reported by Crockett (2000) indicate that coalbed methane is desorbed from coal as a consequence of decreased hydrostatic pressure caused by pumping groundwater. One well started desorbing at 92 percent of the original reservoir pressure. “Most drilling to date has attempted to remain near or above the existing water table to minimize water production” (Montgomery, 1999). Modifications to well spacing and pumping configuration have been cited by Montgomery (1999) as showing some promise for allowing greater production from the water-saturated coal seams in the future. Because the water in the deeper coal seams may be original interstitial water, and recharge from meteoric water might not be an important factor (Montgomery, 1999), dewatering of these coals for the purposes of coalbed methane production might become economically feasible.

Disposal of water produced by coalbed methane wells is an issue at many well locations. Coalbed methane wells are generally pumped constantly, removing as much as 168,000 gallons per day of water from deeper formations (Randall, 1991). Averages of 17,000 gallons per day per well are more common (Powder River Basin Resource Council, 2001). Water produced during the dewatering of coalbed wells is generally discharged to stock ponds, water impoundments (reservoirs), drainages with ephemeral and intermittent streams, and surface waters. A National Pollution Discharge Elimination System permit is required for surface discharge of production water. The water is generally of potable quality in the center of the basin, becoming more saline to the north and south. It is sometimes used for irrigation and watering livestock (DeBruin, 2001). TDS levels are typically less than 5,000 parts per million. The water's salt content is primarily sodium bicarbonate (Quarterly Review, 1993). Average analytical results from 47 USGS water quality analyses of untreated, co-produced water from coalbed methane wells in the Powder River Basin are displayed in Table A5-1 below.

Table A5-1. Average Water Quality Results from Produced Waters (Rice et al., 2000)

Parameter	Result	Units
pH	7.3	N/A
temperature	19.6	^{o}C
specific conductance	1,300	microsiemens
TDS	850	mg/L
fluoride	0.92	mg/L
chloride	13.0	mg/L
sulfate	2.4	mg/L
bromide	0.12	mg/L
alkalinity (as HCO_3)	950	mg/L
ammonium	2.4	mg/L
calcium	32	mg/L
potassium	8.4	mg/L
magnesium	16	mg/L
sodium	300	mg/L
barium	0.62	mg/L
iron	0.8	mg/L

As a result of the rapid growth in the coalbed methane industry, the Wyoming State Engineer's Office (SEO) requested funding for drilling, equipping, and monitoring of observation wells, and the installation of surface water measuring devices to be located in coalbed methane production areas. These monitoring facilities would become part of the SEO statewide observation well network to monitor changes in groundwater levels and stream flow over time. As of 1999, work was underway, but no report of results had yet been made available.

5.4 Summary

Based on the information for the Powder River Basin, the coalbeds that are being developed, or which may be developed, for coalbed methane in the Powder River Basin are also USDWs. Coalbeds in this basin are interspersed with sandstone and shale at varying depths. The Fort Union Formation that supplies municipal water to the City of Gillette is the same formation that contains the coals that are developed for coalbed methane. The coalbeds contain and transmit more water than the sandstones. The sandstones and coalbeds have been used for both the production of water and the production of coalbed methane. TDS levels in the water produced from coalbeds meet the water quality criteria for USDWs.

The information available indicates that currently hydraulic fracturing is not widely used in this region due to concerns about the potential for increased groundwater flow into the coalbed methane production wells and the consequent collapse of open hole wells in coal upon dewatering. According to the available literature, where hydraulic fracturing has been used in this basin, it has not been an effective method for extracting methane. Hydraulic fracturing has been conducted primarily with water, or gelled water and sand, although the recorded use of a solution of KCl was identified in the literature.

Attachment 6
The Central Appalachian Coal Basin

The Central Appalachian Coal Basin is the middle basin of three basins that comprise the Appalachian Coal Region of the eastern United States. It includes parts of Kentucky, Tennessee, Virginia, and West Virginia (Figure A6-1). It covers approximately 23,000 square miles, contains six major Pennsylvanian age coal seams, and contains an estimated 5 trillion cubic feet (Tcf) of coalbed methane (Zebrowitz et al., 1991; Zuber, 1998). These coal seams typically contain multiple coalbeds that are widely distributed (Zuber, 1998). The coals seams, from oldest to youngest (West Virginia/Virginia name), are the Pocahontas No. 3, Pocahontas No. 4, Fire Creek/Lower Horsepen, Beckley/War Creek, Sewell/Lower Seaboard, and Iager/Jawbone (Kelafant et al., 1988). The Pocahontas coal seams include the Squire Jim and Nos. 1 to 7 and Nos. 3 and 4 are the thickest and most areally extensive. The majority of the coalbed methane (2.7 Tcf) occurs in the Pocahontas seams (Kelafant et al., 1988). The highest potential for methane development is in a small, 3,000 square mile area in southwest Virginia and south central West Virginia, where target coal seams achieve their greatest thickness and occur at depths of about 1,000 to 2,000 feet (Kelafant et al., 1988). The Gas Technology Institute (GTI) reported that the entire basin’s annual production was 52.9 billion cubic feet (Bcf) of gas in 2000 (GTI, 2002).

6.1 Basin Geology

The Central Appalachian Basin is characterized structurally by broad, open, northeast-southwest trending folds that typically dip less than five degrees (Kelafant et al., 1988) (Figure A6-2). The only documented exception to this is the Pine Mountain Overthrust Block in the southeast portion of the basin (Kelafant et al., 1988). Faults and folds associated with this 25 mile-wide and 125 mile-long structural feature are more intense as evidenced by overturned beds and even brecciated zones in some locations (Kelafant et al., 1988). The overthrust block is believed to have been transported about five miles from the southeast to the northwest (Kelafant et al., 1988). The two dominant joint patterns within the coals are most likely due to the basin having undergone two distinct patterns of structural deformation. These deformations include the Appalachian Orogeny and the tectonic event associated with development of the Pine Mountain overthrust (Kelafant et al., 1988).

The regional dip of coal-bearing Pennsylvanian strata is to the northwest at a rate of 75 feet per mile (Kelafant et al., 1988). Sedimentation within the Central Appalachian Basin was influenced somewhat by the Rome Trough, an Early Cambrian graben structure. Sediment deposition during early Pennsylvanian time (about 320 million years ago) occurred to the southeast of the Rome Trough in a rapidly but intermittently subsiding basin (Kelafant et al., 1988). As this tectonic activity began to abate in the Central Appalachian Basin, subsidence to the northeast of the Rome Trough began to form the Northern Appalachian Basin. However, subsidence rates in the Northern Appalachian Basin were comparatively slower, enabling the formation of more regionally extensive coalbeds (Kelafant et al., 1988).

There are three coal-bearing formations in the Central Appalachian Basin (Kelafant et al., 1988). From deepest to shallowest, they are the Pocahontas Formation, the New River/Lee Formation, and the Kanawha/Norton Formation. Each formation [Pennsylvanian in age (approximately 320 to 290 million years old)] is part of the Pottsville Group, and has varying nomenclature from state to state (Kelafant et al., 1988).

The Pocahontas Formation directly overlies the Mississippian Bluestone Formation, and was deposited in an unstable basin that was rapidly subsiding to the southeast (Kelafant et al., 1988). This is reflected in the thickness of the formation, which is thickest in the southeast and thins to the northwest. It also thins to the south and west due to erosion caused by the basal sandstone member of the overlying New River/Lee Formation (Kelafant et al., 1988). The Pocahontas Formation reaches its maximum thickness of 750 feet near Pocahontas, Virginia (Kelafant et al., 1988). The formation consists mostly of massively bedded, medium-grained subgraywacke, which can be locally conglomeratic (Kelafant, 1988). Gray siltstones and shales are interbedded within the sandstone (subgraywacke) unit, and coal seams comprise about two percent of the total thickness of the Pocahontas Formation (Kelafant et al., 1988).

The New River/Lee Formation conformably overlies the Pocahontas Formation in the northeastern portions of the basin (i.e., there are no time gaps in the depositional record), but there is an unconformity in the east-central portion of the basin (Kelafant et al., 1988). In the southern portion of the basin, the New River/Lee Formation unconformably overlies the Bluestone Formation. It is difficult to correlate this formation across state boundaries as nomenclature varies (Kelafant et al., 1988). The overall thickness of the formation decreases from east to west, with the thickest portion (1,000 feet) in parts of Virginia and West Virginia, lessening to fewer than 100 feet along the Ohio River in Kentucky (Kelafant et al., 1988). Coalbeds encountered in the New River/Lee Formation include the Fire Creek/Lower Horsepen, Beckley/War Creek, Sewell/Lower Seaboard, and the Iager/Jawbone (Kelafant et al., 1988). These coalbeds thin and pinch-out towards the south and west; therefore, there are no equivalent coalbeds in Kentucky and Tennessee (Kelafant et al., 1988).

The Kanawha/Norton Formation varies from a maximum thickness of 2,000 feet in West Virginia to less than 600 feet in portions of Dickenson and Wise Counties, Virginia (Kelafant et al., 1988). The formation is composed of irregular, thin- to massively-bedded subgraywackes interbedded with shale. Several thin carbonate units also occur within the formation as well as over 40 multi-bedded coalbeds.

All coal seams within the basin occur within the Pennsylvanian Pottsville Group (Figure A6-3). Specific stratigraphic nomenclature varies from state to state within the basin. (Names used in this summary are consistent with the West Virginia/Virginia nomenclature).

The Pocahontas No. 3 coal seam ranges in depth from outcrop along the northeastern edge of the basin to about 2,500 feet, with a thickness ranging up to seven feet (Kelafant et al., 1988). Depths to the Pocahontas No. 4 coal seam are somewhat similar to those for the Pocahontas No. 3 coal seam, as the No. 4 seam overlies the No. 3 seam by roughly 30 to 100 feet. The thickness of the No. 3 coal seam varies, with a maximum of approximately seven feet (Kelafant et al., 1988). The Fire Creek/Lower Horsepen coalbed ranges in depth from roughly 500 feet over half of its area, to a maximum depth of approximately 1,500 feet, with a maximum thickness of roughly six feet (Kelafant et al., 1988). The Beckley/War Creek coalbed is approximately two to five feet thick, and reaches to a maximum depth of about 2,000 feet (Kelafant et al., 1988). The Sewell/Lower Seaboard coalbed is fairly shallow, less than 500 feet in depth over half the area it covers, reaching to a depth over 1,000 feet in one small area. While this coal ranges in thickness from two to six feet, it averages about two feet in West Virginia and one foot in Virginia (Kelafant et al., 1988). The youngest targeted coal seam, the Iaeger/Jawbone, is generally less than 500 feet in depth, reaching its maximum depth of over 1,000 feet in two Virginia Counties. The thickness of the Iaeger/Jawbone coal ranges from two to six feet (Kelafant et al., 1988). Figures A6-4 through A6-9 are isopach maps for the six major coal groups of the Appalachian Coal Basin (adapted from Kelafant, et al., 1988).

6.2 Basin Hydrology and USDW Identification

The primary aquifer in the Kentucky portion of the Central Appalachian Basin is a Pennsylvanian sandstone aquifer underlain by limestone aquifers (National Water Summary, 1984). Water wells are typically 75 to 100 feet deep in the Pennsylvanian aquifer and commonly produce one to five gallons per minute of water (National Water Summary, 1984). The basin is located in a portion of the Cumberland Plateau physiographic province in Tennessee (National Water Summary, 1984). The primary aquifer in this area is a Pennsylvanian sandstone aquifer, comprising water-bearing sandstone and conglomerate subunits with interbedded shale and coal (National Water Summary, 1984). Water wells are typically 100 to 200 feet deep and usually produce 5 to 50 gallons per minute of water (National Water Summary, 1984). In Virginia, the basin is located in a portion of the Appalachian Plateau physiographic province. The primary aquifer in this region is the Appalachian Plateau Aquifer, a consolidated sedimentary aquifer consisting of sandstone, shale, siltstone, and coal (National Water Summary, 1984). Water wells are typically 50 to 200 feet deep, and commonly produce one to 50 gallons per minute of water (National Water Summary, 1984). In West Virginia, the basin is in a portion of the Appalachian Plateaus physiographic province of that state. The primary aquifers in this area are Lower Pennsylvanian aquifers, which include the Pottsville Group (National Water Summary, 1984). Wells are commonly 50 to 300 feet deep and typically produce one to 100 gallons per minute of water (National Water Summary, 1984).

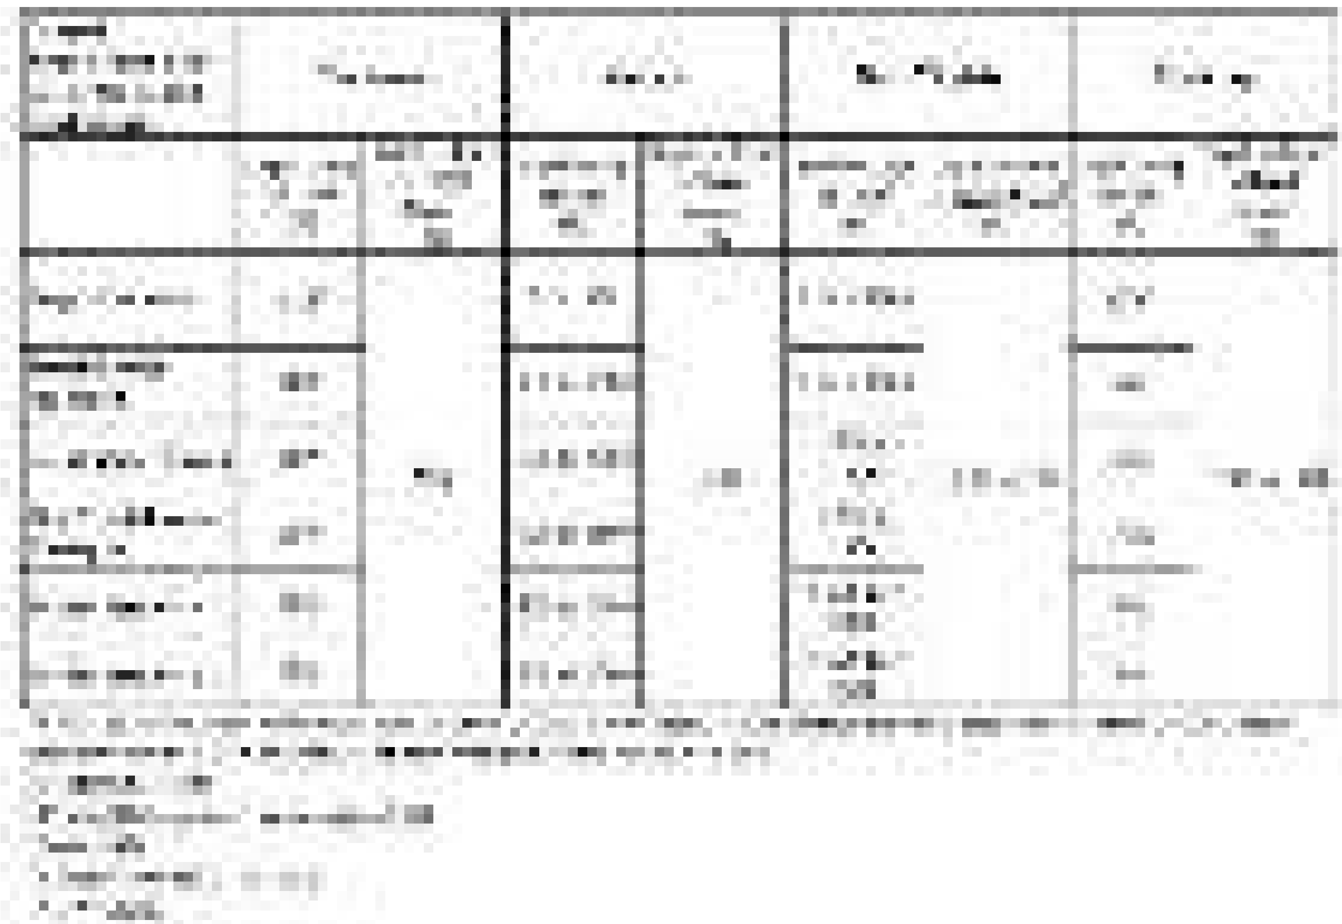
Produced water volumes from coal seams within the Central Appalachian Basin are relatively small, typically only several barrels or less per day per well, with high total dissolved solid (TDS) levels, usually greater than 30,000 milligrams per liter (mg/L) (Quarterly Review, 1993). Half the states (Kentucky and Ohio) within the Central Appalachian Basin have maps to locate the undulating interface between saline and freshwater aquifers. The remaining states (Tennessee and Virginia) have no maps defining this interface. Mike Burton (2001), a geologist with the Oil and Gas Office of the Tennessee Geology Division (TGD), reports that the state has no data relating to coalbed methane, which suggests that little or no coalbed methane extraction occurs inside Tennessee's borders (Burton, 2001). Luke Ewing (Ewing, 2001) of the TGD reported that the state had no aquifer maps. Scotty Sorles (Sorles, 2001) of Tennessee's Underground Injection Control Program mentioned that within the state, produced water disposal methods vary on a site-by-site basis. Depending on site characteristics, all injected waters must either be returned to the formation from which they came, or be treated to drinking water levels prior to injection elsewhere (Sorles, 2001).

Robert Wilson, Director of the Virginia's Division of Gas & Oil, stated that there is no mapping program for underground sources of drinking water (USDWs) or for the fresh/saline groundwater interface in Virginia. He reported that the most potable water is found far above the coal zones used for coalbed methane extraction, with fresh water typically found at less than 300 feet deep. He believes most drinking water in southwestern Virginia comes from wells in fractured bedrock aquifers or shallow coal aquifers, or, in some areas, directly from springs. Mr. Wilson also stated that some coalbed methane exploration has moved to shallower coal seams. The Commonwealth of Virginia has instituted a voluntary program concerning depths at which hydraulic fracturing may be performed (Virginia Division of Oil and Gas, 2002). This program involves an operator's determination of the elevations of the lowest topographic point and the deepest water well within a 1,500-foot radius of any proposed extraction well (Wilson, 2001). Hydraulic fracturing should occur at least 500 feet deeper than the lower of these two points (Wilson, 2001).

According to Mr. Tony Scales of the Virginia Department of Mines, Minerals and Energy, coal seams are the most permeable layers in the geologic subsurface in Virginia. For this reason, many private wells in the coalbed methane-producing counties are finished within the coalbeds. Mr. Scales stated that impacts to water supplies have occurred if the coal seams have been punctured by coalbed methane well drilling. The puncture hole acts as a conduit for the flow of water out of the coals and into lower formations. The puncture hole also allows methane to rise up to the surface (Virginia Department of Mines, Minerals, and Energy, 2002).

The following table contains information concerning the relative locations of the base of the zone of fresh water and potential methane-bearing coalbeds in the Central Appalachian Coal Basin. The table provides useful information that can help in determining whether coalbeds being used or slated for methane development lie within USDWs. Note that the 10,000 mg/L level of TDS in groundwater is the water quality criterion for a USDW. The depth to the USDW will thus lie well below the fresh water/ saline water interface. The area of focus for coalbed methane exploration in the basin only covers parts of Virginia and West Virginia (Figure A6-1). In Virginia, the depth to the base of fresh water is approximately 300 feet, whereas the depths to the bases of USDWs are greater. Thus, as can be seen in Table A6-1, methane-producing coalbeds could lie within USDWs in Virginia. West Virginia's interface between fresh and saline water (Foster, 1980) is based on a qualitative assessment, and is estimated at 280 to 730 feet. Again, the depths to USDWs are greater, and thus the coalbeds of interest could lie within potential USDWs in West Virginia. Finally, in Kentucky the interface between fresh water and saline water is based on a TDS level of 1,000 mg/L (Hopkins, 1966). Although the depths to methane-producing coalbeds in Kentucky are not listed in the Table A6-1, it is possible that, as in Virginia and West Virginia, such depths could be lower than the base of USDWs in Kentucky.

Table A6-1. Relative Locations of USDWs and Methane-Bearing Coalbeds



6.3 Coalbed Methane Production Activity

Coalbed methane operators in the Central Appalachian Basin include Equitable Resources, CONSOL (Consolidation Coal Company), and Pocahontas Gas Partnership, all located in Virginia (Zuber, 1998). GTI reported that the entire basin's annual production was 52.9 Bcf of gas in 2000 (GTI, 2002).

The Nora Field in southwestern Virginia is one of the better known coalbed methane production fields. Equitable Resources operates the Nora Field in southwestern Virginia. According to the

Virginia Division of Gas and Oil, over 700 coalbed methane wells were drilled in the Nora Field in 2002 and more than 1,800 coalbed methane wells were drilled in southwestern Virginia's Buchanan County (VA Division of Gas and Oil, 2002). Foam or water is used as the fracturing fluid and about 70,000 to 100,000 pounds of sand per well serve as proppant (Zuber, 1998). CONSOL and Pocahontas Gas Partnership produce coal methane from coal mine developments in Buchanan County, in southwestern Virginia (Zuber, 1998).

Many other smaller test projects were carried out in the basin in the 1970s, including the New River Coal Company/Lick Run Mine Project, Department of Energy (DOE)/Clinchfield Coal Company Project, U.S. Bureau of Mines (USBM)/Occidental Research/Island Creek Coal Company Project, Gas Research Institute/Wyoming County Co-op Project, USBM Federal No. 1 Project, and the Consolidation Coal Company/ Kepler Mine Project (Hunt and Steele, 1991). These projects were very small (five wells or fewer) and achieved limited success in terms of production. During development of some wells in the DOE/Clinchfield Coal Company project and the USBM Federal Project No. 1, fracture treatments "screened out" (i.e., the proppant placement failed), affecting those coalbed methane wells' production viability.

No coalbed methane production occurred in Tennessee between 1995 and 1997 (Lyons, 1997). Three coalbed methane wells produced gas from 1957 to 1980 in Harlan County, Kentucky, and only one test well was in production in the early 1990s in eastern Kentucky (Lyons, 1997). The Kentucky Department of Mines and Minerals website (2002) indicated that 1,338 gas wells were in operation in Kentucky at the end of 2000, but no indication was given whether these were coalbed methane wells or conventional gas wells.

In August 2001, EPA attended a hydraulic fracturing field visit in the Central Appalachian coal basin in Virginia. Pocahontas Oil & Gas, a subsidiary of Consol Energy, Inc., invited EPA personnel to a well location where a hydraulic fracturing treatment was being performed by Halliburton Energy Services, Inc. This treatment employed a variety of fluids and additives to create fractures in select coal seams at various depths. The main fracturing fluid was nitrogen foam (70% nitrogen / 30% water mixture). Prior to injection of the foam, 6 barrels of 15 percent hydrochloric acid were introduced into the well to dissolve the grout surrounding the injection perforations. Once the fracture was propagated to its maximum extent, 16/30 sand suspended in a 10-pound linear gel was injected to prop the fracture open. All the fluids and additives used were produced by Halliburton, including a scale inhibitor and a microbicide additive. Halliburton staff stated that typical fractures range in length from 300 to 600 feet from the well bore in either direction, but that fractures have been known to extend from as few as 150 feet to as many as 1,500 feet in length. According to the fracturing engineer on-site, fracture widths range from one eighth of an inch to almost one and a half inches (Virginia Site Visit, 2001).

Once a well is drilled and fractured in Virginia, several weeks might elapse before fracturing fluid flowback is initiated because a pipeline system must be constructed to transport the produced coalbed methane away from the well. Flowback fracturing fluids are collected in lined pits and tanks and transported off-site for disposal. The State of Virginia does not regulate the use of any drilling or fracturing fluids (Wilson, 2001).

6.4 Summary

The area with the highest potential for coalbed methane production in the Central Appalachian Coal Basin is southwestern Virginia (Dickenson and Buchanan Counties) and southern West Virginia (Wyoming and McDowell Counties) (Figure A6-1). The coal seams achieve their greatest thickness in these regions and occur at depths of approximately 1,000 to 2,000 feet. Based on Table A6-1, methane-producing coal may lie within a USDW, providing the potential for impact of water supplies.

Hydraulic fracturing is common practice in this region. Foam and water are the fracturing fluids of choice and sand serves as the proppant. Because most of the coal strata dip, a coalbed methane well's location within the basin may determine if hydraulic fracturing during the well's development will likely affect water quality within the surrounding USDW. For instance, on the northeastern side of the basin, the depth to the Pocahontas No. 3 coalbed is less than 500 feet. This depth increases to over 2,000 feet in the western portion of the basin, in the direction of the coal seam dip. Therefore, a well tapping this coal seam in the western portion of the basin may be below the base of a USDW but a well tapping this coal seam in the eastern portion of the basin may be within a USDW. Additionally, the base of the freshwater is not a flat surface, but rather an undulating one. These factors indicate that the relationship between a coalbed and a USDW must be determined on a site-specific basis.

Attachment 7
The Northern Appalachian Coal Basin

The Northern Appalachian Coal Basin is the northernmost of the three basins comprising the Appalachian Coal Region of the eastern United States, and includes parts of the States of Pennsylvania, West Virginia, Ohio, Kentucky, and Maryland (Figure A7-1). The basin trends northeast-southwest and the Rome Trough, a major graben structure, forms the southeastern and southern structural boundaries (Kelafant et al., 1988). The basin is bounded on the northeast, north, and west by outcropping Pennsylvanian-aged sediments (Kelafant et al., 1988). The basin lies completely within the Appalachian Plateau geomorphic province, covering an area of approximately 43,700 square miles (Adams et al., 1984 as cited in Pennsylvania Department of Conservation and Natural Resources, 2002). It consists of six Pennsylvanian age coal units, and contains an estimated 61 trillion cubic feet of coalbed methane (Kelafant et al., 1988). Coal seam depths range from surface outcrops to up to 2,000 feet below ground surface, with most coal occurring at depths shallower than 1,000 feet (Quarterly Review, 1993). Annual coalbed methane production stood at 1.41 billion cubic feet in 2000 (GTI, 2002).

7.1 Basin Geology

The six Pennsylvanian aged coal zones located within the Northern Appalachian Coal Basin are the Brookville-Clarion, Kittanning, Freeport, Pittsburgh, Sewickley, and the Waynesburg. These coal units are contained within the Pottsville, Allegheny, and the Monongahela Groups (Figure A7-3) (Kelafant et al., 1988).

In the Northern Appalachian Basin, the Pottsville stratigraphic group is generally 200 to 300 feet thick, and thins to the north and west into Ohio and Pennsylvania (Kelafant et al., 1988). The coals in this group are interbedded with fluvial and deltaic sands and shales and are capped by marine limestones and shales (Kelafant et al., 1988). Deposition of this group took place on irregular Mississippian terrain, forming thin and erratic coals (Kelafant et al., 1988).

The Allegheny Group reaches a maximum thickness of 200 to 300 feet in western Maryland and thins westward to about 150 to 200 feet in Ohio. Deposition of this group occurred as cyclothem-type sedimentation, resulting in a complex sequence of lenticular, thin- to massive-bedded subgraywacke, shale, and mudstone interbedded with clays and coal (Kelafant et al., 1988). Due to their alluvial and delta plain depositional environments, Allegheny coals, which include the Brookville/Clarion, Kittanning, and the Freeport, are 2 to 6 feet thick and aerially extensive (Kelafant et al., 1988). The coalbeds decrease in number from the eastern to the western edge of the basin (Kelafant et al., 1988).

The Monongahela Group was deposited primarily in lacustrine and swamp environments. Some of the most important economic coals of the basin were deposited in large lakes, such as the Pittsburgh and Sewickley coals (Kelafant et al., 1988). The Monongahela Group is thickest along the Monongahela River at 400 feet and thins to 250 feet in the southwest along the Ohio River. Shales, mudstones, and freshwater limestones are the major rock types of the Group (Kelafant et al., 1988). The Waynesburg coals are also contained within the Monongahela Group. In general, the coalbeds of the Monongahela Group are laterally extensive.

The total thickness of the Pennsylvanian-aged coal system averages 25 feet; however, better-developed seams within the coal zones can increase in thickness by up to twice the average (Quarterly Review, 1993). Within the Pennsylvanian Coal System, the deepest coal, the Brookville-Clarion, ranges in depth from surface exposures in anticlines to 2,000 feet below ground surface. The Kittanning Group reaches a maximum depth of 2,000 feet and is approximately 800 feet deep in more than half the area in which the group occurs. The distance between the Upper and Lower Kittanning is approximately 100 feet (Kelafant et al., 1988). Freeport coals are at a maximum depth of 1,800 feet in the central portion of the Northern Appalachian Coal Basin. The Upper and Lower Freeport are separated vertically by a distance of 40 to 60 feet (Kelafant et al., 1988). The Pittsburgh coals achieve a maximum depth of 1,200 feet and roughly half of the coals can be found at depths greater than 400 feet (Kelafant et al., 1988). Sewickley coals are deeper than 400 feet with the deepest coals located at 1,200 feet below ground surface (Kelafant et al., 1988). The final and youngest group discussed here, the Waynesburg group, is the shallowest, reaching a maximum depth of 800 feet in the center of the basin. Figures A7-4 through A7-9 (adapted from Kelafant et al., 1988) are isopach maps of sediment cover for the six major coal zones of the Appalachian Coal Basin.

7.2 Basin Hydrology and USDW Identification

The Northern Appalachian Basin is situated in the Appalachian Plateaus physiographic province of the region. The primary aquifer in this area is a Pennsylvanian sandstone aquifer underlain by limestone aquifers (National Water Summary, 1984). Water wells are typically 75 to 100 feet in depth in the Pennsylvanian aquifer and commonly produce one to five gallons per minute of water (National Water Summary, 1984). The primary aquifers in the Maryland portion of the basin are Appalachian sedimentary aquifers, which are mostly sandstones, shales, and siltstones with some limestone, dolomite, and coal. Water wells here are typically 30 to 400 feet in depth and usually produce 10 to 100 gallons per minute of water (National Water Summary, 1984).

In Ohio, the primary aquifers are sandstone aquifers, shaly sandstone and carbonate aquifers, and coarse-grained aquifers (comprised of alluvium and glacial outwash) associated with river valleys (National Water Summary, 1984). Water wells within these aquifers typically range from 25 to 300 feet in depth, and common water production rates vary between 1 and 500 gallons per minute (National Water Summary, 1984).

In Pennsylvania, the primary aquifers are sandstone and shale aquifers, with smaller unconsolidated sand and gravel aquifers surrounding river courses (National Water Summary, 1984). Well depths in the sandstone and shale aquifers in Pennsylvania are usually 80 to 200 feet in depth, and the wells typically produce 5 to 60 gallons per minute of water (National Water Summary, 1984).

In West Virginia, the primary aquifer is an Upper Pennsylvanian-aged aquifer consisting of the Dunkard, Monongahela, and Conemaugh Groups (National Water Summary, 1984). This aquifer consists of nearly horizontal beds of shale, sandstone, siltstone, coal, and limestone (National Water Summary, 1984). Water wells typically extend from 50 to 300 feet in depth in this area of West Virginia, and commonly produce 1 to 30 gallons per minute of water (National Water Summary, 1984).

Individual states containing portions of the basin have developed various maps and documents locating underground sources of drinking water (USDWs) and aquifers within their state boundaries, mostly as a part of their respective Underground Injection Control (UIC) Programs. EPA's Regional Office also has information concerning the location of these resources, as not all states within the Northern Appalachian Coal Basin have primacy over their UIC Program. Water quality data from eight historic Northern Appalachian Coal Basin projects show that estimated total dissolved solids (TDS) levels ranged from 2,000 to 5,000 milligrams per liter (mg/L) at depths ranging from 500 to 1,025 feet below ground surface (Zebrowitz et al., 1991), well within EPA's water quality criterion for a USDW of less than 10,000 mg/L of TDS (40 CFR §144.3).

Most states within the Northern Appalachian Basin, including Kentucky, Ohio, and West Virginia have mapped the interface between saline and freshwater aquifers. For Maryland and Pennsylvania, no maps have been identified that define the interface between saline and freshwater aquifers. In Maryland, a deep well drilled in southern Garrett County encountered the fresh/saltwater interface at a depth of 940 feet (Duigon and Smigaj, 1985). Groundwater in Pennsylvania deeper than 450 feet is not considered to be a USDW (Platt, 2001) because of the existence of non-water producing shale from 450 to 1000 feet, and TDS levels in water below this shale that are typically greater than 100,000 mg/L. The following table contains information concerning the relative location of potential USDWs and potential methane-bearing coalbeds in the Northern Appalachian Coal Basin.

As shown in Table A7-1, coalbeds with methane production potential in the Northern Appalachian Basin do occur within USDWs, indicating the potential for impact. West Virginia's interface line between fresh and saline water (Foster, 1980) is based on a qualitative assessment, Ohio's interface line is based on a TDS level of 3,000 mg/L (Sedam and Stein, 1970), and Kentucky's interface line is based on a TDS level of 1,000 mg/L (Hopkins, 1966). In Maryland, the fresh water distinction was probably made based on a TDS level of 1,000 mg/L, as the reference refers to sodium and chloride concentrations of 1,800 mg/L and 2,900 mg/L as "high levels" (Duigon and Smigaj, 1985).

Therefore, in these states, the depth to the 10,000 mg/L level of TDS in groundwater is potentially and likely deeper than the depths presented above (Table A7-1). This assumption is confirmed by a structure elevation map (Figure A7-6) of the Upper and Lower Freeport Sandstones of the Upper Allegheny Group (Figure A7-3) in Ohio. With the increasing depth of these stratigraphic units toward the basin center, much of the formation waters in these units south of the easternmost counties in Ohio contain TDS levels in excess of 10,000 mg/L (Vogel, 1982). Likewise, the Pittsburgh Group Coals in Pennsylvania range in depth from outcrop to 1,200 feet below ground surface (Figure A7-7). Over this length of “dip”, it is likely that the coals intersect drinking water aquifers before they reach depths where TDS levels exceed the 10,000 mg/L TDS water quality criterion of a USDW.

7.3 Coalbed Methane Production Activity

Coalbed methane has been produced in commercial quantities from the Pittsburgh coalbed of the Northern Appalachian Coal Basin since 1932 (Lyons, 1997), after the 1905 discovery of the Big Run Field in Wetzel County, West Virginia (Hunt and Steele, 1991). Coalbed methane production development in the Northern Appalachian Basin has lagged, however, due to insufficient reservoir knowledge, inadequate well completion techniques, and coalbed gas ownership issues revolving around whether the gas is owned by the mineral owner or the oil and gas owner (Zebrowitz et al., 1991). Annual coalbed methane production stood at 1.41 billion cubic feet in 2000 (GTI, 2002). As of October 2002, 185 coalbed methane wells were producing coalbed methane in Pennsylvania (Pennsylvania Department of Conservation and Natural Resources, 2002). Discharge of produced waters has also proven to be problematic (Lyons, 1997) for coalbed methane field operators in the Northern Appalachian Coal Basin.

Some operators in the Northern Appalachian Coal Basin and several test projects are discussed below. As of 1993, O’Brien Methane Production, Inc. had at least 20 wells in southern Indiana County, Pennsylvania (Quarterly Review, 1993). They received a water treatment and discharge permit that allowed O'Brien to discharge produced water into Blacklick Creek. The wells in O’Brien’s field were hydraulically fractured with water and sand. Nitrogen was being contemplated for future fracturing. O’Brien's operations have since been assumed by Belden and Blake. BTI Energy, Inc. also had a few coalbed wells in northern Fayette County, Pennsylvania. Two were completed in 1993 and the firm held permits for eight additional wells.

Other projects in the basin included the Lykes/Emerald Mines Project of the United States Bureau of Mines (USBM) and the Penn State University/Carnegie Natural Gas/U.S. Steel Wells Project, both in Greene County, Pennsylvania. Depths to the top of the Pittsburgh coals in Greene County range from 800 to 1,200 feet below ground surface (Kelafant et al., 1988). Hydraulic fracturing fluids included water and sand, and nitrogen foam and sand (Hunt and Steele, 1991). The Christopher Coal Company/Spindler Wells Project, which took place from 1952 to 1959, fractured one well with 12 quarts of nitroglycerin (Hunt and Steele, 1991). In the Vesta Mines Project of Washington County, Pennsylvania, the USBM used gelled water and sand to complete five wells in the Pittsburgh Seam (Hunt and Steele, 1991).

Within the State of Pennsylvania, there have been complaints of methane migrating into water supplies (Markowski, 2001). According to the Pennsylvania Department of Conservation and Natural Resources (2002), none of these complaints were linked specifically to hydraulic fracturing of coalbed methane wells. During a telephone interview (Markowski, 2001), Ms. Markowski stated methane contamination is due to the fact that many coalbed methane wells in southwestern Pennsylvania are completed in abandoned mine shafts. A puncture in the roof of the mineshaft provides a migration pathway for methane into overlying groundwater. These wells are known as gob wells, and are not usually hydraulically fractured or stimulated.

7.4 Summary

Based on available information, coal seams with methane production potential are located within USDWs throughout the Northern Appalachian Coal Basin, and hydraulic fracturing takes place in this basin. Because most of the coal strata dip, a well's location within the basin determines whether it is within a USDW, and whether the potential for impact exists. For example, in the Pittsburgh Coal Zone in Pennsylvania, the depth to the top of this coal zone varies from outcrop to about 1,200 feet in the very southwestern corner of the state. The approximate depth to the bottom of the USDW is 450 feet. Therefore, production wells operating down to approximately 500 feet could potentially be hydraulically connected to the USDW. However, those wells operating at depths greater than 900 feet would probably not be hydraulically connected to the USDW, unless a fracture extending beyond the coal layers to the shallower aquifer was to occur.

Milici (2002) indicated that the Pittsburgh Coal in Pennsylvania is mined out along its outcrop and the remaining coal resources are deeper (> 450 feet) in the basin. While this situation would greatly minimize the possibility of water quality impacts for this coal zone in Pennsylvania, the potential for contamination from the Pittsburgh coalbeds in other states within the basin still exists (see Table A7-1).

Attachment 8
The Western Interior Coal Region

The Western Interior Coal Region comprises three coal basins, the Arkoma, the Cherokee, and the Forest City Basins, and encompasses portions of six states: Arkansas, Oklahoma, Kansas, Missouri, Nebraska, and Iowa (Figure A8-1). The Arkoma Basin covers about 13,500 square miles in Arkansas and Oklahoma, with an estimated 1.58 to 3.55 trillion cubic feet (Tcf) of gas reserves, primarily in the Hartshorne coals (Quarterly Review, 1993).

The Cherokee Basin is part of the Cherokee Platform Province, which covers approximately 26,500 square miles (Charpentier, 1995) in Oklahoma, Kansas, and Missouri. The basin contains an estimated 1.38 million cubic feet of gas per square mile (Stoeckenger, 1990) in the targeted Mulky, Weir-Pittsburg, and Riverton coal seams of the Cherokee Group (Quarterly Review, 1993). In total, the basin contains approximately 36.6 billion cubic feet (Bcf) of gas. However, the Petroleum Technology Transfer Council (1999) indicates that there are nearly 10 Tcf of gas in eastern Kansas alone. The Forest City Basin covers about 47,000 square miles (Quarterly Review, 1993) in Iowa, Kansas, Missouri, and Nebraska, and contains an estimated 1 Tcf of gas (Nelson, 1999). For the entire region, coalbed methane production was 6.5 Bcf in 2000 (Gas Technology Institute (GTI), 2002).

8.1 Basin Coals

The Arkoma Basin is the southernmost of the three basins comprising the Western Interior Coal Region, and is bounded structurally by the Ozark Dome to the north, the Central Oklahoma Platform and Seminole Uplift on the west, and the Ouachita Overthrust Belt to the south (Quarterly Review, 1993). Middle Pennsylvanian coalbeds occur within the Hartshorne and McAlester Formations (Figure A8-2), as well as the Savanna and Boggy Formations (Quarterly Review, 1993).

The Cherokee Basin is the central basin of the Western Interior Coal Region, and is bounded on the east and southeast by the Ozark Dome, on the west by the Nehama Uplift, and on the north by the Bourbon Arch (Quarterly Review, 1993). Principal coals occur in the Krebs and Cabaniss Formations of the middle Pennsylvanian Cherokee Group (Figure A8-3).

The Forest City Basin (Figure A8-4), the northernmost basin of the Western Interior Coal Region, is a shallow cratonic depression bounded by the Nemaha Ridge to the west, the Thurman-Redfield structural zone to the north, the Mississippi River Arch to the east, and the Bourbon Arch to the south (Bostic et al., 1993). Methane-bearing coals occur in the middle Pennsylvanian Cherokee and Marmaton Groups, with the Cherokee Group being of primary interest (Tedesco, 1992).

8.1.1 Arkoma Basin Coals

The Hartshorne coals of the Hartshorne Formation are the most important for coalbed methane production in the Arkoma Basin. Their depths range from 600 to 2,300 feet in two productive areas in southeastern Oklahoma (Quarterly Review, 1993). Iannacchione and Puglio (1979) estimated that 58 percent of the coalbed methane in the Hartshorne coals in southeastern Oklahoma occurs at 500- to 1,000-foot depths. These coals can reach depths of greater than 5,000 feet, and are three to nine feet thick (Quarterly Review, 1993). Depths to the top of the Hartshorne coal in southeastern Oklahoma range from 380 to 1,540 feet (Friedman, 1982). As of March 2000, there were 377 coalbed methane wells in eastern Oklahoma, ranging in depth from 589 to 3,726 feet (Oklahoma Geological Survey, 2001).

8.1.2 Cherokee Basin Coals

The primary coal seams targeted by operators in Kansas are the Riverton Coal of the Krebs Formation and the Weir-Pittsburg and Mulky coals of the Cabaniss Formation (Quarterly Review, 1993). The Riverton and Weir-Pittsburg seams are about 3 to 5 feet thick and range from 800 to 1,200 feet deep (Quarterly Review, 1993). The Mulky Coal, which ranges up to 2 feet thick, occurs at depths of 600 to 1,000 feet (Quarterly Review, 1993).

8.1.3 Forest City Basin Coals

Individual coal seams in the Cherokee Group in the Forest City Basin range from a few inches to about 4 feet thick, with some seams up to 6 feet thick (Brady, 2002; Smith, 2002). Cumulative maximum coal thickness within the Cherokee Group is about 25 to 30 feet (Brady, 2002; Smith, 2002). Depths to the top of the Cherokee Group coals range from surface exposures in the shallower portion of the basin in southeastern Iowa, to about 1,220 feet in the deeper part of the basin, in northeastern Kansas (Bostic et al., 1993). At one location in Nebraska, the depth to the Cherokee Group is about 1,396 feet, and the base is at a depth of 2,096 feet (Condra and Reed, 1959). Maximum thickness of the Cherokee and Marmaton Groups is about 800 feet in the southeastern tip of Nebraska (Burchett, unpublished paper).

8.2 Basin Hydrology and USDW Identification

8.2.1 Arkoma Basin Hydrology and USDW Identification

In Arkansas, the Arkoma Basin falls within the Interior Highlands physiographic province (Figure A8-5). According to the National Water Summary (1984), there is no principal aquifer in this area, only small alluvial aquifers bounding the Arkansas River (Figure A8-5). In these alluvial aquifers, water wells typically penetrate to depths of 100 to 150 feet, and common well yields are in the order of 1,000 to 2,000 gallons of water per minute (National Water Summary, 1984). In Oklahoma, the Arkoma Basin is contained within the Ouachita and Central Lowland physiographic province (Figure A8-6). Much like in Arkansas, there are no principal aquifers in this portion of the state, but there are smaller alluvium and terrace deposits along the Arkansas, North Canadian, and Canadian Rivers (National Water Summary, 1984) that serve as aquifers (Figure A8-6). Marcher (1969) also identifies these smaller deposits as the most favorable for groundwater supplies. Water well depths in the alluvium and terrace deposits of the Arkansas River in Oklahoma typically range from 50 to 100 feet (National Water Summary, 1984). Water well production rates in all three aquifers commonly range from 100 to 600 gallons of water per minute in alluvium, and 50 to 300 gallons of water per minute in terrace deposits (National Water Summary, 1984).

Bill Prior, a geologist with the Arkansas Geological Commission, stated that within Arkansas, the Arkoma Basin was in the Arkansas River Physiographic Province, which lacks a true aquifer. Most of the rocks within this physiographic province are tight sandstones and shales, and most communities within the province use surface water supplies (Prior, 2001). Doug Hansen of the Arkansas Geological Commission said that there were a few scattered bedrock wells within the Arkoma Basin (Hansen, 2001). Total dissolved solids (TDS) levels in the McAlester Formation in Arkansas (which contains the Hartshorne coals; Potts, 1987) range between 55 to 534 milligrams per liter (mg/L) at depths ranging from 32.4 to 190 feet below land surface (Cordova, 1963). The base of fresh water in the area is about 500 to 2,000 feet below ground surface (Cordova, 1963). However, Cordova (1963) does not define “fresh water;” therefore, it is difficult to determine if the depths reported by Cordova coincide with the base of an underground source of drinking water (USDW).

Water quality test results from the targeted Hartshorne seam in Oklahoma have shown the water to be highly saline (Quarterly Review, 1993). Ken Luza, a geologist with the Oklahoma Geological Survey, stated that a hydrologic atlas prepared by the Oklahoma Geological Survey delineated a 5,000 mg/L TDS water quality contour line in a portion of the state, including the Arkoma Basin (Marcher, 1969; Marcher and Bingham, 1971). Maps such as these atlas maps show that, based on water quality and rock type, very little of the area falls within a zone “most favorable for groundwater supplies” or “moderately favorable for groundwater supplies.” Most of the area falls within a zone designated as “least favorable for groundwater supplies” (Cardott, 2001). Pam Hudson, Manager of the

Geologic Section of the Oklahoma Corporation Commission, stated that the Commission has a series of maps, one for each county in Oklahoma, showing the depth to the 10,000 mg/L TDS line (Hudson, 2001). The water quality criterion for a USDW is a TDS level of less than 10,000 mg/L. The Oklahoma Corporation Commission maps are used to assist drillers in complying with state regulations that require oil and gas wells to be cased through USDWs.

The following table contains information concerning the relative location of potential USDWs and methane-bearing coalbeds in the Arkoma Basin.

Table A8-1 Relative Locations of USDWs and Potential Methane-Bearing Coalbeds, Arkoma Basin

Arkoma Coal Basin, States and Coal Group	**Arkansas**		**Oklahoma**	
	Depth to top of Coal [1] (ft)	Depth to base of Fresh Water [2,3] (ft)	Depth to top of Coal [1] (ft)	Depth to base of USDW [4] (ft)
Hartshorne Coals	0 to < 4,500	500 to 2000	> ~1000	< ~900

[1] Andrews et al., 1998
[2] Note: The base of "fresh water" is not the base of the USDW (depth to the base of the USDW is unknown or not available). Fresh water is within the USDW and the base of fresh water is above the base of the USDW. Cordova (1963) does not define "fresh water."
[3] Cordova, 1963
[4] Oklahoma Corporation Commission Depth to Base of Treatable Water Map Series (2001)

Based on Table A8-1, it can be determined that in Arkansas, there is a possibility for the Hartshorne Coals to be located within a USDW, allowing the potential for impacts. The potential for impacts from fracturing coalbeds below the USDW is not known. Cordova (1963) does not specify the TDS level used to determine the depth of the base of fresh water in the Arkansas Valley region; he merely states that it is the depth to salt water, and he does not provide a definition of "salt water." The position of a coalbed methane well within the basin would ultimately determine if coals and USDWs coincide, as the Hartshorne Coals are typically shallower on basin margins (Andrews et al., 1998) and progressively increase in depth toward the basin's center (where they are potentially too deep to be located within a USDW).

8.2.2 Cherokee Basin Hydrology and USDW Identification

The Cherokee Basin underlies parts of the States of Kansas, Missouri, and Oklahoma. In Kansas, the Cherokee Basin is part of the Central Lowlands and Ozark Plateaus physiographic provinces (Figure A8-7). While the majority of this area does not contain a principal aquifer, the Ozark and Douglas aquifers (Figure A8-7) are contained in the basin (National Water Summary, 1984). The confined Ozark Aquifer, composed of weathered and sandy dolomites, typically contains water wells that extend from 500 to

1,800 feet in depth, commonly yielding 30 to 150 gallons of water per minute (National Water Summary, 1984). The usually unconfined Douglas Aquifer is channel sandstone of Pennsylvanian Age (National Water Summary, 1984). Water wells are usually 5 to 400 feet deep in this aquifer and typically produce 10 to 40 gallons of water per minute (National Water Summary, 1984).

In Missouri, only a very small portion of the basin falls within the Osage Plains area of the Central Lowlands physiographic province (Figure A8-8). The principal aquifers in this portion of Missouri are the Ozark and Pennsylvanian-Mississippian age aquifers (National Water Summary, 1984) (Figure A8-8). Water well depths in the Ozark Aquifer typically range from 200 to 1,700 feet, and those in the Pennsylvanian-Mississippian age aquifers typically range from 100 to 400 feet in depth (National Water Summary, 1984). Common well yields are 15 to 700 gallons of water per minute and 1 to 15 gallons of water per minute in the Ozark and Pennsylvanian-Mississippian aquifers, respectively (National Water Summary, 1984). Only a very small portion of the Cherokee Basin, bounded from the Forest City Basin to its north by the Bourbon Arch, falls within the State of Missouri (Figure A8-9). Jim Vandike, Chief of Missouri's Water Resources Branch at the Missouri Geological Survey, stated that only two public water supplies obtain water from Pennsylvanian strata, and those wells were outside of the Cherokee Basin (Vandike, 2001).

In Oklahoma, the Cherokee Basin lies within the Central Lowland physiographic province (Figure A8-6). In addition to the alluvium and terrace deposit aquifers previously discussed in the Arkoma Basin aquifer descriptions, this area also contains the Garber-Wellington and Vamoosa-Ada Aquifers (Figure A8-6), which are unconfined to confined sandstone with shale and siltstone aquifers (National Water Summary, 1984). The Vamoosa-Ada Aquifer contains some conglomerate aquifers as well. Water well depths in these two aquifers usually range from 100 to 900 feet, and wells typically produce from 100 to 300 gallons of water per minute (National Water Summary, 1984). At least half of the area of this basin in Oklahoma does not contain a principal aquifer (National Water Summary, 1984).

In Kansas, Al Macfarlane, of the Kansas Geological Survey, stated that the Ozark Aquifer was located in the Cherokee Basin in Kansas (Macfarlane, 2001). An Ozark Aquifer Extent map indicates that the "usable" part of the aquifer (defined as having less than 10,000 mg/L of TDS per Macfarlane; no definition of "usable" is provided by the map) covers the three southeastern-most counties (Bourbon, Crawford, and Cherokee) of the state (Figure A8-7) and parts of the adjacent four counties (Linn, Allen, Neosho, and Labette) (DASC Ozark Aquifer Extent Map, 2001c). Because the land surface elevation in that portion of the state is roughly 850 feet above sea level (DASC Kansas Elevation Map, 2001b) and the elevation of the base of the Ozark Aquifer is roughly 900 feet below sea level (Ozark Aquifer Base Map, 2001c), the base of the Ozark aquifer is roughly 1,750 feet below ground surface. Groundwater samples taken from lower Paleozoic aquifers in Kansas show TDS levels ranging from <500 to 5,000 mg/L (Figure A8-10) (Macfarlane and Hathaway, 1987), well within the range for a USDW.

Table A8-2 contains information concerning the relative location of potential USDWs and methane-bearing coalbeds in the Cherokee Basin. The table shows that all or part of the targeted coal seams could be coincident with a USDW, allowing the potential for impacts. Most past coalbed methane production activity within the Cherokee Basin took place in Kansas (Quarterly Review, 1993). However, coalbed methane production activity within the Cherokee Basin in Oklahoma has increased markedly in recent years (Hudson, 2001).

Table A8-2 Relative Locations of USDWs and Potential Methane-Bearing Coalbeds, Cherokee Basin

Coal Group	**Kansas**		**Missouri**		**Oklahoma**	
	Depth to top of Coal [1] (ft)	Depth to base of Fresh Water (USDW) [2] (ft)	Depth to top of Coal [1] (ft)	Depth to base of Fresh Water [3] (ft)	Depth to top of Coal [1] (ft)	Depth to base of Fresh Water (ft)
Mulky	600 to 1000	~ 1750	600 to 1000	N/A[4]	600 to 1000	N/A[4]
Weir-Pittsburg	800 to 1200		800 to 1200		800 to 1200	
Riverton	800 to 1200		800 to 1200		800 to 1200

8.2.3 Forest City Basin USDW Identification

The Forest City Basin includes parts of the States of Iowa, Kansas, Missouri, and Nebraska. In Iowa, the Forest City Basin lies within the Southern Iowa Drift Plain physiographic province (Figure A8-11). The most productive aquifer in this area is the dolomite and sandstone Jordan Aquifer (Figure A8-11). Wells in this aquifer commonly range in depth from 300 to 2,000 feet (some are as deep as 3,000 feet) and usually produce 100 to 1,000 gallons of water per minute (National Water Summary, 1984). This aquifer usually contains in excess of 1,500 mg/L TDS in the southern portion of the state (National Water Summary, 1984). Other aquifers used at various locations in the basin are found in the Silurian-Devonian age and in the Mississippian-age strata (Figure A8-11). Water wells in these aquifers range from 150 to 750 feet deep with variable production (Howes, 2002). Also contained within this basin in Iowa is a portion of the confined, poorly cemented sandstone Dakota aquifer (National Water Summary, 1984) (Figure A8-11). Water wells in this aquifer are typically 100 to 600 feet in depth, and commonly produce 100 to 250 gallons of water per minute (National Water Summary, 1984). An Iowa Division of Natural Resources Geological Survey Bureau geologist, Mary Howes, said that few towns in Iowa use Pennsylvanian strata for water, as they typically contain high concentrations of sulfate and TDSs (Howes, 2001). Most community water supplies in the southern portion of Iowa use surface water and shallow alluvial aquifers as drinking water sources, and there are a few wells in fractured bedrock. Private water supplies typically are derived from seepage wells, shallow bedrock wells, or purchased from a public supply (Howes, 2002).

In Kansas, the basin is located in the Lowlands physiographic province (Figure A8-7), and only the northeastern corner of the state falls within the Forest City Basin boundary. In addition to the Douglas Aquifers described above in the Cherokee Basin Aquifer descriptions, this portion of the Forest City Basin in Kansas also contains a glacial drift aquifer (is this and some alluvial aquifers adjacent to the Kansas River (National Water Summary, 1984) (Figure A8-7). In the glacial drift, wells are typically 10 to 300 feet in depth and usually produce 10 to 100 gallons of water per minute (National Water Summary, 1984). Wells in the alluvium are usually 10 to 150 feet deep and typically produce 10 to 500 gallons of water per minute (National Water Summary, 1984). The glacial drift aquifer's base varies from about 850 to 1,300 feet above sea level (DASC, Glacial Drift Base Map, 2001a). Since the elevation of the land surface in this portion of Kansas is roughly between 1,000 and 1,400 feet above sea level (DASC, Kansas Elevation Map, 2001b), the aquifer appears to extend only to an approximate maximum depth of 150 feet below the ground surface.

In Missouri, the basin lies within the Central Lowland physiographic province (Figure A8-8). The principal aquifer in this area is a glacial-drift aquifer (Figure A8-8). In this aquifer, water wells are typically 100 to 250 feet in depth and produce 5 to 200 gallons of water per minute. In addition to this aquifer, alluvial deposits along the Missouri River are also developed for water (National Water Summary, 1984)(Figure A8-8). Well depths in the alluvium usually range from 80 to 100 feet in depth, and the wells typically produce 100 to 1,000 gallons of water per minute (National Water Summary, 1984). Two public supply wells in Cass County, Missouri, extract water from Pennsylvanian strata for the town of East Lynn. A map of groundwater quality within Paleozoic aquifers of Missouri (Figure A8-12) shows that within the Forest City Basin, water quality ranges from about 500 mg/L TDS to 40,000 mg/L TDS in deeper portions of the basin (Missouri Division of Geological Survey and Water Resources, 1967). A 10,000 mg/L TDS boundary line delineated in the Mississippian aquifers of Missouri (located directly below Pennsylvanian-age strata) includes portions of Cass, Jackson, Lafayette, Carroll, Saline, Ray, Clay, Caldwell, Clinton, and Platte Counties (Netzler, 1982) (Figure A8-8).

Only the southeastern tip of Nebraska (primarily Richardson County) falls within the limits of the Forest City Basin. The principal aquifers in this area are undifferentiated aquifers in Paleozoic-age rocks (National Water Summary, 1984) (Figure A8-13). Locally overlain by saturated Quaternary-age sand and gravel deposits, wells within this area are commonly 30 to 2,200 feet in depth, and produce about 10 to 200 gallons of water per minute. TDS levels in the water can be as high as 6,000 mg/L, but are usually less than 1,500 mg/L (National Water Summary, 1984). The Ground Water Atlas of Nebraska (Flowerday et al., 1998) indicates that Richardson County is within the Southeastern Nebraska Glacial Drift rock unit. The thickness of the aquifer in Richardson County is less than 100 feet and the depth to water is 30 to 200 feet. The information in the Ground Water Atlas of Nebraska (Flowerday et al., 1998) appears to be in conflict with the data presented by the U.S. Geological Survey in the National Water Summary (1984). Matt Jokel of the Nebraska Conservation and Survey Division said it is very difficult to obtain water in this portion of the state, and most people use valley fill materials and paleochannels as water supply sources. He also believes that the coal resources, which could possibly be used for methane extraction, are probably too deep to be located coincident with the shallow water supplies in the area (Jokel, 2001).

Table A8-3 contains information concerning the relative location of potential USDWs and potential methane-bearing coalbeds in the Forest City Basin.

Table A8-3 Relative Locations of USDWs and Potential Methane-Bearing Coalbeds, Forest City Basin

	Iowa		Kansas		Missouri		Nebraska	
Coal Group	Depth to top of Coal [1] (ft)	Depth to base of fresh water[3] (ft)	Depth to top of Coal [1] (ft)	Depth to base of fresh water [4] (ft)	Depth to top of Coal [1] (ft)	Depth to base of fresh water [5] (ft)	Depth to top of Coal[1,6] (ft)	Depth to base of fresh water [2,7] (ft)
Cherokee Group	0 to >230	N/A[8]	720 to 1220	~ 150	300 to 1100	N/A[8]	1220 to 1396	129 to 299

[8] Not Available

Presently, there does not appear to be a USDW located at the same depth as the coals of the Cherokee Group in the Forest City Basin. However, very little is known about the coal resources of this basin (Quarterly Review, 1993). Further research is required to delineate the possible link between coalbed methane resources and USDWs in the Forest City Basin.

8.3 Coalbed Methane Production Activity

GTI places total coalbed gas production in the Western Interior Coal region at 6.5 Bcf for the year 2000 (GTI, 2002).

8.3.1 Arkoma Basin Production Activity

In 1989, Bear Production Company became the first company to target coalbed methane production from the Hartshorne Coals of the Arkoma Basin in Haskell County, Oklahoma (Quarterly Review, 1993). As of 1993, Bear Production had 38 wells in operation, Aztec Energy Corporation had 19 wells, and Redwine Resources, Inc. had 40 wells in the Arkoma Basin (Quarterly Review, 1993).

As of 1993, Bear Production was not fracturing its wells, but rather completing them as open holes without perforated casings (Quarterly Review, 1993). However, other production companies were fracturing their wells for methane production. Before 1992, water, linear gel, acid, and nitrogen foam fracturing fluids were used, with most operators using foam with small sand volumes (35,000 to 60,000 lbs) (Quarterly Review, 1993). In 1993, slick water fracturing fluids containing no proppant were becoming more common (Quarterly Review, 1993). Well fracturing data from 36 wells in the Spiro Southeast Field of LeFlore County, Oklahoma show that either water or nitrogen foam was the base fracturing fluid used to carry sand proppant into coal cleats (Andrews et al., 1998). Fracturing continues in the Arkoma Basin today, at least in Oklahoma, where undisclosed amounts of initial water production are "frac" waters introduced during fracture stimulation (Cardott, 2001). Both Wendell (2001) and Marshall (2001) outline current hydraulic fracturing practices within the Arkoma Basin, and Wendell (2001) includes acids, benzene, xylene, toluene, gasoline, diesel, solvents, bleach, and surfactants as detrimental hydraulic fracturing substances in his "lessons learned" category.

A search of the Oklahoma Coal Database, updated on January 17, 2001, indicated that over 360 coalbed methane wells had been completed in Haskell, Le Flore, and Pittsburg counties alone, targeting the Hartshorne, McAlester, and Savanna coals. Additional operators in the Arkoma Basin today include Continental Resources, SJM Inc., Brower O & G, Mannix Oil, and OGP Operating (Oklahoma Coal Database, 2001).

Apparently there is little to no coalbed methane activity in the Arkoma Basin in Arkansas, based on the Arkansas Geological Commission's Web site, which states,

"…there exists the potential for coalbed methane production in this area of the state" (Arkansas Geological Commission, 2001). The low coalbed methane activity in this Basin is further confirmed by Andrews et al. (1998), which outlines Arkansas' restrictive field-spacing policy from the 1930s of only one well per 640-acre section for each producing zone in the Hartshorne. This policy effectively made exploration uneconomical. A change in field-spacing rules in 1995 has stimulated new interest among independent producers in Arkansas to develop methane from the Hartshorne coals (Andrews et al., 1998).

8.3.2 Cherokee Basin Production Activity

In the Cherokee Basin, unknown amounts of coalbed methane gas have been produced with conventional natural gas for over 50 years (Quarterly Review, 1993). Targeted coalbed methane production increased in the late 1980s, and at least 232 coalbed methane wells had been completed as of January 1993 (Quarterly Review, 1993). During this timeframe, development was centered on Montgomery County, Kansas, with the most active operators being Great Eastern Energy and Development Corporation with 81 wells, Kan Map Inc. with 47 wells, and Stroud Oil Properties Inc. with 35 wells, (Quarterly Review, 1993). In addition to these operators, Bonanza Energy Corporation, Conquest Oil Company, Foster Oil & Gas, Hunter, Quantum Energy, Uranus, and U.S. Exploration had active development programs, and Derrick Industries was planning a program (Quarterly Review, 1993).

The coalbed methane wells were typically fractured with water or nitrogen-based fluids and sand, although the shallower Mulky coal received fracturing treatments of 40-pound linear gel and sand (Quarterly Review, 1993). On average, 5,000 pounds of sand were used per foot of coal (Quarterly Review, 1993). Another technique used in Kansas consists of injecting 4 barrels of 15 percent hydrochloric acid mixed with 16 barrels of potassium chloride and 15,000 standard cubic feet of nitrogen (Stoeckinger, 1990). In the Sycamore Valley field in Kansas, Stroud Oil Properties used 426 barrels of cross-linked fluid with 52 percent pad and 3 percent flush, and 30,000 pounds of 12/20 sand mixed at one to nine pounds per gallon injected at 20 barrels per minute. Operators were avoiding large-volume treatments due to a fear that fractures could be induced in thick water-bearing sands above and below the coals, which would have created excess water production (Quarterly Review, 1993). Stoeckinger (2000) reports that current hydraulic fracturing practices in the Cherokee Basin in Kansas are water only, no gel, with nitrogen being popular and "slick-water down tubing."

Pam Hudson, of the Oklahoma Corporation Commission, indicated that coalbed methane extraction was beginning to grow in the Cherokee Basin in the northeastern section of Oklahoma, and more development was now centered on that region as opposed to the Arkoma Basin to the south. Ms. Hudson expected that much of the development would be focused on Washington, Nowata, and Craig Counties (Hudson, 2001).

In Missouri, there appears to be little to no coalbed methane extraction within the Cherokee Basin. David Smith, a geologist with the Missouri Geological Survey, stated that coalbed methane extraction in Missouri is essentially non-existent (Smith, 2001).

8.3.3 Forest City Basin Production Activity

The Forest City Basin was relatively unexplored in 1993, with about ten coalbed wells concentrated in Kansas' Atchison, Jefferson, Miami, Leavenworth, and Franklin Counties (Quarterly Review, 1993). The wells were hydraulically fractured with 500 to 30,000 pounds (with an average of 5000 pounds) of sand proppant. The types of fluids used during the fracturing process were not mentioned (Quarterly Review, 1993).

David Smith, believes that at one time there were some coalbed methane wells just south of Kansas City in Cass County (Smith, 2001). Sherri Stoner, of the Missouri Geological Survey, confirmed this in February 2001, and remarked that they were no longer in operation (Stoner, 2001). An Iowa Division of Natural Resources Geological Survey Bureau geologist, Mary Howes, stated that presently there was no coalbed methane production in Iowa (Howes, 2001).

Information concerning coalbed methane production activity in Nebraska could not be found.

8.4 Summary

Based on depths to the Hartshorne Coal and the base of fresh water presented in Table A8-1, it appears that coalbed methane extraction wells in the Arkoma Basin could be coincident with potential USDWs in Arkansas, potentially allowing for impacts. Based on maps provided by the Oklahoma Corporation Commission (2001), which depicts the depths to the10,000 mg/L of TDS groundwater quality boundary in Oklahoma, the location of coalbed methane wells and USDWs would most likely not coincide in Oklahoma. This is based on depths to coals typically greater than 1,000 feet (Andrews et al., 1998) and depths to the base of the USDW typically shallower than 900 feet (Oklahoma Corporation Commission, 2001).

Table A8-2 supports the possibility that coalbed methane wells in the Cherokee Basin targeting the Cherokee Group coals in Kansas may coincide with USDWs, indicating the potential for impacts to drinking water. In Missouri, more water quality data is required prior to any determination of coalbed methane well/USDW conflict. In addition, since only a very small portion of the Cherokee Basin falls within the state, this portion of the basin needs to be delineated more precisely to see which USDWs lay within this small part of the basin. However, current levels of coalbed methane activity in Missouri are minimal.

Last, in the Forest City Basin, there appears to be little physical relationship between coalbeds that may be used for coalbed methane extraction and water supplies. However, aquifer and well information from the National Water Summary (1984) indicate that a co-location of the two could exist in Nebraska. More information would be needed to fully investigate the relationship between coalbeds and USDWs in the Forest City Basin.

Attachment 9
The Raton Basin

The Raton Basin covers an area of about 2,200 square miles in southeastern Colorado and northeastern New Mexico (Figure A9-1). It is the southernmost of several major coal-bearing basins along the eastern margin of the Rocky Mountains. The basin extends 80 miles north to south and as much as 50 miles east and west (Stevens et al., 1992). It is an elongate asymmetric syncline, with 20,000 to 25,000 feet of sedimentary rock in the deepest part. Coalbed methane resources in the basin, which have been estimated at approximately 10.2 trillion cubic feet (Tcf), are contained in the upper Cretaceous Vermejo Formation and upper Cretaceous and Paleocene Raton Formation (Stevens et al., 1992). In 2000, the average gas production rate per well in the Raton Basin was close to 300,000 cubic feet per day, and annual production was 30.8 billion cubic feet (Bcf) (GTI, 2002).

9.1 Basin Geology

The Raton structural basin is an asymmetric synclinal sedimentary basin containing sedimentary rocks as old as Devonian overlying basement Precambrian rocks, with Holocene sediments at the surface. The coal occurs in the Vermejo and the Raton Formations, which overlie the Trinidad Sandstone, a basin-wide regressive marine sandstone (Figure A9-2). The Vermejo and Raton Formations consist of deltaic lower coastal plain and fluvial deposits (Flores and Pillmore, 1987). Numerous discontinuous and thin coalbeds are located in the Vermejo Formation and the Raton Formation, which overlie the Trinidad Sandstone (Figure A9-3). The top of the Trinidad Sandstone forms the lower boundary of the Raton coal basin as shown in Figure A9-1. Development of coalbed methane wells has focused on development of the Vermejo coals rather than the Raton coals because the former are thicker and more abundant. The coalbeds are of limited extent and cannot be correlated over more than a few miles.

Individual coalbeds in the Vermejo Formation range from a few inches to about 14 feet thick, and total coal thickness typically ranges from 5 to 35 feet. An isopach map of total coal thickness in the Vermejo Formation, based on 92 well logs and measured sections, was published by Stevens et al. (1992) (Figure A9-4). Total coal thickness in the Raton Formation ranges from 10 feet to greater than 140 feet, with individual seams ranging from several inches to greater than 10 feet thick. Although the Raton Formation is much thicker and contains more total coal than the Vermejo Formation, individual coal seams in the Raton are less continuous and generally thinner. Additionally, because of extensive erosion of the Raton Formation, particularly in the eastern part of the basin, much of the original coal is no longer present (Stevens et al., 1992). Between 5 and 15 individual coalbeds produce coalbed methane for wells in the basin (Hemborg, 1996).

Middle Tertiary igneous intrusions are present in the central part of the basin (Steven, 1975). Sills and dikes have invaded sediments of the basin including both the Vermejo and Raton Formations. Sills have intruded along the coal seams destroying tremendous quantities of coal (Carter, 1956).

Coal seam depth is an important variable used to estimate gas production potential. Figure A9-5 is a thickness of overburden map from Stevens et al. (1992). The map shows the depth below land surface to the midpoint depth of the coal-bearing interval, using coal thickness as a weighting factor. Overburden thickness ranges from less than 500 feet near the basin perimeter to greater than 4,100 feet in the deep northwestern part of the basin. Many of the differences in thickness of overburden can be attributed to variations in topography and are thus a consequence of erosion and not necessarily subsurface geologic structure.

Stratigraphic cross-sections constructed to illustrate the regional subsurface geologic structure and the distribution of coal seams and igneous intrusions, as well as the areal locations of these cross-sections, are shown in Figures A9-6 through A9-8. The cross-sections use the top of the Trinidad Sandstone as the horizontal datum. The Vermejo Formation has a relatively uniform thickness of about 350 feet throughout the basin. The Raton Formation varies from about 0 to 2,100 feet thick. It grades westward into and is overlain by the conglomeratic Poison Canyon Formation (Flores, 1987; Flores and Pillmore, 1987).

A study of the relationship between coal cleat orientation and the compression stresses due to tectonic forces can indicate areas likely to have increased coal seam permeability and provide increased coalbed methane yield (Stevens et al., 1992). Cleats, or small-scale fractures in the coal, are commonly oriented perpendicularly to the maximum stress. These fractures tend to expand, thereby providing greater permeability and coalbed methane yields on the axes of the anticlines, such as the Vermejo Park anticline. Wells drilled near the axis of the La Veta syncline, in contrast, did not encounter adequate permeability (Stevens et al., 1992). Initially it was thought that sills that intrude along the bedding plane of the coal seams would reduce methane production, but several operators have noted that elevated methane contents have sometimes been measured in coal seams that have been intruded by igneous rocks (Stevens et al., 1992).

9.2 Basin Hydrology and USDW Identification

Regional groundwater flow in the Raton Basin is dependent on geologic structure and topography. Regional flow is generally down-slope from west to east or southeast (Figure A9-9). In the northern part of the basin, however, flow is radial away from Spanish Peaks (Howard, 1982; Geldon, 1990). Additionally, along the eastern margin of the basin, sediments dip to the west and groundwater flow is locally down-dip to the west. While recharge occurs primarily at elevations greater than 7,500 feet, discharge is mainly through streams and by evapotranspiration in the central and eastern parts of the basin.

Principle bedrock aquifers in the basin are the Cuchara-Poison Canyon, the Raton-Vermejo-Trinidad, the Fort Hayes-Codell, the Dakota-Purgatoire, and the Entrada (Geldon, 1990) (Figure A9-3). The pressure regime in the basin is poorly understood. Under-pressured conditions, or hydraulic heads in deep bedrock aquifers that are lower than those in shallow formations, appear to exist throughout much of the basin (Howard, 1982; Geldon, 1990; Tyler et al., 1995). This hydraulic head difference suggests that the deep bedrock aquifers are not in communication with shallow formations. Meteoric circulation, however, is indicated by the regional freshness of the produced waters (Stevens et al., 1992; Tyler et al., 1995).

All of the water produced along with coalbed methane in the Raton Basin has a total dissolved solids (TDS) content of less than 10,000 milligrams per liter (mg/L) (the water quality criterion for an underground source of drinking water (USDW)), and the aquifers from which the gas is produced meet the water quality criterion for a USDW (National Water Summary, 1984). A scatter diagram of potentiometric head versus TDS from coalbed methane wells in the Raton Basin (Figure A9-10) shows little correlation between potentiometric head and water quality. More importantly, this figure shows that all of the water had less than 10,000 mg/L of TDS, nearly all had a TDS of less than 2,500 mg/L, and more than half had a TDS of less than 1,000 mg/L. Two producers used injection wells for disposal, but operating permits issued to one gas producer (Evergreen Resources, Inc.) by the Colorado Department of Public Health and Environment allowed discharge of produced water into streambeds and stock ponds, indicating that the water was not too saline for surface discharge. Hemborg (1998) suggests that the wells yielding larger quantities of groundwater might be connected to the underlying water-bearing Trinidad Sandstone.

9.3 Coalbed Methane Production Activity

Hydraulic fracturing employed for enhancement of coalbed methane production is designed to enable gas within the rock to flow more readily to an extraction well. Coalbed methane well stimulation using hydraulic fracturing techniques is a common practice in the Raton Basin. Records show that fluids used are typically gels and water with sand proppants.

Hemborg (1996) reported that the average water production from coalbed methane wells in the Raton Basin was 700 barrels per million cubic feet (Mcf), and average daily production for 42 wells in the Spanish Peak Field was 0.309 Mcf (Hemborg, 1998). Conversion of these rates from coalbed methane industry units to those commonly used for water supplies gives an average water production rate for those wells of only 6.3

gallons per minute. These rates are generally not considered sufficient for public water supply or irrigation; however, they meet the water supply volume criterion for a USDW.

Hemborg (1998) showed that in most cases water yield decreased dramatically as coalbed methane production continued over time (Figure A9-11). However, some wells exhibited increased water production as coalbed methane production continued or increased over time (Figure A9-12). Two causal factors were suggested (Hemborg, 1998) for the rise in water production:

1. Well stimulation had increased the well's zone of capture to include adjacent water-bearing sills or sandstones that were hydraulically connected to recharge areas; or

2. Well stimulation had created a connection between the coal seams and the underlying water-bearing Trinidad Sandstone.

The Trinidad Sandstone is a bedrock aquifer confined by the Pierre Shale below and the shales and siltstones of the Vermejo Formation above (Figure A9-2). The Trinidad Sandstone exhibits low vertical and horizontal permeabilities of 0.186 and 0.109 meters per day, respectively, as reported by Howard (1982) in Stevens et al. (1992). One gas company reported that lower water production and improved gas production were achieved by avoiding known water-bearing horizons and by selectively completing the coal zones (Quarterly Review, 1993).

In-place coalbed methane resources in the Vermejo and Raton Formations were estimated by Stevens (1992) to be between 8.4 and 12.1 Tcf with a mean estimate of 10.2 Tcf. As of 1992, 114 coalbed methane exploration wells had been drilled in the basin (Quarterly Review, 1993). Soon after the Picketwire Lateral was constructed to convey gas from the fields to Trinidad and then to markets, gas well development in the basin increased significantly. The Purgatoire River Valley (Figure A9-1), which had been identified as having the highest coalbed methane potential in the basin, up to 8 Bcf per square mile (Stevens et al., 1992), became the focus of development. The Purgatoire Valley area was considered favorable for development because total coal thickness ranges from 5 to over 15 feet, drilling depths are shallow and coalbed methane content is high. The New Mexico portion of the basin was estimated to have methane resources ranging from 4 Bcf per square mile in the southern and eastern margins of the basin to more than 8 Bcf per square mile in the area south of the Vermejo Park anticline. Coal seams in the Vermejo Park area (Figure A9-1) are relatively thick, but shallow and of low rank, making estimates of coalbed methane content relatively low (Stevens et al., 1992).

The Spanish Peak Field, in the Purgatoire River development area in Las Animas County, Colorado (Figure A9-1), had 53 active wells in December 1996. Plans had been announced by Evergreen Resources, Inc. to drill and complete an additional 40 wells in 1997 (Hemborg, 1998). In 1996, the Purgatoire development area was projected to be capable of producing 122-137 Mcf per day in 3 to 4 years (Figure A9-1) (Hemborg, 1996). Total coalbed methane production within the Raton Basin was 30.8 Bcf per year in 2000 (GTI, 2002).

Methane production wells have generally been completed with 5.5-inch (outer diameter) casing with two to eight perforations per foot through the casing at the depths of the coal seams. The coal seams are stimulated with hydraulic fracturing treatments of sand and gelled-water, but detailed information on the nature, volumes, and use of hydraulic fracturing fluids in gas well development in this basin are not readily available. Water and gels with 10/40-mesh sand proppant seem to be the fluids of choice for fracturing practices in the Raton Basin. Stevens et al. (1992) report that multiple zones in one well are typically developed with 200,000 pounds of 10/20 or 20/40-mesh sand with 100,000 gallons of cross-linked gel per well. In one series of tests, wells were hydraulically fractured with 283,000 to 532,000 pounds of 12/20 and 20/40-mesh sand as proppant and 110,000 to 769,000 barrels of water or gel. The wells were fractured in two stages, one for a 25-foot thick upper zone and another for a 75-foot thick lower zone (Quarterly Review, 1993). Relatively high rates of water flow in these wells may be the result of fractures penetrating sandstones as well as coal seams. Another set of tests led a different methane producer to conclude that high water production was the consequence of induced fractures that intercept water-bearing sandstone and intrusive rocks. While operators initially assumed that large hydraulic fracture stimulations were necessary to link the thin and widely-spaced coal seams, it was found that such fracturing increased unwanted water production from associated sandstones, sills and water-bearing faults (Quarterly Review, 1993).

9.4 Summary

There are two major coal formations in the Raton Basin, the Vermejo Formation and the Raton Formation. The Vermejo coals range in thickness from 5 to 35 feet while the Raton coal layers range from 10 to over 140 feet thick. The coal seams of the Vermejo and Raton Formations, developed for methane production, also contain water that meets the water quality criteria for a USDW; therefore, it can be assumed that the Raton Basin coals are located within a USDW. The Cuchara-Poison Canyon, Fort Hayes-Codell, Dakota-Purgatoire, Entrada and Trinidad Sandstone and other sandstone beds within the Vermejo and Raton Formations, as well as intrusive dikes and sills, also contain water of sufficient quality to meet the USDW water quality criteria. Hydraulic fracturing may create connections to the Trinidad Sandstone, as shown by increases in water withdrawal from production wells over time. On the other hand, hydraulic connections to other adjacent water-bearing formations may also account for the increase in water production.

Executive Summary

ES.1 Hydraulic Fracturing Study Objectives

The Inglewood Oil Field was discovered in 1924 by Standard Oil, and encompasses an approximate 1,000-acre area of the Baldwin Hills of Los Angeles County (Figure ES-1). Plains Exploration & Production Company (PXP) has operated the oil field since December 2002.

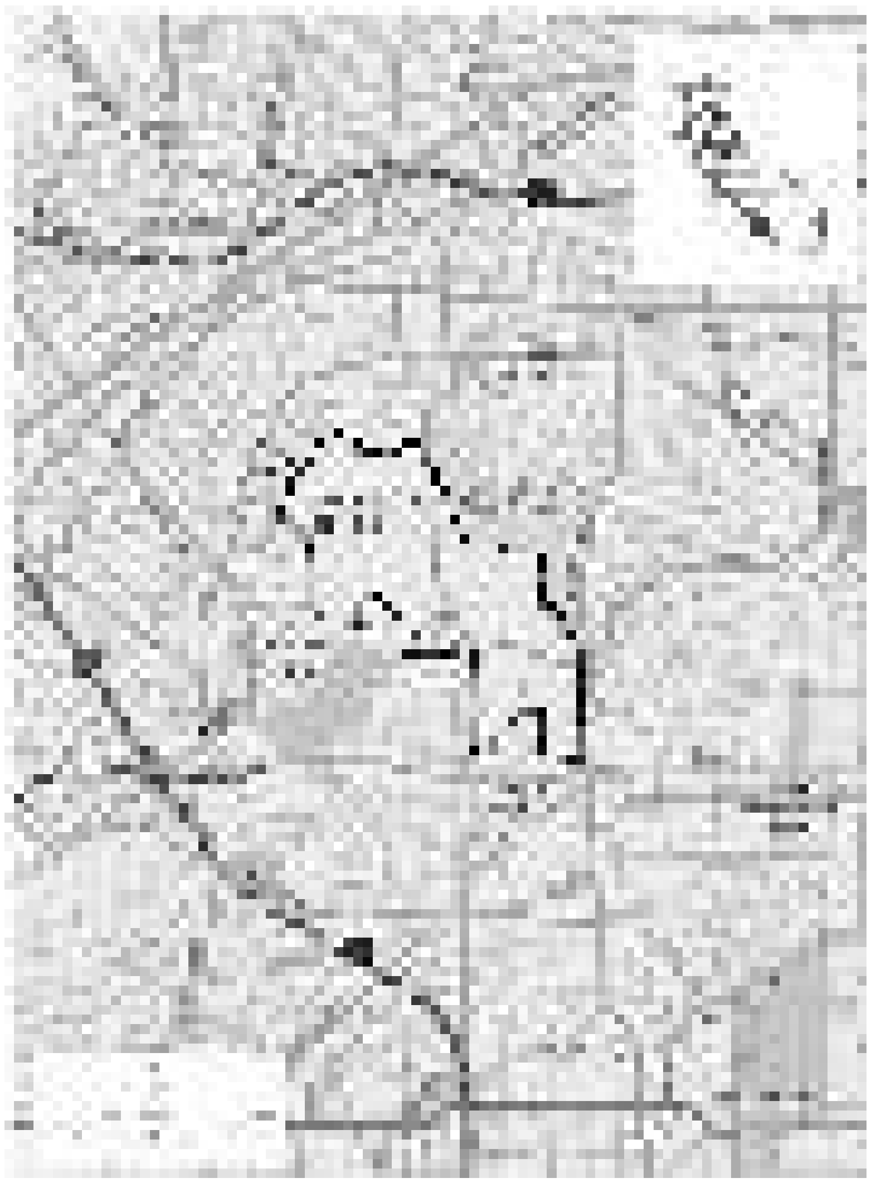

Figure ES-1 Regional Location Map

In October 2008, the County of Los Angeles (County) approved the Baldwin Hills Community Standards District (CSD), creating a supplemental district to improve the compatibility of oil production with adjacent urban land use. A lawsuit was filed in late 2008 against the County and PXP challenging the validity of the CSD. The lawsuit was settled July 15, 2011. This Hydraulic Fracturing Study is the direct result of Term 13 of the Settlement, which states:

> *PXP shall pay for an independent consultant to conduct a study of the feasibility and potential impacts (including impacts to groundwater and subsidence) of the types of fracturing operations PXP may conduct in the Oil Field. The study will also consider PXP's historic and current use of gravel packing. Such study will be completed within twelve (12) months of the date of this Agreement. Such study and all the back-up information for such study shall be provided to a qualified peer reviewer selected by the County and PXP, who shall review the study, back-up materials, and conclusions for completeness and accuracy. PXP must provide the independent expert with all materials requested and reasonably necessary for an accurate and verifiable study. The peer reviewer will be provided with access to all the data and materials provided to the independent expert. The peer reviewer shall agree to keep all proprietary information confidential. If the peer reviewer determines that the study is materially inadequate, incomplete or inaccurate, it shall so advise PXP's consultant who will complete the study as reasonably recommended by the peer reviewer and provide the revised study to the peer reviewer within 90 days. Upon acceptance by the peer reviewer, the study and all supporting material, including comments by the peer reviewer, shall be forwarded to the County, DOGGR, the Regional Water Quality Control Board ("RWQCB"), CAP and Petitioners and be available to the public, with any proprietary information redacted.*

This study draws on several sources, including sources in the peer-reviewed literature, the Inglewood Oil Field CSD, the 2008 Environmental Impact Report (EIR) conducted for the CSD, data and analyses provided by the contractor who conducted the recent hydraulic fracturing and high-rate gravel packing operations at the field, and from numerous contractors performing monitoring studies before, during, and after the recent hydraulic fracturing and high-rate gravel packing operations at the field.

In accordance with the Settlement Agreement, this study was reviewed by peer reviewers, jointly selected by the County and PXP. The peer reviewers, John Martin, Ph.D. and Peter Muller, Ph.D., C.P.G., were provided with the draft study and all reference materials. The peer reviewer's comments on the study, and their statement indicating that the revised study addressed all comments adequately and completely, thereby determining the study compete, is provided in Appendix A.

ES.2 Summary of Findings

The following are the primary findings of the Hydraulic Fracturing Study:

1. **Microseismic Monitoring:** The microseismic monitoring of high-volume hydraulic fracturing indicated that proppant-filled fractures were confined within the deep shale formations beneath the Inglewood Oil Field. Microseismic monitoring showed all fractures

were separated from the designated base of fresh water by 7,700 feet (1.5 miles) or more. Monitoring also showed all high-rate gravel packs stayed within their target zones.

2. **Groundwater:** Groundwater beneath the Inglewood Oil Field is not a source of drinking water, although the water quality must meet the standards for such a source. Groundwater beneath the Baldwin Hills is geologically isolated from the surrounding Los Angeles Basin and any water supply wells. Routine tests by the water purveyor show the community's water supply meets drinking water standards, including the period of high-rate gravel packs and conventional hydraulic fracturing, as well as the first high-volume hydraulic fracture in September 2011. In addition, the Inglewood Oil Field has an array of groundwater monitoring wells to measure water quality. Apart from arsenic, which is naturally high in groundwater of the Los Angeles Basin, the analyzed constituents meet drinking water standards. Before-and-after monitoring of groundwater quality in monitor wells did not show impacts from high-volume hydraulic fracturing and high-rate gravel packing.

3. **Well Integrity:** Tests conducted before, during and after the use of hydraulic fracturing and high-rate gravel packing showed no effects on the integrity of the steel and cement casings that enclose oil wells. There is also an ongoing program of well integrity tests at the Inglewood Oil Field.

4. **Methane:** Methane analyzed in soil gas and groundwater, as well as carbon and hydrogen isotopic rations in methane, at the Inglewood Oil Field did not show levels of concern. There was no indication of impacts from high-volume hydraulic fracturing or high-rate gravel packing.

5. **Ground Movement and Subsidence:** Before-and-after studies of high-volume hydraulic fracturing and high-rate gravel packing at the Inglewood Oil Field showed no detectable effect on ground movement or subsidence.

6. **Induced Earthquakes:** Before-during-and-after measurements of vibration and seismicity, including analysis of data from the permanently installed California Institute of Technology accelerometer at the Baldwin Hills, indicates that the high-volume hydraulic fracturing and high-rate gravel packs had no detectable effects on vibration, and did not induce seismicity (earthquakes).

7. **Noise and Vibration:** Noise and vibration associated with high-volume hydraulic fracturing and high-rate gravel packing operations at the Inglewood Oil Field were within the limits set forth in the CSD.

8. **Air Emissions:** Emissions associated with high-volume hydraulic fracturing were within standards set by the regional air quality regulations of the South Coast Air Quality Management District.

9. **Community Health:** The Los Angeles County Department of Public Health conducted a community health assessment that found no statistical difference of the health of the local community compared to Los Angeles County as a whole. Conventional hydraulic fracturing and high-rate gravel packs operations took place at the oil field, within the period addressed by the health assessment. Given the fact that public health trends in the area surrounding the

field were consistent with public health trends throughout the L.A. Basin it is reasonable to conclude that the conduct of hydraulic fracturing during the analyzed period did not contribute or create abnormal health risks

The Baldwin Hills CSD, and the associated Environmental Impact Report (EIR), together addresses the issues that are part of a hydraulic fracturing operation, such as truck traffic, water use, community compatibility (noise, light and glare, etc.), air emissions from vehicles and equipment used during the well development process, and other environmental resource categories. In addition, the EIR evaluates cumulative impacts, and environmental justice. These two documents support this Hydraulic Fracturing Study, which evaluates the effects measured and monitored during the high-volume hydraulic hydraulic fracturing and high rate gravel packing operations conducted in 2011 and 2012, as well as past activities of this type. The Hydraulic Fracturing Study did not identify a new impact not analyzed in the EIR, nor did it identify impacts greater in significance than those analyzed in the EIR.

Exacting protective measures and close monitoring are required by the Baldwin Hills CSD and by county, regional and federal agencies. These field-specific reviews and public and agency interactions compel PXP to enforce real-time compliance with all environmental standards in the Inglewood Oil Field. The long history of oil production in the area provides operators with an excellent understanding of the local subsurface conditions and reduces standard risks and uncertainties that would be present in new operations.

ES.3 Oil Production in the Los Angeles Basin and the Inglewood Oil Field

California is the fourth largest oil producing state in the U.S. (U.S. Energy Information Agency 2012), and the Los Angeles Basin is the richest oil basin in the world based on the volume of hydrocarbons per volume of sedimentary fill (Biddle 1991). Oil was first discovered in the area at the Brea-Olinda Oil Field in 1880, followed by numerous fields, including the Inglewood Oil Field in 1924 (Figure ES-2). As of this writing, there are 42 active fields in the Los Angeles Basin.

The Los Angeles Basin represents, from a global perspective, the ideal conditions for the generation and accumulation of hydrocarbons (Barbat 1958, Gardett 1971, Wright 1987a). The relatively recent geologic, tectonic, and structural history of the region has provided a thermal history that brings the organic-rich material into the “oil window”; the thermal regime that is optimum for development of oil and gas from organic precursors.

Discovery and development of the Los Angeles Basin oil fields accompanied rapid urbanization. Many oil fields were later covered by residential or commercial development, sometimes with continuing oil production. Chilingar and Endres (2005) evaluated urban encroachment on active and inactive oil fields, primarily in the Southern California area. They conclude that “a clear case is made for the urgent need for closer coordination and education by the petroleum industry of the local government planning departments…and in establishing mitigation measures for dealing with long-term environmental hazards.” The Inglewood Oil Field CSD, the associated EIR, and this Hydraulic Fracturing Study are coordinated processes that are meant to address such concerns.

PLAINS EXPLORATION & PRODUCTION COMPANY

Figure ES-2
Location of Los Angeles Basin Oil Fields
09 | 21 | 12

The approximately 1,000-acre Inglewood Oil Field is one of the largest contiguous urban oil fields in the United States, with an estimated recovery of 400 million barrels of oil. Oil and natural gas produced from the field is sold and used entirely in California. The oil field is adjacent to the County of Los Angeles communities of Baldwin Hills, View Park, Windsor Hills, Blair Hills and Ladera Heights, as well as the City of Culver City.

The Baldwin Hills consist of rolling hills up to 511 feet above sea level, cut by canyons and gullies, and form part of a chain of low hills along the Newport-Inglewood Fault Zone. The Baldwin Hills have been uplifted above the Los Angeles basin by folding and faulting of the underlying geological formations.

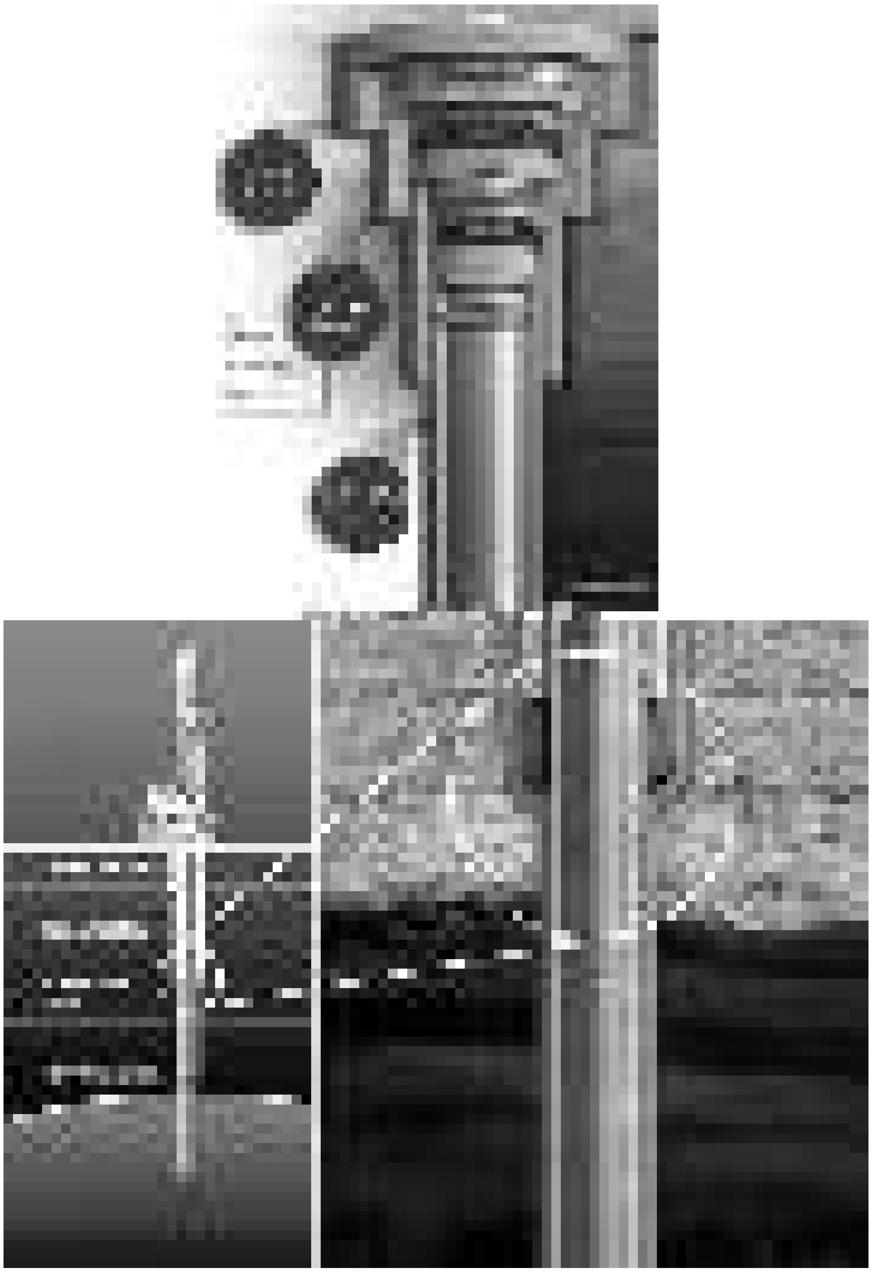
The petroleum producing zones in the Inglewood Oil Field comprise nine strata that range in depth from approximately 900 to 10,000 feet below the ground surface. In order of increasing depth and geologic age, the producing formations are: Investment, Vickers, Rindge, Rubel, Upper and Lower Moynier, Bradna, City of Inglewood, Nodular Shale, and Sentous. Water that is recovered along with the oil and gas, known as produced water, can make up to 90 percent or more of the total fluids pumped. The produced water has been reinjected in to the shallow depressurized Vickers and Rindge zones (known as a waterflood for enhanced oil recovery) since 1954, with much lesser amounts injected into the deeper Rubel and Moynier zones.

A total of 1,475 wells have been drilled over the life of the oil field; currently these are active, idle, or plugged. Many have been directionally drilled and are non-vertical. As of this writing, there are approximately 469 active production wells and 168 active waterflood injection wells operating at the Inglewood Oil Field.

ES.4 Well Drilling and Completion

Well drilling is the process of drilling a hole in the ground for the purposes of extracting a natural substance (e.g., water, oil, or gas). Oil wells are drilled using a drill string which consists of a drill bit, drill collars (heavy weight pipes that put weight on the bit), and a drill pipe. As the well is drilled and drilling fluid (i.e. mud, water and soil) is removed by the cementing process, a series of steel pipes known as casings are inserted and cemented to prevent the boring from closing in on itself (Figure ES-3). Cemented casing also serves to isolate the well from the surrounding formation. Each length of casing along the well is commonly referred to as a casing string. Cemented steel casing strings are a key part of a well design and are essential to isolating the formation zones and ensuring integrity of the well. Cemented casing strings protect against migration of methane, fugitive gas, and any formation fluid and protect potential groundwater resources by isolating these shallow resources from the oil, gas, and produced water inside of the well.

When initial drilling extends just below the base of fresh water, which is typically isolated from deeper saline formation water with an impermeable confining layer below it, the casing is placed into the drilled hole. The casing used in wells at the Inglewood Oil Field meets the State of California Department of Conservation, Division of Oil, Gas and Geothermal Resources (DOGGR) regulations and American Petroleum Institute (API) standards, which include requirements for compression, tension, collapse and burst resistance, quality, and consistency so that it is able to withstand the anticipated pressure from completing and producing the well (API 2009).



Source: Halliburton 2012

Figure ES-3 Depiction of Casing Strings

The space between this casing and the drilled hole (wellbore) is called the annulus. The annulus is filled with cement, permanently holding the casing in place and further sealing off the interior of the well from the surrounding formation. Cement serves two purposes: (1) it protects and structurally supports the well; and (2) it provides zonal isolation between different formations, including full isolation of the groundwater. Cement is fundamental in maintaining integrity throughout the life of the well, and after the well is idled and abandoned. It also protects the casing from corrosion. This bonding and the absence of voids stops the development of migration paths and isolates the production zone (Halliburton 2012, API 2009).

The final steps to install an oil-producing well are collectively known as well completion. Well completion includes the application of techniques such as sand control and well stimulation, including hydraulic fracturing, and installation of the production tubing and other downhole tools.

Well completions are not a part of the drilling process, but are applied after the well is drilled, sealed, and the drilling equipment has been removed. The first step to complete a well is to perforate the casing to allow the fluid from the producing formation to enter the well. Perforations are simply holes that are made through the casing. Once the casing is perforated, the well stimulation or sand control process is then initiated, depending on which technique is required. There are four types of well completion techniques described in this study that have occurred or may occur at the Inglewood Oil Field: conventional hydraulic fracturing and high-volume hydraulic fracturing, to stimulate and enhance production; and high-rate gravel packing and gravel packing, for sand control.

ES.4.1 Hydraulic Fracturing

In general, the process of hydraulic fracturing consists of injecting water, sand, and chemical additives into the well over a short period of time (typically less than one hour) at pressures sufficient to fracture the rocks to enhance fluid movement through the perforations and into the wellbore. Water and small granular solids such as sands and ceramic beads, called proppants, make up approximately 99.5 percent of the fluid used in hydraulic fracturing (Halliburton 2012). The flow of water acts as a delivery mechanism for the sand, which enters the newly-created fractures and props them open. These proppant-filled fractures allow oil and gas to be produced from reservoir formations that are otherwise too tight to allow flow. If proppant does not enter a new fracture, then the pressure of the overlying rocks forces the fracture closed once the overpressure is stopped, typically in less than one hour.

The chemical additives consist of a blend of common chemicals that increase water viscosity and help the sand and water mixture be carried further out into the fracture network. Additives include gels, foams, and other compounds. Additives have two primary functions: (1) to open and extend the fracture; and (2) to transport the proppant down the length of the fracture to maintain the permeability. Additives also perform critical safety functions such as controlling bacterial growth and inhibiting corrosion to help maintain the integrity of the well, which in turn protects groundwater. Most of the additives are recovered in the water that flows back after the hydraulic fracture (15 to 80 percent depending on the completion), and the remainder is recovered once the oil well is brought on to production and begins pumping fluids from the zone that was fractured (Halliburton 2012, USEPA 2010).

Hydraulic fracturing applied in oil and gas completions typically takes one of two forms, although some hybrid approaches are also in use. As indicated in the descriptions below, the process of fracturing in both forms are the same; the difference generally lies in the type of reservoir where the fracturing is occurring.

ES.4.1.1 Conventional Hydraulic Fracturing

This completion approach uses water, sand, and additives to fracture and stimulate the producing formation itself to a distance of up to several hundred feet from the well. This method is intended to affect the formation surrounding the perforated zone of the well, and enhance the permeability of the target producing zone itself. It is typically applied in sandstone, limestone, or dolomite formations.

ES.4.1.2 High-Volume Hydraulic Fracturing

This higher energy completion approach is generally applied to shales rather than sandstones that typically require a greater pressure to fracture. Sand and additives are used in the process, similar to conventional hydraulic fracturing; however, the primary distinguishing factor is the amount of fluid used in the process.

ES.4.2 High-Rate Gravel Packing

This completion approach uses water, gravel, and additives to place sand and gravel near the well itself with the objective of limiting entry of formation sands and fine-grained material into the wellbore, i.e., sand control. In this process, the space between the formation and the outer casing of the well is packed, at a high-rate, with gravel that is small enough to prevent formation grains (sand) and fine particles from mixing and entering the wellbore with the produced fluids, but large enough to be held in place by the well perforations. This relatively low-energy completion approach creates a fracture using water, sand, and additives that improve the proper placement of the gravel filter. This process is not intended to increase the permeability of the producing formation, and it only affects the area near the well itself.

Gravel packing, in contrast to high-rate gravel packing, does not exceed the local geological fracture pressure. In gravel packing operations, a steel screen is placed in the wellbore and the surrounding annulus packed with prepared gravel of a specific size designed to prevent the passage of formation sand. The primary objective is to stabilize the formation while causing minimal impairment to well productivity (Schlumberger 2012a). The gravel is circulated into place rather than pumped in under high pressure.

ES.5 Summary of Past and Future Hydraulic Fracturing and High-Rate Gravel Packing at the Inglewood Oil Field

Both conventional and high-volume hydraulic fracturing have been used at the Inglewood Oil Field. Figure ES-4 shows the location of Inglewood Oil Field wells that have either been completed by high-volume hydraulic fracturing or conventional hydraulic fracturing since 2003 when PXP began operating the field. All of the hydraulic fracturing has been completed on producing wells, that is, on pumping wells rather than injection wells. After the completion, flowback water brings back most of the additives used during the hydraulic fracturing operation to the surface. After the stimulation operation is completed, the well is brought on line and begins pumping, and any residual hydraulic fracturing fluids are drawn towards the well during pumping.

Figure ES-4

Locations of Hydraulic Fracturing Operations at Inglewood Oil Field

10 | 01 | 12

In conjunction with this Hydraulic Fracturing Study, PXP conducted high-volume hydraulic fracturing tests at two wells at the Inglewood Oil Field (VIC1-330 and VIC1-635). Only one stage was conducted as part of each of these tests. These are the only two high-volume hydraulic fracture jobs known to have been performed on the Inglewood Oil Field. The stages are representative of anticipated future hydraulic fracturing in terms of pressure, water use, and other factors.

Conventional hydraulic fracturing has been conducted on 21 wells in the deep Sentous, Rubel, Moynier, Bradna, City of Inglewood, and/or the Nodular Shale formations. Combined, a total of approximately 65 stages of conventional hydraulic fracturing have occurred at the Inglewood Oil Field since 2003.

PXP expects that, in the future, high-volume hydraulic fracturing and conventional hydraulic fracturing may be conducted in the deeper Rubel, Bradna, Moynier, City of Inglewood, Nodular, and Sentous zones (all located greater than 6,000 feet below ground surface).

PXP expects that, in the future, high-volume hydraulic fracturing and conventional hydraulic fracturing may be conducted in the deeper Bradna, City of Inglewood, Nodular, and Sentous zones (all located greater than 6,000 feet below ground surface).

PXP has operated the Inglewood Oil Filed since December 2002, and since that time, has conducted high-rate gravel pack completions on approximately 166 wells, in the Vickers and the Rindge formations, and one completion in the Investment Zone. Each high-rate gravel pack included an average of 5 stages per well. Approximately 830 stages of high-rate gravel packs have been completed at the Inglewood Oil Field since PXP began operating the field.

It is anticipated that high-rate gravel packing operations may be conducted on as many as 90 percent of all future production wells drilled within sandstones on the Inglewood Oil Field. This procedure results in less sand being drawn into the well during pumping, and reduces the amount of formation sand that must be managed at the surface. High-rate gravel pack operations use less water (~1,000 barrels vs. ~3,000 barrels) and lower pressures (~1,900 psi vs. ~9,000 psi) than hydraulic fracturing operations.

ES.5.1 Recent Hydraulic Fracturing Completions

PXP conducted two high-volume hydraulic fracture jobs at separate wells on the Inglewood Oil Field for the purposes of this study. The first hydraulic fracture completion was conducted on September 15 and 16, 2011, at the VIC1-330 well. The second completion was conducted on January 5 and 6, 2012, at the VIC1-635 well. Only one stage was completed during each operation.

Both of these operations were conducted in the Nodular Shale, a subunit of the Monterey Shale, approximately 8,000 to 9,000 feet below ground surface. The hydraulic fracture completions were conducted by Halliburton Energy Services with PXP oversight. Microseismic monitoring and fracture mapping was conducted by Schlumberger on the VIC1-330 and by Pinnacle (a Halliburton Company) on the VIC1-635. Halliburton (2012) contains a full report of both operations.

The applied pressure, water use, and monitored effects are expected to be similar between these two high-volume hydraulic fracture jobs and any future high-volume hydraulic fracture jobs to be conducted at the field. However, future high-volume hydraulic fracturing completions would likely utilize more than one fracturing stage each. In hydraulic fracture jobs that consist of more than one stage, each stage is conducted one after the other, never simultaneously. Therefore any one stage will be similar to those described in this section. The amount of water and chemicals used would be proportional to the number of stages.

Although both VIC1-330 and VIC1-635 are vertical wells, in the future, hydraulic fracturing may be conducted using horizontal wells, and with more stages. The high-volume hydraulic hydraulic fracturing job itself and the monitored effects would be the same in each stage as those measured during this study. The intent of the two high-volume hydraulic fracture jobs was to bound the potential effects of this process on the field. In the future, the only difference between these two jobs could be the construction of the well, including the number of stages applied. Each stage would be an isolated event, and each stage would be similar to the two analyzed in this Study. Although a horizontal well can be much longer than a vertical well in the same formation, the hydraulic fracture completion targets an individual zone, and so the amount of water, sand, and additives used would be the same, stage for stage. Horizontal wells, by drilling along the producing zone itself at depth, significantly reduce the number of wells needed to produce the same formation. As such, horizontal wells minimize the surface footprint of the oil production operation.

Water for the hydraulic fracturing operations at the Inglewood Oil Field is provided either from produced water at the field or, if a potassium-chloride gel is used, fresh water provided by California American Water Company, the provider of all fresh water used at the Inglewood Oil Field. For both of the high-volume hydraulic fracturing operations on the field, PXP used fresh water. Water produced from the target reservoirs during hydraulic fracturing operations, known as flowback water or flush water, is transported by pipeline to the field water treatment plant where it is mixed with other produced water generated on the field and processed. The treated water is then reinjected into the oil and gas producing formations as part of the waterflood process. This operation is in accordance with CSD Condition E.2(i), which requires that all produced water and oil associated with production, processing, and storage be contained within closed systems at all times. This process substantially reduced air emissions from the fluids. The total volume of additives is small and is diluted in the fluids of the producing zone.

ES.5.2 Recent High-Rate Gravel Pack Completions

PXP also conducted high-rate gravel pack jobs at two wells on the Inglewood Oil Field to collect data for this study. The first high-rate gravel pack was a five-stage completion performed on January 9, 2012, at the TVIC-221 well. The second high-rate gravel pack was a six-stage completion performed on the same day at a different well, TVIC-3254. Both of these operations were conducted in the Vickers and Rindge formations. The high-rate gravel pack operations were conducted by Halliburton with PXP oversight. The conditions of the high-rate gravel packs are representative of other high-rate gravel packs previously conducted across the field, and are also representative of future high-rate gravel pack jobs that could be expected to be conducted at the oil field.

The maximum applied pressure during both high-rate gravel packs was 1,900 pounds per square inch (psi). In comparison the high-volume hydraulic fracturing projects described in ES.6.1, had an average treatment pressure of 2,971 psi (VIC1-330) and 6,914 psi (VIC1- 635). The high-rate gravel pack influenced the zone within 125 feet of the well within the target oil-producing zone;

whereas, the high-volume hydraulic hydraulic fractures affected areas up to 1,100 horizontal feet from the subject wells (2,200 feet in length tip to tip, Halliburton 2012).

ES.6 Monitoring Conducted During Hydraulic Fracturing and High-Rate Gravel Packing at Inglewood Oil Field

ES.6.1 Hydrogeology, Water Quantity and Quality

In all parts of the world, fresh (not salty) groundwater lies at relatively shallow depths. At greater depths the water is saline, not drinkable, and is sometimes called formation water. The United States Environmental Protection Agency (USEPA) recognizes this distinction in the Safe Drinking Water Act which requires that the shallow, fresh water is protected from contamination by deeper, saline formation water. In most of the Los Angeles Basin, the base of the fresh water zone, below which saline formation water is found, is defined by the top of a marine geological unit called the Pico Formation. The zone at the Baldwin Hills considered to potentially contain fresh groundwater is from the ground surface to a depth of approximately 500 feet. Below approximately 500 feet, a "hydrocarbon seal" (or a nearly impermeable geologic formation) separates the fresh water zone from the oil producing zones and saline water containing formations below.

Nineteen groundwater borings have been drilled on the Inglewood Oil Field since 1992, only eleven of which encountered any water. Where water is encountered, it can range from 30 to 500 feet below ground surface, in zones less than 10 feet thick. The four deepest wells were installed to reach the "base of the fresh water zone," that is, the top of the Pico Formation. As such, current understanding of groundwater hydrogeology and water quality at the Inglewood Oil Field is based on a well-documented investigation of the entire zone beneath the surface that has any potential to contain fresh water. Although many borings for wells did not encounter any water, those that did were found to pump dry rapidly at low flow rates and recharge slowly. These data indicate that the water bearing zone from which they draw is limited in extent and not suitable for a water supply that could serve the oil field or the surrounding community.

None of these thin, discontinuous water-bearing zones within the Inglewood Oil Field connect to the aquifers of the Los Angeles Basin (USGS 2003, DWR 1961, this Study). The observed zones are perched within the folded and faulted confines of the field. In groundwater models of freshwater flow in the Los Angeles Basin aquifer systems prepared by the U.S. Geological Survey (USGS 2003), the Baldwin Hills are modeled as a "no flow" zone since the sediments beneath the Baldwin Hills are disconnected from the regional aquifers and groundwater flow is discontinuous across the Baldwin Hills. The California Department of Water Resources (DWR 1961) states "the Baldwin Hills form a complete barrier to groundwater movement, where the essentially non-water bearing Pico Formation crops out" (DWR 1961). The findings of the studies and ongoing groundwater monitoring of the Baldwin Hills commissioned by PXP and summarized in this study are in complete agreement with the findings of the USGS and DWR. Due to this lack of water in the geological formations beneath the Baldwin Hills, groundwater in the area is not suitable as a water supply (DWR 1961, USGS 2003, County of Los Angeles 2008).

The local community does not receive water from any formations beneath the Baldwin Hills, or from any well within 1.5 miles of the Baldwin Hills. Rather, approximately two-thirds of the community's water is delivered from sources in northern California (the Sacramento - San Joaquin River Delta) or sources such as the Colorado River. The nearest groundwater supplies outside the

Baldwin Hills are all very limited in supply and are geologically separated from the subsurface geologic formations of the Inglewood Oil Field. Therefore, activities associated with oil and gas development in the Baldwin Hills do not affect the community's drinking water supply.

All of the water service providers to the communities surrounding the Baldwin Hills must test their water from local wells at least four times a year and report the results to the water users. These reports indicate that the community receives water that meets USEPA's drinking water standards. Ongoing (four times per year) monitoring corroborates that this portion of the water supply meets these standards. The most recent data posted by the water purveyor covers the high-volume hydraulic fracturing that occurred in September 2011, as well as earlier conventional hydraulic fracturing and high-rate gravel packs. All public water supplies in California must also meet these requirements.

ES.6.1.1 Groundwater Monitoring Before and After Hydraulic Fracturing and High-Rate Gravel Packing

The Los Angeles Regional Water Quality Control Board (LARWQCB) Water Quality Control Plan, or Basin Plan, establishes beneficial uses of surface and groundwater in the Los Angeles Basin. Based on the State Board Resolution No. 88-63, "Sources of Drinking Water Policy", all groundwater in the state must be considered a potential source of drinking water, and carry a beneficial use designation of Municipal Supply (or MUN). This designation does not imply that the groundwater has sufficient capacity to support a municipal supply, presently or in the future. The designation addresses requirements to maintain groundwater quality in the sense of meeting drinking water standards.

As such, any water that may be encountered beneath the Inglewood Oil Field, regardless of its ability to actually supply water, must carry the beneficial use designation of MUN. Groundwater is collected from monitoring wells within the oil field, and is analyzed on a quarterly basis. A review of quarterly groundwater monitoring reports for 2010 and 2011 indicates that the perched, isolated groundwater meets the water quality requirements for MUN waters with the exception of arsenic, the concentrations of which are likely due to the high background level that naturally occurs in Southern California (Chernoff et al. 2008, Welch et al. 2000). As documented by USEPA, when "compared to the rest of the United States, western states have more systems with arsenic levels greater than USEPA's standard of 10 parts per billion (ppb)" (USEPA 2012a). Arsenic delineation maps produced by the USGS in 2011 have documented increased levels of arsenic in both the County of Los Angeles and Southern California as a whole (Gronberg 2011).

These data are also consistent with soils data from the 2008 California Department of Toxic Substance Control (DTSC) memo "Determination of a Southern California Regional Background Arsenic Concentration in Soil" (Chernoff et al. 2008). Areas in Southern California have been shown to have higher than average levels of arsenic present in soil and thus, through the release of naturally occurring arsenic in sediments, levels can be inferred to also be higher than average in groundwater resources throughout Southern California.

Monitoring was also conducted in April and August, three months and seven months after high-volume hydraulic fracturing and high-rate gravel packs conducted in January. The water was analyzed for the following constituents: pH, total petroleum hydrocarbons (TPH), benzene, toluene, ethylbenzene, total xylenes, methyl tertiary butyl ether (MTBE), total recoverable petroleum hydrocarbons (TRPH), total dissolved solids (TDS), nitrate, nitrite, metals, and biological oxygen demand (BOD5). These compounds include those used in hydraulic fracturing. The results of this monitoring were consistent with past groundwater monitoring and results. Groundwater will continue to be collected, analyzed, and reported consistent with the CSD and irrespective of when hydraulic fracturing and high rate gravel pack operations are conducted in the future.

Based on comparison of two sampling rounds after the high-volume hydraulic fracturing operations and high-rate gravel pack operations with the quarterly sampling rounds conducted prior to the operations, none of the analytical results indicated constituents above the state drinking water standard, with the exception of arsenic, which occurs naturally in soil and rock formations in Southern California. For the compounds detected, the concentrations after hydraulic fracturing were within the range of concentrations detected during the baseline period before hydraulic fracturing. The only exception was a minor increase in chromium from one well, MW-7 (2.7 to 3.0 µg/L, both results were well below the 50 µg/L state standard). Chromium is not associated with hydraulic fracturing additives.

Several new groundwater monitoring wells were installed after high-volume hydraulic hydraulic fracturing and high-rate gravel packing operations were conducted. Accordingly, the pre and post-hydraulic fracturing and high-rate gravel packing data in these specific wells cannot be compared. However, we can compare the results in the new wells with the pre- and post-hydraulic fracturing and high-rate gravel packing results from the pre-existing wells. In comparing the results of groundwater collected from new wells installed after hydraulic fracturing and high-rate gravel packing with the existing wells, the results were also consistent. No compounds violated the drinking water standard except for arsenic, as was the case with the pre-existing wells. The new wells were within the ranges of values detected in the pre-existing wells, with the new wells ranging to slightly higher total dissolved solids, zinc, and biological oxygen demand. The total dissolved solids and zinc may be due to conditions at depth, closer to the saline formation water. The biological oxygen demand is not associated with hydraulic fracturing additives.

Groundwater monitoring shows similar groundwater quality results before and after high-volume hydraulic fracturing and high-rate gravel packing. The Inglewood Oil Field's groundwater is not a source of drinking water. The groundwater bearing water bodies of the Baldwin Hills are geologically isolated from the nearest groundwater wells used for the municipal supply; and, two-thirds of the community water supply is from Northern California (the Sacramento-San Joaquin Delta) or the Colorado River. The local community does not receive water from closer than 1.5 miles to the Baldwin Hills. Community water supply is tested on a quarterly basis by the water purveyor, meets drinking water standards, and the results are publicly available.

ES.6.2 Well Integrity

During each stage of the hydraulic fracturing and high-rate gravel pack operations, the well casing of the subject well is tested in order to ensure integrity prior to injection of fracturing fluids (Halliburton 2012). Information about the well integrity tests is described in the post job reports. Well integrity testing is done by pressure testing the well up to 70 percent of the strength of the casing, in conformance with field rules established by the DOGGR. Offset wells, production wells, and injection wells are also tested for proper zonal isolation (i.e., annular cement) prior to any hydraulic fracturing operations. All measurements of well integrity during the hydraulic fracture and high-rate gravel pack operations conducted for this study indicated that there were no losses in pressure. The offset wells easily withstood the pressures of high-volume hydraulic fracturing; and no evidence of damage to the offset well was demonstrated by the pressure testing. The applied energy of the high-volume hydraulic fracturing rapidly decreases away from the completed well, and as such surrounding wells would not be adversely affected by the operation.

In addition to the well-integrity tests conducted for the high-volume hydraulic fracturing and high-rate gravel pack operations, active injection wells at the Inglewood Oil Field are surveyed annually (and pressure tested after each well work) per DOGGR requirements pursuant to CCR, Chapter 4, Article 3, §1724.10(j)3. PXP also monitors active injection wells weekly for injection rates and pressures (what also indicates the integrity of the wellbore and confinement of fluids to the injection zone) and reports to DOGGR on a monthly basis, pursuant to CCR Chapter 4, Article 3, §1724.10(c).

Tests conducted before, during and after the use of high-volume hydraulic hydraulic fracturing and high-rate gravel packing showed no impacts on the integrity of the steel and cement casings that enclose oil and gas wells.

ES.6.3 Containment of High-Rate Gravel Packs and High-Volume Hydraulic Fractures to the Target Zones

The measured distribution of fractures caused by the high-rate gravel pack completions were all less than 250 feet from the well, and were confined to the perforated zone within the Vickers and Rindge formations. The measured distribution of fractures from the high-volume hydraulic fracture completions were less than 1,100 feet in length from the well, and, with minor exceptions, were contained within the target zone (Halliburton 2012). For the few fractures that were outside the Nodular Shale target zone, they were deeper (with the oil-bearing Sentous Shale) and not filled with proppant. They therefore would reseal after the cessation of the increased pressure of hydraulic fracturing. Fractures grew either horizontally from the well or at angles less than 20 degrees depending on the local angle of the geological formations. Vertical fracture growth was very limited. The high-volume hydraulic fracture completions were conducted between 8,000 and 9,000 feet below the ground surface, and fractures did not form at shallower depths than approximately 8,000 feet below the ground surface. By comparison, the deepest groundwater encountered that had relatively low salinity was at a depth of 500 feet below the ground surface, corresponding to the base of fresh water beneath the Inglewood Oil Field, 1.5 miles above the hydraulic fracturing.

The results of microseismic monitoring indicate that fractures created during the high-volume hydraulic hydraulic fracturing operations were contained to the deep Nodular Shale with the exception of a minor few that were not filled with proppant. The fractures were all greater than 7,500 feet below the designated base of fresh water. The fractures created during all high-rate gravel packs were confined to the target zones.

ES.6.4 Subsurface Occurrence of Methane

Most of the oil and natural gas in the Los Angeles Basin lies trapped beneath both shales and faults, allowing it to accumulate at depth. However, some surface seeps do occur, as at the La Brea Tar Pits, and were the initial targets in the development of the Los Angeles Basin fields. In accordance with the CSD, field-wide methane monitoring is conducted at the Inglewood Oil Field on an annual basis to gauge for shallow occurrences of methane, and detections are investigated to determine the cause and remediate it.

Due to the potential of methane gas migration from the naturally occurring, prolific oil and gas province underlying the entire Los Angeles Basin, the City of Los Angeles has established a zoning ordinance identifying two zones, a Methane Zone and a Methane Buffer Zone, with special requirements for new construction, existing construction, and methane monitoring. The Baldwin Hills are outside the City of Los Angeles, and therefore are not classified on the methane map; however, they are adjacent to such zones. Although past methane detections have either been low or associated with a well to be re-abandoned, methane concentrations beneath portions of the field would reflect the relatively high background levels of methane in the Los Angeles Basin. All shallow detections of methane associated with the monitoring have been biogenic, based either on the composition (almost pure methane) or isotopic composition. Monitoring of shallow methane after high-volume hydraulic fracturing and high-rate gravel packing did not detect increases in soil gas methane concentrations.

Groundwater was not measured for methane prior to high-volume hydraulic fracturing or high-rate gravel packing. Samples collected after high-volume hydraulic fracturing detected dissolved methane in all but one well (MW-7), with concentrations up to 9.7 mg/L methane; all but two of the detections were less than 0.2 mg/L. Methane is not toxic and so there is not a drinking water standard established for it in water. There are few standards that have been promulgated for the nuisance effects of methane; the most widely applied are those of the U.S. Office of Surface Mining and the U.S. Bureau of Land Management. The highest value measured in groundwater at the Inglewood Oil Field is within the levels considered safe (10 mg/L), and well within levels that would actually trigger contingency actions (28 mg/L). The City of Los Angeles methane zoning ordinance does not address methane in groundwater; the ordinance only addresses levels in soil gas and applies construction standards as contingencies. Based on isotopic analysis of the dissolved methane in groundwater, it is thermogenic (from the oil-bearing formations) in origin, whereas detections in shallow soil gas are biogenic in origin. There are shallow occurrences of oil in the Investment Zone, within the Pico Formation. Since these zones are in closest proximity to the water bearing zones, and the occurrence of methane is pervasive in the monitoring results, it does not appear to be related to oil and gas production activity but to the natural occurrence of the underlying oil and gas. The occurrence is also not correlated to the locations of high-volume hydraulic fracturing or high-rate gravel packing.

The results of methane testing in soil and groundwater showed no influence from high-volume hydraulic fracturing or high-rate gravel packing.

ES.6.5 Slope Stability, Subsidence, Vibration, and Induced Seismicity

Slope stability is a primary geologic concern in the Baldwin Hills, and is addressed by conditions in the CSD that require ongoing monitoring. The California Department of Conservation, Division of Mines and Geology (CDMG), has studied the occurrence of slope instabilities and related geological issues of the Baldwin Hills (CDMG 1982). The study notes widespread damage from slope failures caused by rains in 1969, 1978, and 1980, and less widespread damage in other years. The study concludes that slope stability is a substantial problem in the Baldwin Hills because the terrain that has been developed for residential use consists mostly of steep natural slopes underlain by soft sedimentary rocks that are prone to land sliding and erosion. In addition, many of the communities in the Baldwin Hills were developed prior to the enactment of strict grading codes by local government, and therefore lack adequate protections against these natural geological conditions. The CDMG study notes that the Inglewood Formation is particularly susceptible to slope instability because the surficial soils developed on the formation are clay-rich. The study also notes that the Culver Sands are particularly susceptible to erosion. Monitoring for vibration and subsidence did not detect a change due to hydraulic fracturing or high-rate gravel packing. As such, hydraulic fracturing and high-rate gravel packing would not affect surface slope stability.

Subsidence is another geological concern in the Baldwin Hills. As described in the Baldwin Hills CSD EIR, prior to 1971, the maximum cumulative subsidence of any of the areas along the Newport-Inglewood fault zone was centered over the Inglewood Oil Field. Injection of produced water into the active producing zones began in 1957 to counteract this subsidence, and since 1971, water injection into the shallow production horizons has effectively eliminated subsidence associated with oil and gas production. The oil field has an ongoing program of annual subsidence monitoring that is reported in the framework of the CSD. To date, no changes in ground surface are attributed to oil and gas production activities. In evaluating pre- and post-hydraulic fracturing and high-rate gravel packing subsidence, none were attributed to the hydraulic fracturing or high-rate gravel packing.

ES.6.5.1 Subsidence and Ground Movement Monitoring during Hydraulic Fracturing

The CSD requires an annual ground movement survey at the Inglewood Oil Field. Surveying for both vertical and horizontal ground movement is accomplished using satellite-based GPS technology. Accumulated subsidence or uplift is measured using repeat pass Differentially Interferometric Synthetic Aperture Radar technology. The data are then evaluated to determine whether oil field operations (oil production and/or produced water injection volumes) are related to any detected ground motions or subsidence. Baseline survey points were collected in 2010 and then resurveyed in January 2011 and February 2012 (following the hydraulic fracturing operations of VIC1-330 and VIC1-635 and the high-rate gravel packing operations of TVIC 221 and TVIC 3254) to calculate annual subsidence or uplift at each point (Fugro NPA 2011, Psomas 2012). Based on a comparison of the ground movement survey results in 2011 and 2012 to operations production and injection records over the same time periods, there is no correlation between measured elevation changes and field activities.

The high-volume hydraulic fracturing and high-rate gravel packing had no detectable effect on ground movement, vibration, seismicity or subsidence, based on the results of studies conducted before and after the activities. As such, there would also be no detectable effect on slope stability.

ES.6.5.2 Vibration and Induced Seismicity

PXP retained Matheson Mining Consultants, Inc. to conduct vibration and ground surface monitoring during the high-volume hydraulic fracturing operations at the VIC1-330 and VIC1-635 wells, and at TVIC-221 and TVIC-3254 for the high-rate gravel pack jobs.

Vibration records for the VIC1-330 and VIC1-635 wells were collected using four and eight seismographs, respectively, installed at different locations in relation to the high-volume hydraulic fracture operations. The TVIC-221 and TVIC-3254 wells are directly adjacent to one another; therefore, the same seismographs were used to monitor the high-rate gravel packs on these wells. Based on analysis of the seismograph data, Matheson Mining Consultants, Inc. concluded that no seismic activity was produced by any of the high-volume hydraulic fracturing or high-rate gravel pack operations. In addition to the seismic monitoring conducted by Matheson Mining Consultants, Inc., seismic data collected by the permanently installed California Institute of Technology (Cal-Tech) accelerometer (seismometer) at the Baldwin Hills was reviewed for the time periods before and during the high-volume hydraulic fracturing and high-rate gravel pack operations. Background levels range from 0.0003 to 0.0006 inch per second (ips); however, random spikes occur in the record approximately every two to three hours. These spikes are likely related to local traffic or some other passing noise source, and are common in urban areas. The data collected from the seismograph during the VIC1-635 operation showed two minor spikes during the time period reviewed (the largest measuring 0.0012 ips). Analysis of the data by Dr. Hauksson, a Senior Research Associate in Geophysics with the Cal-Tech Seismological Laboratory, concludes that these spikes are not indicative of any seismic events above background levels were recorded (Matheson Mining Consultants, Inc. 2012a). The data collected from the seismograph during the TVIC high-rate gravel pack operations showed some spikes during the time period reviewed but no significant signals above the background levels. No data above background levels were recorded on the Cal-Tech seismograph during the VIC1-330 operation.

Petersen and Wesnousky (1994) evaluated all seismic events greater than Magnitude 2 on the Newport-Inglewood Fault zone, and determined that most epicenters are located at depths between 3.5 miles and 12 miles deep (Petersen and Wesnousky 1994, Hauksson 1987). In comparison, the waterflood operation at the Inglewood Oil Field extends to depths of up to 3,000 feet (0.57 mile) and the deepest hydraulic fracturing occurs at less than 10,000 feet depth (1.9 miles). Therefore, oil field operations are much shallower than the zones typically associated with earthquake epicenters along the Newport-Inglewood Fault zone.

Results of studies conducted before and after high-volume hydraulic fracturing and high-rate gravel packing operations indicate that the operations had no detectable effect on vibration, and did not induce seismicity at the surface.

ES.6.6 Noise and Vibration

To address concerns regarding perceptible vibration and noise during high-volume hydraulic fracturing operations, PXP commissioned Behrens and Associates, Inc., a firm specializing in noise and vibration studies, to measure produced vibration during the VIC1-330 and VIC1-635 high-volume hydraulic fractures and the TVIC-221 and TVIC-3254 high-rate gravel pack events. The ground-borne vibration survey for each event was completed while all equipment was operated under normal loads and conditions.

The high-volume hydraulic fracturing treatment on September 16, 2011, was completed on the VIC1-330 well, located in the northwestern portion of the field. Measured levels indicate that the maximum ground-borne vibration produced during the operation was 0.006 inch per second, as measured 40 feet from the operation. At 160 feet from the operation, measured vibration was 0.001 inch per second. Both of these levels are imperceptible to humans (Behrens and Associates, Inc. 2011).

In addition to ground-borne vibration measurements, Behrens and Associates, Inc. also took sound level measurements during the high-volume hydraulic fracturing operation at VIC1-635 and the high-rate gravel pack operations at TVIC-221 and TVIC-3254 using a calibrated sound level meter. The microphone was set at 5 feet above ground surface. The measured noise level at 100 and 200 feet from the operation at VIC1-635 was 68.9 and 68.4 decibels (dBA), respectively (Behrens and Associates, Inc. 2012a), The measured noise level at 100 and 200 feet from the TVIC-221 and TVIC-3254 operations was 68.1 dBA and 63.5 dBA, respectively (Behrens and Associates, Inc. 2012b). These measured noise levels are all in compliance with CSD limits.

The noise and vibration associated with the high-volume hydraulic fracturing and high-rate gravel pack operations did not exceed CSD limits.

ES.6.7 Air Emissions

Air emissions on the Inglewood Oil Field are monitored as described in an Air Monitoring Plan in accordance with Section E.2(d) of the Baldwin Hills CSD. This plan requires monitoring for hydrogen sulfide and total hydrocarbon vapors. It also requires that drilling or completions operations shut down if monitoring detects concentrations of hydrogen sulfide greater than 10 ppm or hydrocarbon concentration of 1,000 ppm or greater. Vehicle use for on-road and off-road vehicles and construction equipment is also regulated by the CSD under Sections E.2(j) through E.2(n).

Mass emissions of criteria pollutants and greenhouse gases (GHG) for off-road equipment and on-road vehicles were calculated using emission factors published by the South Coast Air Quality Management District (SCAQMD 2008) and USEPA (2011a, 2011b). The project schedule and equipment/vehicle list provided by PXP and Halliburton served as the basis for the analysis. The results of the analysis are presented in the emissions summary tables contained in section 4.7 of this study. These levels are consistent with those considered in the CSD.

Air emissions associated with high-volume hydraulic fracturing and high-rate gravel packing were compliant with the regulations of the South Coast Air Quality Management District and the CSD.

ES.6.8 County of Los Angeles Department of Public Health Study

The County of Los Angeles Department of Public Health (LAC DPH) conducted a community health assessment on the population living in communities surrounding the Inglewood Oil Field in 2011. The assessment was designed to determine if health concerns in the communities surrounding the Inglewood Oil Field reflect a higher than expected rate or an unusual pattern of disease. The report was sent to three external peer reviewers who found it to be technically sound.

The conclusions of the health assessment indicate that the health of the community adjacent to the Baldwin Hills is not statistically different from that of Los Angeles County as a whole, including cancer rates in the community. The report acknowledges that the data cannot determine adverse health effect below its detection limit, nor can the data address the contribution of other, non-quantifiable health-related issues such as smoking, lack of exercise, and social determinants of health.

Conventional hydraulic fracturing and high-rate gravel packing have occurred at the field since 2003, along with other oil and gas development activity. Based on the results of the health assessment, these activities had no detectable adverse effect on the health of the local community.

The health assessment recommends careful monitoring of the oil field operations to ensure compliance with regulations and standards to protect community health and safety. In compliance with the CSD, such monitoring occurs via Environmental Compliance Coordinator weekly inspections and an annual Environmental Quality Assurance Program (EQAP) audit.

The Los Angeles County Health Study found no detectable health consequences to the local community from oil and gas development (including hydraulic fracturing and high-rate gravel packing) at the Inglewood Oil Field. The study recommends careful monitoring of the oil field operations to ensure compliance with regulations and standards to protect community health and safety.

ES.6.9 Issues Associated with Hydraulic Fracturing in Shale Gas and Relevance of Inglewood Oil Field Hydraulic Fracturing Study Results

Since high-volume hydraulic fracturing has been used for shale gas development in the northeastern United States, there has been extensive media coverage of controversies surrounding its use. Although most of the news has been about the development of shale gas, tight sands and coalbed methane deposits rather than the type of oil and natural gas development that occurs at the Inglewood Oil Field, community outreach conducted as part of this study has indicated that many of the concerns surrounding shale gas development are shared by the local community and applied to oil development. The primary environmental and health issues of concern associated with hydraulic fracturing operations include:

- Potential for contamination of groundwater, including drinking water supplies, and gas migration;
- Environmental hazards associated with the chemical additives used during hydraulic fracturing operations;
- Potential for hydraulic fracturing operations to cause earthquakes;
- Issues related to well integrity; and,
- Air emissions and greenhouse gas emissions of hydraulic fracturing operations in comparison to regular oil field operations.

A description of each of these issues as they relate to hydraulic fracturing operations is provided in the study, along with the direct measurements taken at the Inglewood Oil Field to determine their relevance.

ES.7 Regulatory Perspective on the Inglewood Oil Field

The federal, state, and local laws, ordinances, regulations, and standards that govern oil field development throughout the United States require protections against the potential environmental impacts of the entire development process. These protections range from provisions in the Clean Air Act, Clean Water Act, Safe Drinking Water Act, Endangered Species Act, and through extensive California regulation addressing air quality, water resources, biological resources, and cultural resources, and at the local level. The Inglewood Oil Field is unusual in that it has much greater regulation and oversight of its operations than most other onshore oil fields as a result of the County of Los Angeles CSD.

The current national regulatory framework and government-sponsored studies of hydraulic fracturing are summarized in Section 5 of this Study to provide a national perspective to this Hydraulic Fracturing Study. Most of these studies address hydraulic fracturing associated with the development of shale gas, which is different than oil and gas development. Although the Inglewood Oil Field is not a shale gas field, and many of the concerns associated with the development of shale gas do not apply to the Inglewood Oil Field, the findings presented in Section 5 are intended to place concerns commonly seen in the news media in the local context of the Inglewood Oil Field.

The Baldwin Hills CSD, and the associated EIR, together address most of the issues that are part of a hydraulic fracturing operation, such as truck traffic, water use, community compatibility (noise, light and glare, etc.), air quality, and other environmental resource categories. In addition, the EIR evaluates cumulative impacts, and environmental justice. These two documents support this Hydraulic Fracturing Study, which evaluates the effects measured and monitored during the high-volume hydraulic hydraulic fracturing and high rate gravel packing operations conducted in 2011 and 2012, as well as past activities of this type. The Hydraulic Fracturing Study did not identify a new impact not analyzed in the EIR, nor did it identify impacts greater in significance than those analyzed in the EIR.

Exacting protective measures and close monitoring are required by the Baldwin Hills CSD and by county, regional and federal agencies. These field-specific reviews and public and agency interactions compel PXP to enforce real-time compliance with all environmental standards in the Inglewood Oil Field. The long history of oil production in the area provides operators with an excellent understanding of the local subsurface conditions and reduces standard risks and uncertainties that would be present in new operations.

Chapter 1

Introduction

Plains Exploration & Production Company (PXP) operates the Inglewood Oil Field, an approximately 1,000 acre area of the Baldwin Hills in Los Angeles County (Figure 1-1). Oil was discovered in the Baldwin Hills in 1924 by Standard Oil, and the oil field was operated by Chevron (successor company to Standard Oil), followed in 1990 by Stocker Resources, Inc., which was then acquired by Plains Resources, Inc. in 1992. PXP was incorporated in September 2002, and acquired all of Plains Resources, Inc.'s California operations, including the Inglewood Oil Field, in December 2002. PXP has operated the oil field since late 2002.

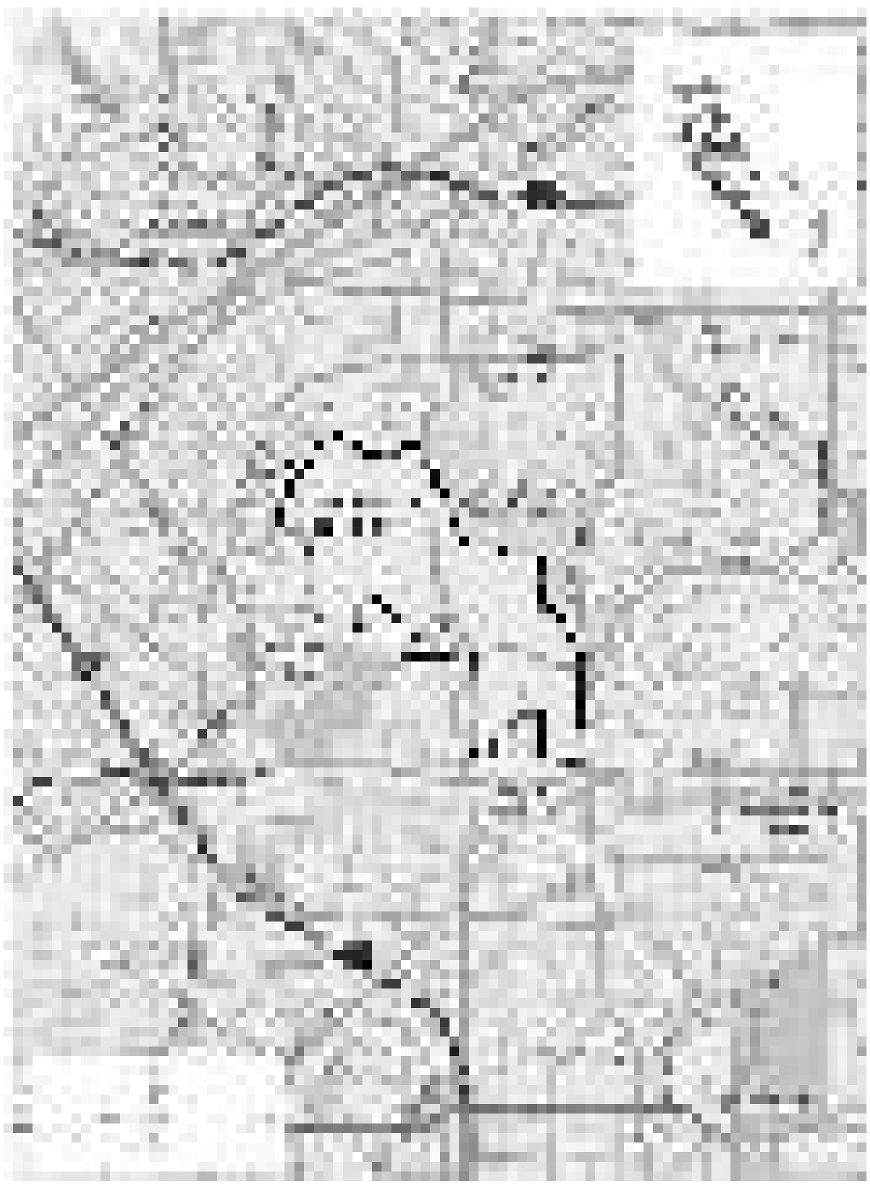

Figure 1-1 Regional Location Map

In October 2008, the County of Los Angeles (County) approved the Baldwin Hills Community Standards District (CSD), which created a supplemental district within the County to address the compatibility of oil production with adjacent urban land use. The CSD established permanent development standards, operating requirements, and procedures for the Los Angeles County portion of the Inglewood Oil Field. The northernmost areas of the field are within the city limits of Culver City, and PXP has voluntarily complied with the provisions of the CSD in that portion of the oil field as well.

Following adoption of the CSD, a lawsuit was filed against the County and PXP in late 2008, challenging the validity of the ordinance. The lawsuit was resolved through a Settlement Agreement that was signed on July 15, 2011 by the City of Culver City, Natural Resources Defense Council, Concerned Citizens of South Los Angeles, Citizens Coalition for a Safe Community, Community Health Council, the California Attorney General's Office, PXP, and the County of Los Angeles. The Settlement Agreement augments the protections contained in the CSD with 15 additional terms. This Hydraulic Fracturing Study is the direct result of Term 13, which states:

> *PXP shall pay for an independent consultant to conduct a study of the feasibility and potential impacts (including impacts to groundwater and subsidence) of the types of fracturing operations PXP may conduct in the Oil Field. The study will also consider PXP's historic and current use of gravel packing. Such study will be completed within twelve (12) months of the date of this Agreement. Such study and all the back-up information for such study shall be provided to a qualified peer reviewer selected by the County and PXP, who shall review the study, back-up materials, and conclusions for completeness and accuracy. PXP must provide the independent expert with all materials requested and reasonably necessary for an accurate and verifiable study. The peer reviewer will be provided with access to all the data and materials provided to the independent expert. The peer reviewer shall agree to keep all proprietary information confidential. If the peer reviewer determines that the study is materially inadequate, incomplete or inaccurate, it shall so advise PXP's consultant who will complete the study as reasonably recommended by the peer reviewer and provide the revised study to the peer reviewer within 90 days. Upon acceptance by the peer reviewer, the study and all supporting material, including comments by the peer reviewer, shall be forwarded to the County, DOGGR, the Regional Water Quality Control Board ("RWQCB"), CAP and Petitioners and be available to the public, with any proprietary information redacted.*

The Settlement Agreement Term 13 requires that the practice of high-rate gravel packing be included in this Hydraulic Fracturing Study. The process of high-rate gravel packing does not serve the same purpose as hydraulic fracturing and is a different process. Nonetheless, the practice is fully discussed in this study, in compliance with the agreement.

This study draws on several sources, including peer-reviewed literature, the Inglewood Oil Field CSD, the 2008 Environmental Impact Report (EIR) conducted for the CSD, data and analyses provided by Halliburton, who conducted the recent hydraulic fracturing operations at the field, and from numerous contractors performing monitoring studies before, during, and after the recent hydraulic fracturing and high-rate gravel pack test operations at the field.

In accordance with the Settlement Agreement, this study was reviewed by peer reviewers, jointly selected by the County and PXP. The peer reviewers, John Martin, Ph.D. and Peter Muller, Ph.D., C.P.G., were provided with the draft study and all reference materials. The peer reviewer's comments on the study, and their statement indicating that the revised study addressed all comments adequately and completely, thereby determining the study complete, is provided in Appendix A.

This Hydraulic Fracturing Study is organized as follows:

- **Chapter 1** presents the Study objectives.
- **Chapter 2** presents a brief summary of the distribution of oil production in the Los Angeles Basin providing regional perspective for the Hydraulic Fracturing Study. Chapter 2 also describes the geological setting at the Inglewood Oil Field, including the results of a 3-D depiction of the subsurface geology.
- **Chapter 3** describes oil and gas well drilling and completion methods. Hydraulic fracturing is a completion method and is described in the context of the overall well drilling and completion process. This Chapter describes hydraulic fracturing jobs performed at the Inglewood Oil Field by PXP, including a discussion of past, current, and potential future methods of hydraulic fracturing that have occurred, or may occur, at the field, and the two high-volume hydraulic fracture tests and two high-rate gravel pack tests conducted in 2011 and 2012.
- **Chapter 4** describes the setting, methods and results of extensive environmental monitoring conducted in conjunction with the hydraulic fracturing and high-rate gravel pack tests. Chapter 4 also includes a discussion of each environmental issue as raised in regulatory proceedings, agency studies, university studies, and in the media regarding high-volume hydraulic fracturing as applied in shale gas and tight sands reservoirs, principally in the northeastern United States, Texas, New Mexico and Colorado. Although exploration and development of shale gas differs from oil and gas production at the Inglewood Oil Field, the issues and concerns in states like Pennsylvania have helped shape public perceptions in the local community surrounding the oil field. The relevance of these issues to the Inglewood Oil Field is addressed in the context of the environmental monitoring conducted at the Inglewood Oil Field.
- **Chapter 5** describes the regulatory framework that governs hydraulic fracturing, drawing on information from across the country. This chapter also summarizes recent and ongoing studies by federal and state agencies on the environmental effects of hydraulic fracturing.
- **Chapter 6** provides the qualifications of the preparers of this document.
- **Chapter 7** provides supporting material and references, with complete citations and internet addresses for all sources used in this study.

Chapter 2

Oil Production in the Los Angeles Basin and at the Inglewood Oil Field

2.1 Introduction

California is the fourth largest oil producing state in the U.S. (U.S. Energy Information Agency 2012), and the Los Angeles Basin is the richest oil basin in the world based on the volume of hydrocarbons per volume of sedimentary fill (Biddle 1991). Oil was first discovered in the area at the Brea-Olinda Oil Field in 1880, followed by the development of the Los Angeles City Oil Field in 1893, the Beverly Hills Oil Field in 1900, the Salt Lake Oil Field in 1902, the Long Beach Oil Field in 1921, the Inglewood Oil Field in 1924, the Wilmington Oil Field in 1932, and many others. Figure 2-1 shows the distribution of major oil fields in the Los Angeles Basin (refer to Table 2-1 for the names of each oil field corresponding to the numbers on the figure). The size of this province, and its continuing potential for new discoveries and technologies, ensure its continued development into the future.

The Los Angeles Basin represents, from a global perspective, the optimum conditions for the generation and entrapment of hydrocarbons (Barbat 1958, Gardett 1971, Wright 1987a). Barbat, in particular, considered eight major controls on the occurrence and amount of oil in different basins around the world. He concluded that, “no matter how the Los Angeles Basin may differ from other oil-producing areas, the differences favor the Los Angeles Basin” (Barbat 1958).

The unique abundance of oil in the Los Angeles Basin derives from a thick section of layered sediments and organic-rich materials. The relatively recent geologic, tectonic, and structural history of the region has provided an optimal thermal history to bring the organic-rich material into the “oil window,” the thermal regime that is ideal for oil production. This means that as the sediments and organic materials were buried, these source rocks reached high enough pressures and temperatures that they transformed to oil and natural gas.

The oil and natural gas migrated then from the source rocks, typically the Monterey shale formation, into overlying sandstones. The sandstones acted as reservoir rocks, accumulating and holding the oil and natural gas underground. The Los Angeles Basin is folded and faulted, and as a result, after migrating into the sandstone reservoir rocks, the oil and gas deposits become trapped by the folds and faults which are impermeable (do not allow for the passage of fluid), as well as relatively impermeable shale rocks which are also present. Therefore, the traps allow oil in the reservoir rocks to continue to accumulate at depth and not continue to migrate up to the surface. These traps are not ubiquitous, and in some locations oil continued to rise to the surface as seeps. The most famous local surface seep of oil is the La Brea Tar Pits.

2.2 Petroleum Geology of the Los Angeles Basin

The Los Angeles Basin is approximately 70 miles long and 10 miles wide. It is a coastal sediment-filled trough located between the Peninsular Mountain Ranges and the Transverse Mountain Ranges in southern California. The Los Angeles Basin contains the central part of the city of Los Angeles as well as its southern and southeastern suburbs (both in Los Angeles and Orange counties).

The Los Angeles Basin was formed in a strike-slip tectonic setting (crust generally sliding side-to-side along faults). Two different phases of motion were involved: early extension overlain on the strike-slip motion, followed by more recent compression overlain on a weakening strike-slip system. These phases of evolution are in part illustrated by the number of faults that cut other faults in the subsurface (Biddle 1991). The following paragraphs describe this history in greater detail.

The Los Angeles Basin originated as a depositional basin caused by crustal extension overlapping with the regional, right-lateral strike-slip movement. Prior to five million years ago the Los Angeles Basin was submerged approximately 5,000 feet under the waters of the Pacific Ocean. During this period the marine basin collected sand, silt, and clay sediment from the surrounding upland areas. As surrounding mountain ranges (including the San Gabriel and Santa Monica mountains) rotated clockwise, the crust cracked, extended, and released molten rock from below. Over time the crust thinned and formed a basin, or bowl, with boundaries formed by the San Gabriel Mountains, Santa Monica Mountains, Santa Ana Mountains, and the Palos Verdes Peninsula. Sand, silt and clay from the sea and ancient rivers poured into the bowl-shaped depression. The sedimentary formations resulting from this deposition extend more than 30,000 feet downward before reaching bedrock.

The more recent history of faulting represents shortening of the basin caused by compression (counteracting the earlier extension), and a reduction in the amount of strike-slip motion, beginning approximately five million years ago. Compression of the basin created thrust faults. A thrust fault is a type of a break in the earth’s crust in which older rock is uplifted over younger rock material. In the Los Angeles Basin, faults of this type uplifted the sediments and rock that had once lain at the ocean floor and brought them to the surface. This rock from the ocean floor consisted of alternating layers of sandstones and shales that had also previously folded and faulted. As it rose above sea level, this pile of sediment began forming the Los Angeles Basin.

Each of these phases of activity affected the oil producing characteristics of the basin. The extensional phases created a container into which sediments poured: both the Monterey shale, which is the source of the hydrocarbons, and the overlying sedimentary rocks that acted as the reservoir rocks once the oil formed and rose towards the surface. The more recent shortening of the basin has changed the overall shape of the basin, and modified the traps that allowed oil to accumulate in the reservoir sediments. The rapidly-subsiding, deep, Los Angeles Basin formed at the right time, and in the right place, with an appropriate geometry and thermal history, to form this uniquely rich oil province (Biddle 1991).

2.3 Petroleum Production in the Los Angeles Basin

The Los Angeles Basin is one of California's most prolific crude oil and natural gas regions. Figure 2-2 shows the amount of oil produced from Southern California oil fields since the discovery of the first field, Brea Olinda. Table 2-1, taken from Biddle (1991), summarizes the oilfields of the area, including the year of discovery and amount of oil and gas produced.

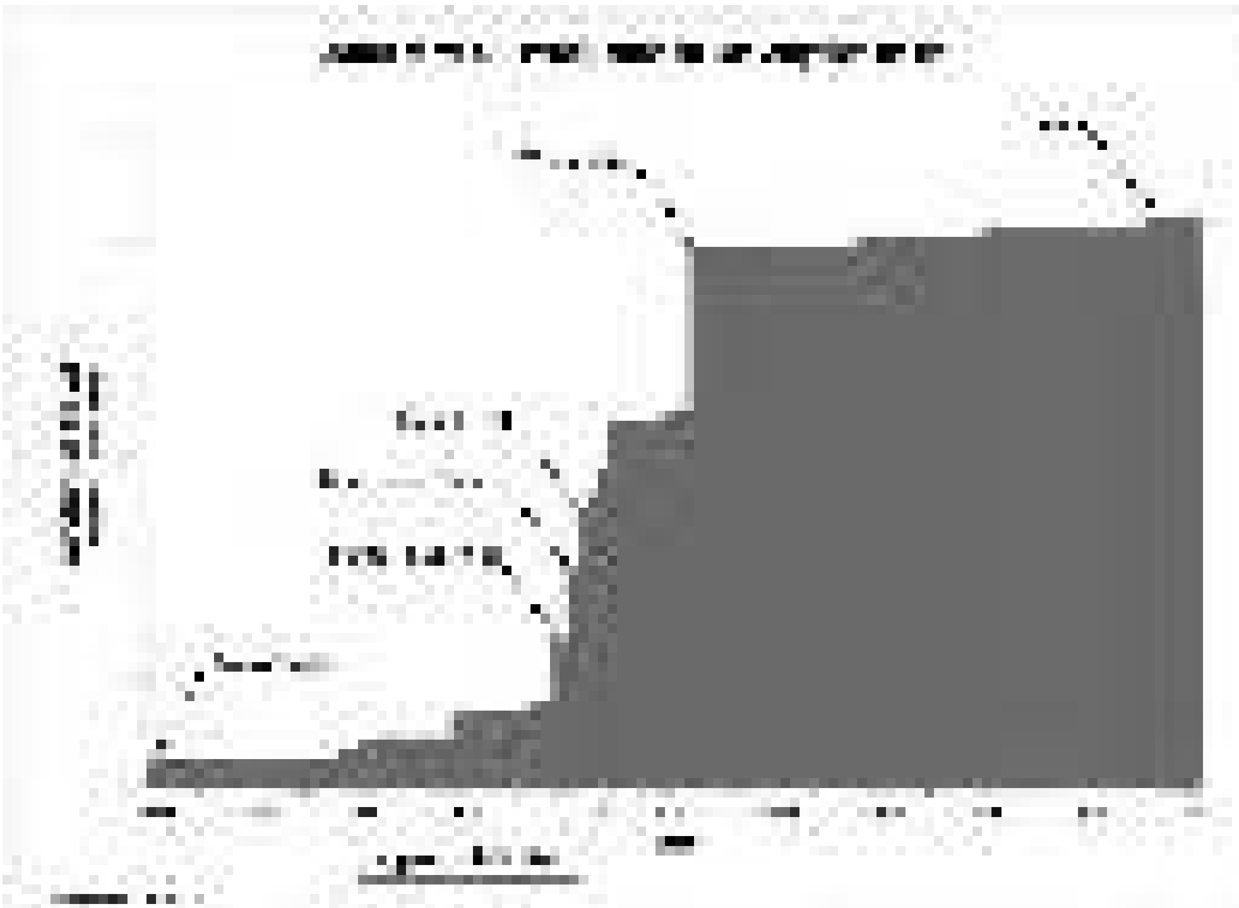

Figure 2-2 Cumulative Oil Production in the Los Angeles Basin

As of 2011, there are currently 42 active fields in the Los Angeles Basin. In 2011, the combined onshore and offshore oil production in California totaled approximately 197 million barrels, of which the Los Angeles Basin accounted for approximately 18 percent. Since 2007, an average of 2,700 wells has been drilled statewide annually (DOGGR 2011). Figure 2-3 shows the number of barrels of oil produced annually in California over the past decade (DOGGR 2007, 2011).

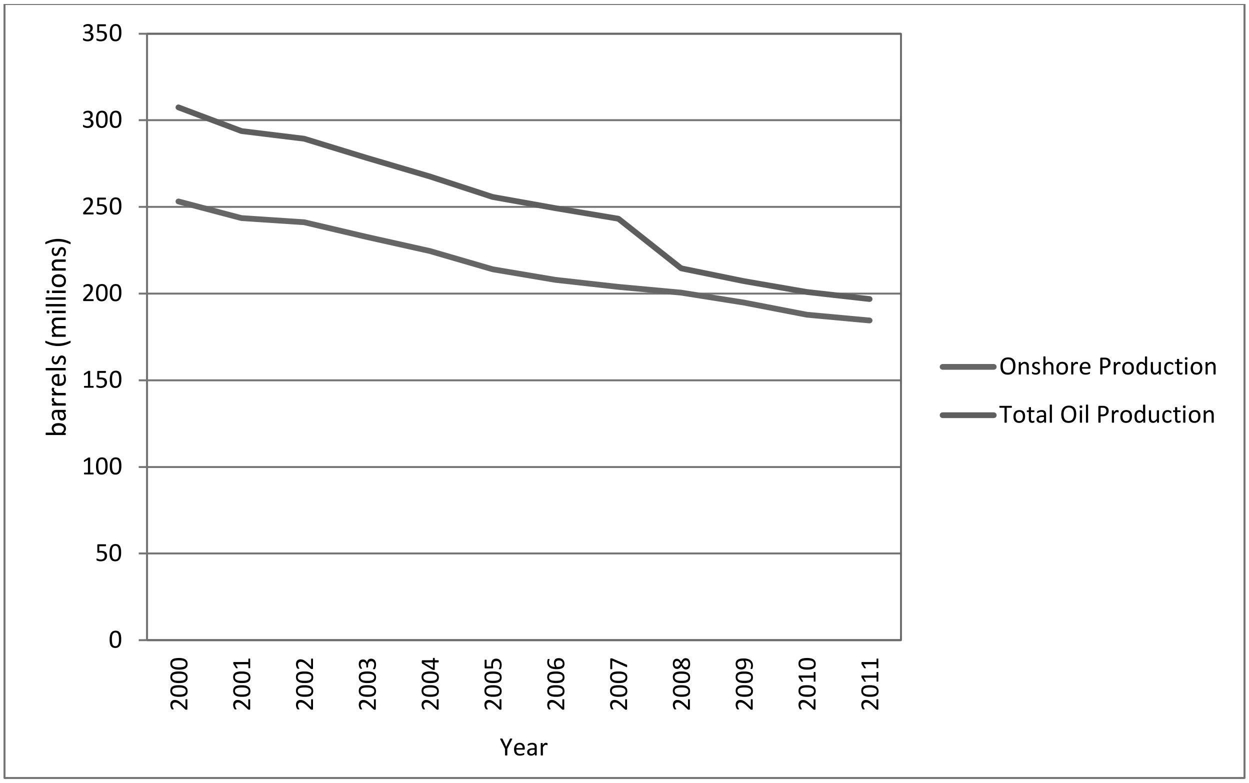

Figure 2-3 California Oil Production Since 2000

2.4 Petroleum Geology and Production at the Inglewood Oil Field

The approximately 1,000-acre Inglewood Oil Field is one of the largest contiguous urban oil fields in the United States. The Inglewood Field was discovered in 1924 and has produced an estimated cumulative production of 400 million barrels of oil. Oil and natural gas produced from the field is sold and used entirely in California. The oil field is adjacent to Culver City and the Los Angeles County communities of Baldwin Hills, View Park, Windsor Hills, Blair Hills and Ladera Heights. As of 2010, the U.S. Census Bureau estimated Los Angeles County's population to be 9.8 million. The area surrounding the field had a population of 65,892 in 2000. The population of this area has since remained relatively stable in comparison to the 2000 census data (U.S. Census Bureau 2010).

The Inglewood Oil Field was first commercially produced by Standard Oil in 1924, when livestock grazing (primarily by sheep) was the prevailing economic use of the land. The cultivated croplands had been reclaimed from the low-lying swampy terrain (cienegas) in the gently sloping portions of the Los Angeles Basin that surrounded the Baldwin Hills. Many of these lands were gradually converted to residential suburbs. With the incorporation of the City of Inglewood, residential development was spurred by transportation improvements, including the growth of highway network that transformed farmlands and displaced brick making industrial areas to the south of the Baldwin Hills.

In Culver City, both residential development and the foundation of movie studios and their associated supporting industries encroached upon the foothill slopes of the Baldwin Hills from the west and northwest. The northeastern and eastern sides of the Baldwin Hills were encroached upon by the westerly spread of the suburban growth of the City of Los Angeles (County of Los

Angeles 2008). Chilingar and Endres (2005) evaluate urban encroachment on active and inactive oil fields, primarily in the Southern California area. They conclude that "*a clear case is made for the urgent need for closer coordination and education by the petroleum industry of the local government planning departments…and in establishing mitigation measures for dealing with long-term environmental hazards*". The Baldwin Hills CSD, the associated EIR, and this Hydraulic Fracturing Study are examples of this advice put into practice.

2.4.1 Inglewood Oil Field Geology

Overview

The Baldwin Hills form part of a chain of low hills along the Newport-Inglewood Fault Zone. The Baldwin Hills are the highest of these hills, reaching an elevation of 511 feet above mean sea level. The hills are in sharp relief against the relatively flat Los Angeles Basin, and include rolling hills cut by canyons and gullies. The northern flank of the Baldwin Hills has been deeply incised by erosion while the southern flank slopes gently to the Torrance Plain and Rosecrans Hills.

Figure 2-4 provides three geologic cross sections illustrating the sub-surface geology (cross section locations shown in Figure 2-6), while Table 2-2 provides details regarding the thickness of each formation. The southernmost cross section in Figure 2-4 shows the Newport-Inglewood Fault as cutting all the petroleum-producing units at the field. Moving north to the central part of the field, the cross section depicts the dissipation of the Newport-Inglewood Fault as it approaches the relatively east-west Santa Monica fault further to the north. At depth, the Newport-Inglewood Fault transitions to the series of folds and thrust faults at depth. Moving to the northernmost cross section, the Newport-Inglewood Fault is no longer present, and the movement here and further to the north is likely accommodated by a combination of folds and thrust faults. This depiction of the geology is based on the data collected by well drilling and by seismic surveys, and is described in Wright (1991).

The Baldwin Hills have been uplifted by folding and faulting of the underlying geological formations. A northwest-trending anticline (upward-directed fold) is developed in sediments of Tertiary and Pleistocene age (23 million to 1.8 million years ago–see Table 2-3) beneath the Baldwin Hills. Two principal northwesterly trending, nearly parallel faults offset the central portion of the hills, developing a down-dropped trench, or graben, across the crest of the anticline. The more easterly of the two structures is the Newport-Inglewood Fault; the other fault is unnamed. Both faults are offset by secondary cross faults which trend northeast. The block east of the Newport-Inglewood Fault is composed of sediments of Pliocene age (approximately 5 million years ago) and older and is cut by several small unnamed faults. The modified geological timescale (Figure 2-5) summarizes the intensity of tectonic activity with time, as well as the major units that formed during each phase and the principal biological markers used to identify the units.

Figure 2-5 Chronology of Major Cenozoic Events in the Los Angeles Region

Figure 2-6 depicts the surface geology. Compared to the surrounding Los Angeles Basin, the geology of the Baldwin Hills exposes older and deeper geological formations. In addition, the Newport-Inglewood Fault and other related faults are shown as they are interpreted to occur near the surface. This structural discontinuity between the Baldwin Hills and the surrounding basin in part explains the occurrence of oil and gas at this location, and the discontinuity of shallow groundwater with deeper groundwater formations in the Los Angeles Basin (USGS 2003).

3-D Depiction of Inglewood Oil Field Geology

As part of the development of this study, Halliburton was retained to develop a three-dimensional (3-D) geological depiction of the subsurface of the Baldwin Hills, from the depth of the Sentous, the lowest known formation (10,000 feet below ground surface), up to the surface. The 3-D depiction is based on geological and structural data from drilling oil wells. The objective was to assist in the interpretation of the results of the high-volume hydraulic fracturing operation, and to better understand the relationship between the deep oil-producing formations and the shallow subsurface including the occurrence and distribution of shallow groundwater. The following discussion describes each formation, ending in the present-day land surface. The final 3-D model is used to depict the results of hydraulic fracturing, and of the discontinuous, fragmented water-bearing zones at shallow depths beneath the field, and the units that constitute the hydrocarbon seal that traps oil and gas in the deep subsurface (Figure 2-7).

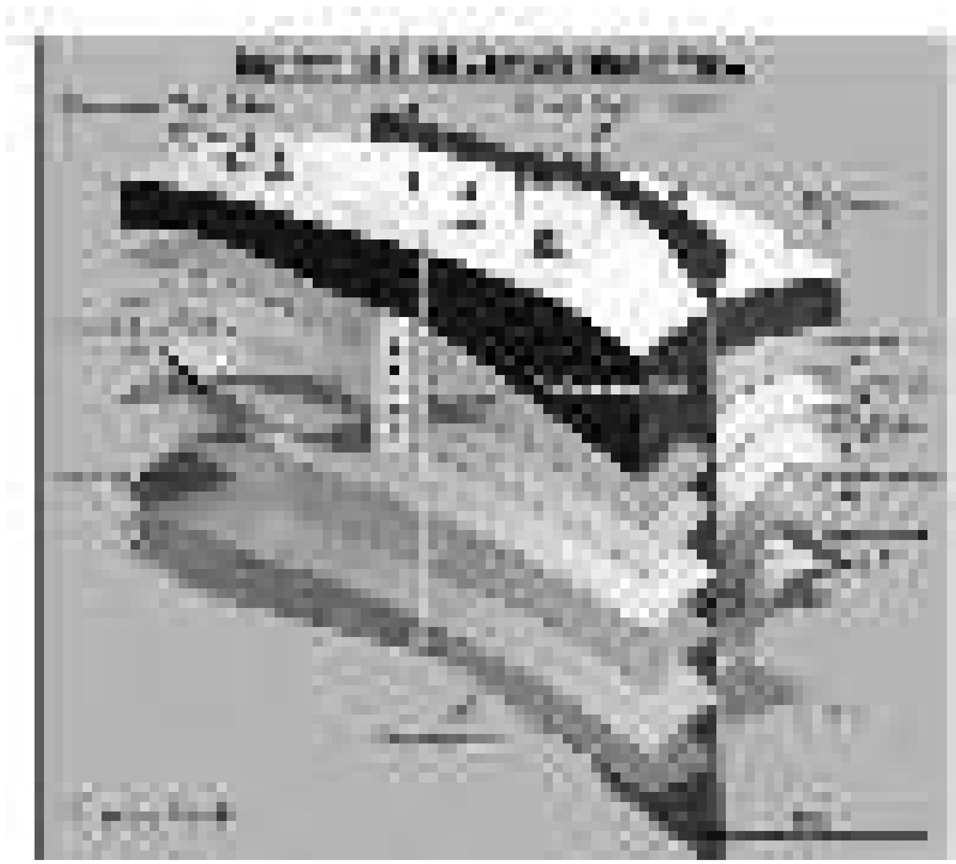

Figure 2-7 Cross Section of the Inglewood Oil Field Earth Model

In the following, each figure shows the progressive development of the field, starting with the deepest, oldest unit evaluated, the Sentous Sandstone. This presentation is used to show the growth of the formations and the folding and faulting specific to the area beneath the Inglewood Oil Field, as it is currently understood. Once constructed, this 3-D depiction is used to illustrate some of the study results later in the study.

Also shown for reference are the two wells that had high-volume hydraulic fracturing (VIC1-330 and VIC1-635), four wells that had conventional hydraulic fracturing in the past in the Sentous formation, and the two wells that had high-rate gravel packs (TVIC-221 and TVIC-3254). The yellow marker is the surface location of the well, and the red line is the length of the well. Each layer represents the top of one of the formations described above, and the space in between would be filled with that particular geologic formation (shale or sandstone). The fault planes are shown as colored layers cross-cutting the geologic formations. All the depictions are constrained by geological and structural data for the oil field.

Figure 2-8A Sentous Surface

Figure 2-8B Nodular Surface on Top

The top of the Sentous sandstone is shown in Figure 2-8A. The Sentous is also known as the Topanga Formation elsewhere in the Los Angeles Basin. This was a period of active volcanic activity; the basin was under an extensional regime and a strike-slip regime, forming a pull-apart basin that was actively subsiding. The volcanic intrusions into the sediments filled from the bottom, and at the same time erosion from distant land areas fed sandy sediments to form the Sentous sandstone. The microfauna indicate a depth of 3,000 to 4,000 feet below the ocean surface during this time. There are similar microfauna now in the Gulf of California, indicating that water temperatures were higher than today. All of the volcanic deposits are found below this layer.

The base of the Nodular Shale is also the top of the Sentous (Figure 2-8B). The Nodular Shale grades directly from the Sentous sandstone. This organic rich shale that is the source rock for much of the oil found here, and is approximately 150 feet thick; at the time of deposition, it may have been as much as 400 feet thick but has since been compressed. The mineralogy of the shale includes plagioclase derived from the volcanic rocks, and clay from the distant landmass depositing in the basin. The grain size became finer because of a decrease in the land-based sediment, leading to dominantly marine shale deposit. The Nodular Shale was deposited across the Los Angeles Basin. The subsidence of the Los Angeles Basin ceased approximately 2 million years ago.

Figure 2-8C Bradna Surface on Top

Figure 2-8D Bradna Surface with Faults

The Pasadenan Orogeny (mountain building) began about 2 million years ago. The activity led to uplift and rotation of plates, and a transition from a strike slip and extensional regime to a strike slip and compressive regime. Compaction and uplift forms the Baldwin Hills at this time, and is ongoing today. During this time period, the traps started to form; the folds and faults act as impermeable zones that allow oil to accumulate beneath them. It is believed that the Newport-Inglewood Fault may have originated as a normal fault giving it a steep angle, and accommodated the strike-slip motion. The two grey faults in Figure 2-8D are thrust faults accommodating the compression. This block was likely oriented NW-SE, but has rotated to E-W.

The Newport-Inglewood Fault is also shown in Figure 2-8D. The Newport-Inglewood Fault terminates in the northern portion of the field, as depicted in Figure 2-4, and Figure 2-8D expands on that termination. The fault likely transitions to folds or thrust faults as it approaches the Santa Monica Fault to the north.

The interval above the Nodular Shale at Inglewood includes the Bradna Shale. In other Los Angeles Basin fields, such as Long Beach and Beverly Hills, sands were deposited instead of the Bradna Shales. It is thought that the Inglewood area at the time formed a topographic high, such as a submarine knoll.

Figure 2-8E Moynier Surface on Top

Figure 2-8F Moynier Surface with Faults

The Moynier formation is shale, likely reflecting the submarine knoll that is more or less unique to the Inglewood Oil Field compared to other parts of the Los Angeles Basin. Some sand channels begin to appear in Moynier time, but they are minor.

Figure 2-8G Rubel Surface on Top

Figure 2-8H Rubel Surface with Faults

The Rubel marks the return of sand after the Sentous sandstone. It is the first major sand unit, and is the first major petroliferous zone at Inglewood. Approximately 90 percent of oil production is from the sandy submarine debris flow deposits (turbidities), first represented by the Rubel formation. These are deep-sea fans that funnel land-derived sands down to the deep ocean area. These formations are overlapping fans, and are currently active offshore of Southern California.

Figure 2-8I Rindge Surface on Top

Figure 2-8J Rindge Surface with Faults

The Rindge Formation is another productive sandstone for oil development. New structures are represented here in Figure 2-8J. These are interpreted as normal faults. The area was still dominantly strike slip with compression, but we interpret these as relatively shallow normal faults. These form the graben structure in the southeastern portion of the field. These could also be dominantly strike-slip faults with a normal component.

Figure 2-8K Vickers H-Sand Surface on Top

Figure 2-8L H-Sand Surface with Faults

The Vickers unit is another productive sandstone, similar to the description for the Rindge.

Figure 2-8M Vickers Surface on Top

Figure 2-8N Vickers Surface with Faults

Figure 2-8O UIHZ Surface on Top

Figure 2-8P UIHZ Surface with Faults

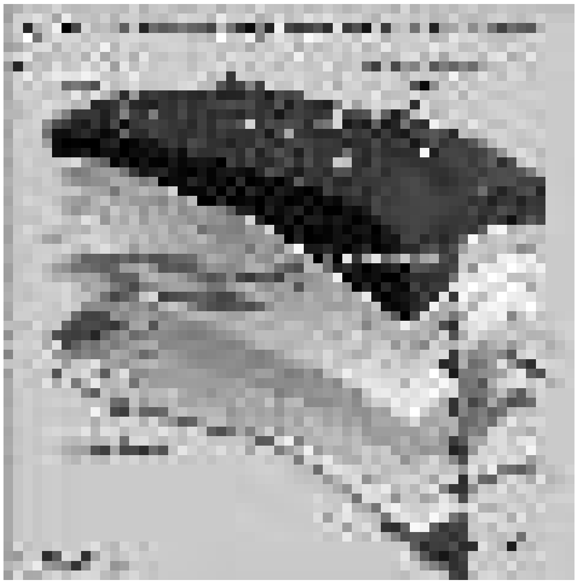

Figure 2-8Q Vickers Reservoir Hydrocarbon Seal with Faults

Figure 2-8R PICO Surface on Top

There is a prominent, relatively impermeable layer at the top of the Vickers, within the upper portion of the Pico Formation. The impermeable layer is more shale-rich than the underlying sandstones and forms a seal, inhibiting further upward migration of oil and gas. There are limited oil and gas deposits in the lowermost portion of the hydrocarbon seal; these are known as the Investment Zone. The folded and faulted units below act as traps beneath this seal. The depositional environment is still similar to that of the sandstones: submarine turbidite fans. However, this time may have been relatively less active, so the deposits are finer grained and formed a relatively impermeable shale instead of a sandstone.

Figure 2-8S PICO Surface with Faults

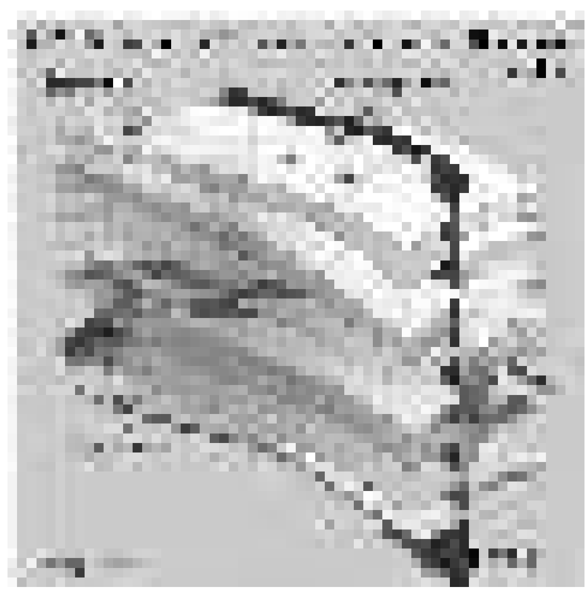

Figure 2-8T PICO Surface w/ Discontinuous Water Bodies & Faults

The top of the Pico Formation is also considered the Base of Fresh Water across much of the Los Angeles Basin. The Pico is a marine formation similar to the underlying units, and the formation water is salty. At shallower depths, above the Pico (Figure 2-8T), water is relatively fresh, but occurs in isolated, discontinuous water bearing zones that do not provide a sufficient yield for water supply, and are separated from the water-bearing zones elsewhere in the Los Angeles Basin. The aerial photograph of the Inglewood Oil Field is overlain on the geologic strata to provide reference (Figure 2-8U).

Figure 2-8U Ground Surface & Aerial Photo on Top

2.4.2 Petroleum Producing Zones

The field produces oil, natural gas, and saline water from interbedded sandstone and shale sediments ranging from Miocene Upper Topanga Formation (approximately 15 million years in age) to late Pliocene Upper Pico Formation (approximately 2 million years in age). See Table 2-3 for Geologic Time Scale. Production within the field is from nine zones that range in depth from about 900 to 10,000 feet. In order of increasing depth and increasing geologic age, the producing horizons are: Upper Investment-Investment, Vickers, Rindge, Rubel, Upper and Lower Moynier, Bradna, City of Inglewood, Nodular Shale, and the Sentous (refer to Figure 2-4, which illustrates the geology of the Baldwin Hills). The shallow reservoir zones (Vickers and Rindge zones) have been undergoing waterflood treatment since 1954. Each of the producing formations, along with the active wells completed in each zone, is summarized in Table 2-4.

Table 2-4 Summary of Active and Idle Wells within Each Oil and Gas-bearing Formation on the Inglewood Oil Field

Series	Formation	Average Depth Below Ground Surface	Number of Active Wells		Number of Idle Wells	
			Producer	Injector	Producer	Injector
Upper Pico	Upper Investment-Investment	1,000 feet	5		9	
	Vickers	2,000 feet	188	83	45	28
	Vickers-Rindge[1]	2,000 – 3,000 feet	167	67	27	33
Lower Repetto	Rindge	3,000 feet	10	3	5	1
	Rubel	4,000 feet	8	4	6	3

Source: Fugro Consultants 2011, PXP 2012

[1]These wells are completed in both the Vickers and Rindge formations
[2]These wells are completed in both the Rubel and Moynier formations

A total of 1,475 oil wells have been drilled on the Inglewood Oil Field; these are active, idle, or plugged. Many have been directionally drilled and are non-vertical (i.e., drilled on a slant or angle). There were 469 active production wells and 168 active waterflood injection wells operating as of the writing of this study. Table 2-4 identifies the number of producing (pumping) well and injection wells in each zone, divided between active and idle wells. Plugged and abandoned wells are not included in Table 2-4.

Vickers and Rindge Formations

The Vickers and Rindge zones accounted for more than 74 percent of the total cumulative production at the Inglewood Oil Field in 2011 and 2012 (to date). Overall, the shallow and extensive Vickers and Rindge zones have produced more than half of all the oil produced over the life of the Inglewood Oil Field. In the context of this study, all of the high-rate gravel packs have been completed in these two zones.

The primary development focus in the Vickers and Rindge zones occurs between 2,000 and 4,000 feet below the ground surface; limited production from the Investment Zone occurs at approximately 1,000 feet. The formations are cut by faults, which act as barriers to fluid flow because they cut off permeable sand formations.

Nodular Shale Formation

The Nodular Shale is the name given to that portion of the Upper and Middle Miocene rocks of the Western part of the Los Angeles Basin that carry large phosphatic nodules. It is a subunit of the Monterey Formation. The Nodular Shale is known to underlie several oil fields of the Los Angeles Basin including Playa Del Rey (Hoots 1931, Wissler 1943), El Segundo (Porter 1938, Wissler 1943), Inglewood (Wissler 1943), Torrance (Wissler 1943), and Wilmington (Wissler 1943). It is also suspected to underlie the Beverly Oil Field (Hoots 1931) and the Lawndale Oil Field. In the context of this Hydraulic Fracturing Study, the only two high-volume hydraulic fracture completions that have occurred at the Inglewood Oil Field have been done within this formation.

The Nodular Shale is a highly organic, dark brown to black shale, and has produced small amounts of oil in several wells at Inglewood. This distinctive unit was deposited on deeply submerged offshore ridges and slopes through the slow accumulation of biological debris, diluted by clay particles carried in suspension by circulating ocean currents. The high organic content of the Nodular Shale indicates the presence of anaerobic conditions seen in the northern area of the Nodular deposition.

Sentous Formation

The Sentous Formation is the deepest unit produced at the Inglewood Oil Field, and is below the Nodular Formation at greater than 9,000 feet below the ground surface. The Sentous is the geologically oldest producing zone in the Inglewood Oil Field and also along the Newport-Inglewood Fault trend. Since the early 1990s, the exploration and development focus in the Inglewood Oil Field has been on the Lower Pliocene and Upper and Middle Miocene, particularly the Sentous. Sentous sands were deposited in approximately 1,000 feet water depth during the opening of the rifted basins of the Southern California continental borderland. Oil accumulated in the Sentous sands down the northwest plunge of the Inglewood anticline; however, the sands become impermeable higher up on the anticlinal crest due to filling of the pore spaces with calcite cement. This loss of permeability has created a stratigraphic trap for this reservoir (Halliburton 2012). In the context of the Hydraulic Fracturing Study, the conventional hydraulic fracture completions have been conducted either solely in the Sentous zone or combined in the Sentous and either the Moynier or the Bradna.

2.5 Future of Oil and Gas Development in the Los Angeles Basin

The Monterey Shale is the primary source of oil and natural gas found in Southern California. The organic-rich shale was heated and compressed during tectonic activity, producing oil and gas. Some of the oil and natural gas migrated upwards into the overlying, more permeable, sandstone layers, where the hydrocarbons were then trapped by overlying impermeable shales and faults. Across Southern California, the deep source rocks, approximately 2 miles below the ground surface, of the Monterey Formation are now an exploration objective. High-volume hydraulic fracturing is being explored as a possible well completion method to allow the extraction of oil and natural gas from this geologic formation.

At a 2012 meeting of the American Association of Petroleum Geologists, the U.S. Geological Survey presented an assessment of the amount of oil remaining in the Los Angeles Basin. They note that, during much of the twentieth century, discovery and development of the Los Angeles Basin oil fields went hand in hand with rapid urbanization, which impacted field development from the first day of drilling. In spite of one of the world's greatest concentrations of oil per unit area, the oil recovery efficiency in the major fields continues to decrease (Gautier et al. 2012). Many small fields have been covered by residential or commercial development while still in primary production. For example, along the Wilmington Anticline and Newport-Inglewood Fault Zone, at least six fields have estimated original oil volumes in excess of one billion barrels. These fields have been in production for about 90 years. However, future recovery in such major fields could reasonably be expected to almost equal the total amount of oil recovered so far. It is predicted that oil volumes well in excess of one billion barrels could be recovered going forward from existing fields in the Los Angeles Basin through widespread application of current best practice industry technology such as improved imaging, advanced directional drilling, and other techniques (Gautier et al. 2012).

Along with continued oil and gas development in the Los Angeles Basin, hydraulic fracturing has been occurring to explore the resource potential of the Monterey Shale throughout California and in the Los Angeles Basin. Hydraulic fracturing is likely to continue to be utilized during recovery of the remaining petroleum resources. Figure 2-9 displays the location of wells in the southern California where hydraulic fracturing was reported in either 2011 or 2012 (as reported on www.fracfocus.org).

Chapter 3

Hydraulic Fracturing at Inglewood Oil Field: Past, Present, and Future

3.1 Oil and Gas Well Drilling, Including Hydraulic Fracturing Completions

Well drilling is the process of drilling a hole in the ground for the purposes of extracting a natural substance (e.g., water, oil, or natural gas). Drilling and completing a well consists of several sequential activities, which are listed below in order (note that these activities may be conducted multiple times during the drilling of a well, or be already completed and not needed for a particular well):

- Building the well pad and installing fluid handling equipment;
- Setting up the drilling rig and ancillary equipment and testing all equipment;
- Drilling the hole;
- Running formation evaluation logs and other instruments down the well;
- Running casing (steel pipe) to line the wellbore;
- Cementing the casing;
- Removing the drilling rig and ancillary equipment;
- Logging the casing to ensure bonding of cement to the formation and casing;
- Perforating the casing;
- Stimulating the well;
- Installing surface production equipment;
- Beginning production of the well;
- Monitoring well performance and integrity; and
- Reclaiming the parts of the drilling location that are no longer needed and removing equipment no longer used.

In the exploration and development of oil and natural gas fields, wells must be designed to carry the extracted fluids directly from the producing zone at depth to the surface completely within the well, without allowing fluid to escape into surrounding formations. Wells are designed and constructed to prevent any communication (migration and/or transport of fluids) between these subsurface layers, which have acted as a barrier for millions of years (API 2009).

In most parts of the Los Angeles Basin, including the Inglewood Oil Field, there are impermeable rock formations that lie between the hydrocarbon producing formations and shallow zones including groundwater-bearing formations and the land surface. These formations provide additional, natural protection against migration of oil and gas to the shallower formations. These impermeable formations and confining faults at the Inglewood Oil Field isolate, or trap, the hydrocarbons from the near surface formations. If these impermeable formations did not exist, the naturally buoyant oil would continue rising until reaching the surface, similar to areas such as the La Brea Tar Pits.

3.1.1 Drilling, Casing, and Cementing

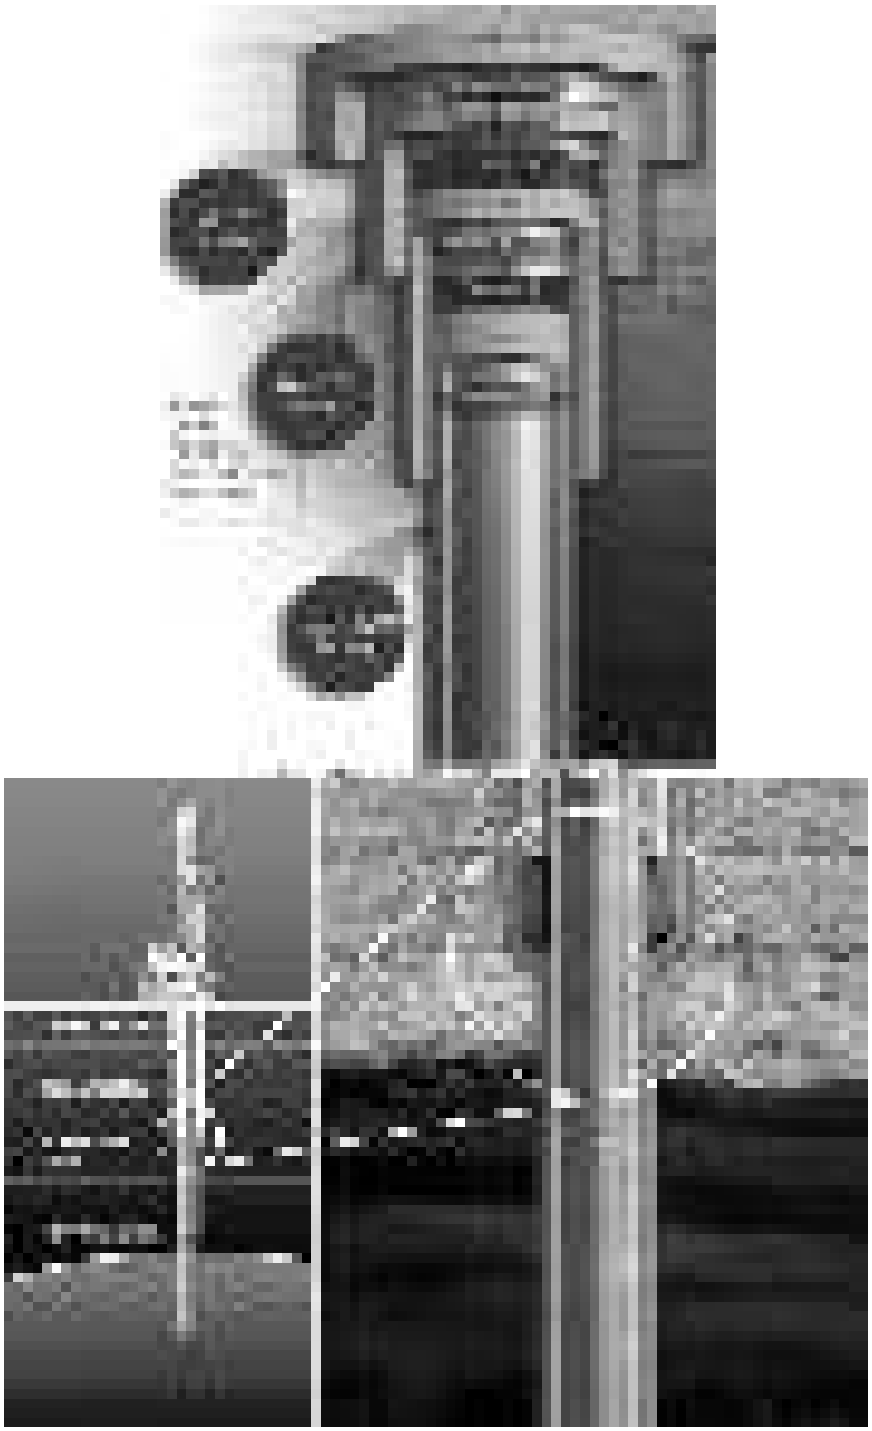
This section describes the methods used during drilling to ensure oil, natural gas, and water that are pumped from the deeper formations are brought to the surface without loss to shallower zones.

Wells are drilled using a drilling rig equipped with a drill string. The drill string consists of a drill bit, drill collars (heavy weight pipes that put weight on the bit so that it cuts through the formation), and a drill pipe. The drill string is assembled and suspended at the surface on a drilling derrick and run into the hole in the ground. It is then rotated using a turntable, or motor, in order to cause the drill bit to advance downward through the formations and thereby extend the hole deeper into the ground.

While the hole is drilled, fluid (drilling mud) is circulated down the drill string and up the space between the drill string and the hole. This drilling fluid serves to lubricate the drilling assembly, remove the sediments that are drilled, maintain pressure control of the well and stabilize the hole being drilled (prevent collapse of sediments back into the hole). Drilling fluid is generally a mixture of water, clays, and additives that prevent fluid loss, control density, and suspend the drilled cuttings. The first hole drilled is for installation of the surface protection casing. This is followed by sequentially deeper holes so that the well can be completed (API 2009).

The first step in completing a well is to case the hole (Figure 3-1). As the well is drilled and drilling fluid is removed, a series of steel pipes known as casings are inserted to prevent the boring from closing in on itself. Cemented casing also serves to isolate the well from the surrounding formation. Each length of casing along the well is often referred to as a casing string. The steel casing strings are a key part of well design and essential to isolating the formation zones and ensuring integrity of the well. Cemented casing strings protect against methane migration and protect groundwater resources (if present) by isolating these shallow resources from the oil, natural gas, and produced water (water produced during operation of a well) inside of the well. It is important to note that the shallow portions of the well have multiple strings of steel casing installed (Halliburton 2012, API 2009).

When drilling nears the base of fresh water, typically sealed naturally from deeper saline water by an impermeable confining layer, as at the Inglewood Oil Field, the casing is placed into the drilled hole. The design and selection of the casing is important since the casing has to be able to withstand various forces (for example compression by surrounding formation), as well as any pressure it might be subjected to during the well's life. The casing is threaded on each end that allows it to join to the next pipe. When several joints of casing are screwed together, they form a continuous string that isolates the hole.



Source: Halliburton 2012

Figure 3-1 Depiction of Casing Strings

The casing used in wells at the Inglewood Oil Field meet the American Petroleum Institute (API) standards. API standards entail strict requirements for compression, tension, collapse, burst resistance, quality, and consistency so that casing is able to withstand the anticipated pressure from well completion, fracturing and production, as well as environmental conditions that could cause corrosion (API 2009).

The space between the casing and the drilled hole (wellbore), called the annulus, is filled with cement, permanently holding the casing in place and further sealing off the interior of the well from the surrounding formation. Cementing is accomplished by pumping the cement (commonly known as slurry) down the inside of the casing into the well to displace the existing drilling fluids and to fill in the space between the casing and the actual sides of the drilled well. Once the cement has set, drilling continues to the next depth. This process is repeated, using smaller steel casing each time, until the targeted oil and gas-bearing reservoir is reached and cement is no longer used.

Oilfield cements are carefully designed products, formulated to meet the requirements of individual well designs. Cementing serves two purposes — it provides protection and structural support to the well while also providing zonal isolation between different formations, including full isolation of the groundwater. Cement is fundamental in maintaining integrity throughout the life of the well and protecting the casing from corrosion. Placement of the cement completely around the casing and at the proper height above the bottom of the drilled hole are two of the primary factors in achieving successful zone isolation and integrity. Proper isolation requires complete filling of the annulus and tight cement bonding to both the casing and the surrounding geologic formation. This bonding and the absence of voids prevents the development of migration pathways and isolates the production zone (Halliburton 2012, API 2009).

3.1.2 Hydraulic Fracturing as a Completion Technique

The final steps to a producing well are known as "well completion." Well completion includes perforations and any sort of well stimulation techniques, including hydraulic fracturing, sand control measures, installing the production tubing, and other downhole tools.

Perforating

Once the well is drilled to the target producing zone, cased and cemented in place, the areas outside the well are sealed off by the casing and cement. At this point in the process, there is a solid steel casing across the target producing zone. In order to pump out oil, natural gas, and water from this zone, a mesh of open space must be made in the casing. The process of creating the open holes within the target producing zone is called perforating; perforations are simply holes that are made through the casing. Perforating uses a series of small, specially designed shaped charges, which are lowered to the desired depth in the well and activated (Figure 3-2). These shaped charges create the holes in the steel casing that connect the inside of the production casing to the geological formation.

The perforations are isolated by the cement. Additionally, the producing zone itself is isolated outside the production casing by the cement above and below the zone. This isolation ensures that hydrocarbons and other fluids are unable to migrate anywhere except between the perforations and the wellbore.

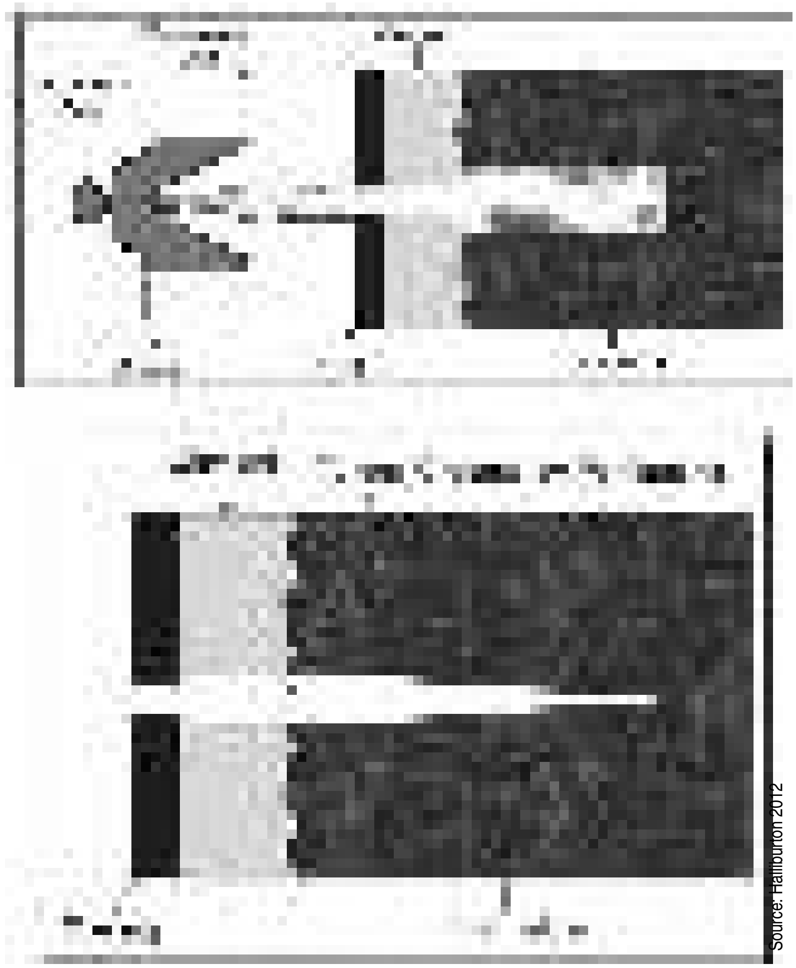


Figure 3-2 Perforation Process

Hydraulic Fracturing Process

Hydraulic fracturing is not part of the drilling process, but is a completion technique applied after the well is drilled, sealed, and perforated and the drilling rig has moved to another site. It is a well completion technology that results in the creation of fractures in rocks that allows oil and gas in the source rock to move more freely through the rock into the well. Hydraulic fracturing is a well stimulation process used to maximize the extraction of underground resources. Hydraulic fracturing is sometimes referred to as "fracking."

Hydraulic fracturing for stimulation of oil and natural gas wells was first tested in the United States in 1947. It was first used commercially in 1949, and was rapidly adopted because of increased well performance and increased yields of oil and gas from relatively impermeable rock units. It is now used worldwide in tens of thousands of oil and natural gas wells annually. The method has also been used at more shallow depths to assist in cleanup of contaminated industrial sites that have relatively impermeable zones.

In general, the process of hydraulic fracturing consists of injecting water, sand, and additives into the well over a short period of time (typically less than an hour) at pressures sufficient to fracture the rocks of a formation. Water and small granular solids such as sands and ceramic beads, called proppants, make up approximately 99 percent or more of the fluid used in a typical hydraulic fracturing operation (Halliburton 2012). This is consistent for both conventional and high-volume hydraulic fracturing. The flow of water acts as a delivery mechanism for the sand, which enters the newly-created fractures and props them open. If proppant does not enter a new fracture, then the pressure of the overlying rocks forces the fracture closed. These proppant-filled fractures allow oil and gas to be produced from reservoir formations that are otherwise too tight to allow flow.

The additives in the water help the sand to be carried farther into the fracture network. Such additives used to increase the viscosity of the water include gelling materials and/or foaming agents. Other liquid and solid additives that may be incorporated in the fracturing fluid are surfactants, a soap-like product designed to enhance water recovery, friction reducers, biocides to prevent microorganism growth, oxygen scavengers and other stabilizers to prevent corrosion of metal pipes, and acids to remove drilling mud damage. Figure 3-3 illustrates the composition of a typical fluid used in high-volume hydraulic fracturing. The specific products used at Inglewood Oil Field are described in Section 3.2.

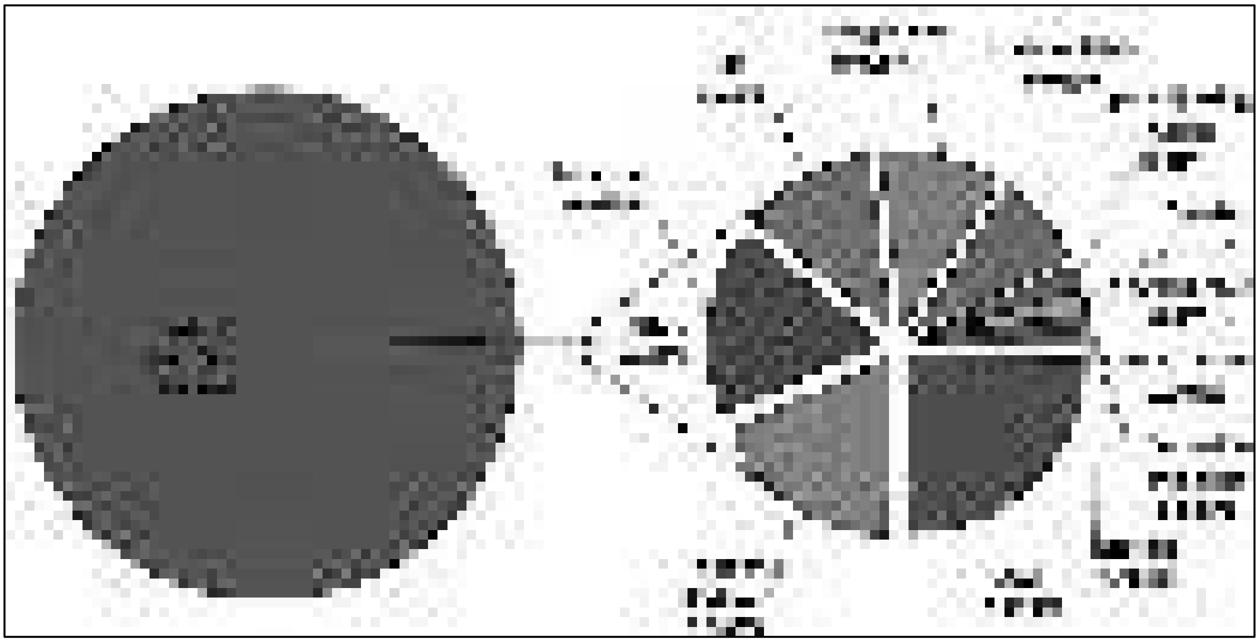

Figure 3-3 Composition of a Typical Fracturing Fluid

There are several steps during the hydraulic fracturing process. Taken together, these steps constitute one stage. Horizontal wells that are completed by hydraulic fracturing typically have several stages. Stages are not completed simultaneously. After the first stage is complete, the pressure is reduced, and the downhole equipment is moved to setup the second stage. When ready, the pressure is increased for the second stage. The following describes the steps that can be conducted during a hydraulic fracturing stage.

- **Step 1.** This optional step places water mixed with a dilute acid such as hydrochloric or muriatic acid into the sealed well. The volume of acid used is low and it is spent (used up) within inches of the fracture entry point and yields calcium chloride, water and small amount of CO_2. No acid is returned to the surface (King 2012). This step serves to clear cement debris in the wellbore and provide an open conduit for other hydraulic fracturing fluids by dissolving carbonate minerals and opening fractures near the wellbore. This step is not always performed, depending on the characteristics of the well and the formation.

- **Step 2.** The hydraulic fracturing fluid pad step (water with friction reducing additives) helps initiate and then propagate the fracture and assist in the placement of proppant material.
- **Step 3.** A proppant concentration step consists of several steps of adding water combined with proppant material (sand) to the well. This step may collectively use several hundred thousand gallons or more of water. Proppant material may vary from a finer particle size to a coarser particle size throughout this sequence and the proppant concentrations will vary during the treatment – starting with a lower concentration and then ramping to a higher concentration.
- **Step 4.** A flush step consists of a volume of fresh water or brine sufficient to flush the excess proppant from the wellbore.
- **Step 5.** Most of the fluid used for hydraulic fracturing is heated in the deep formation, becomes less viscous, flows more readily, and is recovered as it comes back up the well to the surface; this fluid is known as flowback. The amount recovered depends on the characteristics of the formation, and of the fluid used for hydraulic fracturing. The fluid that does not flow out of the well as flowback remains in the formation until the well is brought on production to pump and recover oil and gas. Any remaining fracturing fluids are also pumped out of the ground. Therefore, any remaining hydraulic fracturing fluid that does not return as flowback is captured by the pumping of the well. The only period of elevated pressure is during the brief (typically less than an hour) hydraulic fracturing operation itself (Halliburton 2012).

Uses of Hydraulic Fracturing

Within the last decade, the combination of horizontal wells installed with GPS-mounted drill heads to precisely guide the drill bit through relatively thin reservoir formations, and high-volume hydraulic fracturing completions has allowed the production of natural gas and oil from deep shale and tight sands deposits. Previously, the oil and gas-bearing shales were thought of as the source rocks of petroleum, from which oil and gas could not be economically produced directly. With the advent of new technology, companies now have the ability to precisely drill a horizontal well to be entirely within a relatively thin shale and tight sand bed using GPS technology, and then to precisely fracture that shale and prop open the fractures with sand to produce hydrocarbons from formations that previously were not economical.

This ability to capture hydrocarbon resources from zones that previously could not be produced is one form of development of “unconventional sources of oil and gas”. As applied to shale gas, this technique has completely changed the estimate of economic natural gas reserves. U.S. natural gas reserves had previously been thought to be in decline. To supply the nation’s energy needs, numerous plans to import gas from overseas as liquefied natural gas (LNG) were proposed between 2000 and 2005. Now, however, development of shale gas has led to the U.S. becoming the world’s largest producer of natural gas, surpassing Russia in 2009. The abundance of this relatively clean-burning fuel is beginning to displace the use of coal in U.S. generating stations, thus reducing greenhouse gas emissions.

At the Inglewood Oil Field, the uses of hydraulic fracturing are to create a permeable channel (propped fracture) within the shale and sandstone units so that the oil can be produced economically from these deeper formations. All activity occurs on an active, closely monitored oil and gas field using existing cleared areas for new wells whenever feasible. The activity differs from other parts of the country where areas not located in active oil and gas developments are converted to this use, and where the principal target is natural gas.

Types of Hydraulic Fracturing and Gravel Packing

Hydraulic Fracturing

Hydraulic fracturing as applied in oil and natural gas completions can take one of two forms, although some hybrid approaches are also in use. The process of fracturing in both forms is the same; the difference generally lies in the type of reservoir in which the fracturing is occurring, either tight sandstone or shale. The two forms are as follows:

- **Conventional Hydraulic Fracturing.** This completion approach uses water, sand, and additives to fracture and stimulate the producing formation to a distance of up to several hundred feet from the well. This method is intended to enhance the permeability of the target producing zone itself, and stimulate the reservoir. It is typically applied in tight sandstone formations and some shales.
- **High-Volume Hydraulic Fracturing.** This higher energy completion approach is generally applied to shales rather than sandstones. Sand and additives are used in the process similar to how they are used in conventional hydraulic fracturing; however, the primary distinguishing factor is the amount of fluid and pressure used in the process. Since shales have extremely low permeability, it is essential to increase the formation surface area contact with a permeable fracture channel. The high-volume hydraulic hydraulic fracturing process accomplishes this by increased treatment rates and material volumes.

Gravel Packing

In addition to hydraulic fracturing, the Settlement Agreement requires that gravel packing also be described and evaluated in this study. Gravel packing differs from hydraulic fracturing in that it is not intended to create fractures in the producing formation in order to pump out more water, oil, and gas. Rather, it is intended to place sand and gravel outside and adjacent to the well itself, with the intention of limiting the amount of fine-grained material that is pumped from the formation along with the fluids. As such, the purpose and techniques of gravel packing are distinctly different from hydraulic fracturing. Although the objective and techniques of gravel packing are very different from hydraulic fracturing, they are described in this study in accordance with the Settlement Agreement:

- **High-Rate Gravel Pack.** Since 2003, high-rate gravel packing has been conducted above the fracture pressure to improve well production performance through sand control. This operation uses much lower pressures than conventional and high-volume hydraulic fracturing. This completion approach, which is sometimes referred to as a “frack pack,” uses water, gravel, and additives to place sand and gravel near the well itself with the objective of limiting entry of formation sands and fine-grained material into the wellbore. In this process, the space between the formation and the outer casing of the well is packed, at a high-rate, with gravel that is small enough to prevent formation grains (sand) and fine particles from mixing and entering the wellbore with the produced fluids, but large enough to be held in place by the well perforations. This relatively low-energy completion approach can create limited fractures, using water, sand, and additives that improve the proper placement of the gravel filter. This process is not intended to increase the permeability of the producing formation, and it only affects the area near the well itself. Sand and finer particles that are entrained from the formation by pumping reduce the life of surface equipment such as valves, pipelines, and separators. In addition, produced sand can reduce oil production and impair the performance of injection wells.

- **Gravel Pack.** Prior to 2003, gravel packing was done at lower rates and lower applied pressures. The objective was the same as high-rate gravel packing, and the methods were also very similar, but the gravel packing process was always conducted at pressures less than the fracture pressure. In the past, some gravel packing was conducted using produced crude oil as part of the fluid mixture (a total of 11 completions); this oil was injected into the oil-producing formations themselves and not into shallow formations. Although PXP does not use oil as a fluid in gravel packing any more, it is noteworthy that such activity would not require an Underground Injection Control (UIC) permit since the operation did not use diesel fuel.

3.2 Hydraulic Fracturing at the Inglewood Oil Field

Conventional hydraulic fracturing has been conducted on 21 wells in the past at the Inglewood Oil Field. These completions were conducted in the Sentous Moynier, , Bradna ,City of Inglewood, Rubel, and Nodular shale formations. Combined, a total of approximately 65 stages of conventional hydraulic fracturing have occurred at the Inglewood Oil Field since 2003 when PXP began operating the field.

In conjunction with this Hydraulic Fracturing Study, PXP conducted high-volume hydraulic fracturing tests at two wells at the Inglewood Oil Field (VIC1-330 and VIC1-635). These are the only two high-volume hydraulic fracture jobs that have been performed on the Inglewood Oil Field.

Figure 3-4 shows the location of Inglewood Oil Field wells that have either been completed by high-volume hydraulic fracturing or conventional hydraulic fracturing since PXP took over field operations. All of the hydraulic fracturing has been completed on producing wells, that is, on pumping wells rather than injection wells.

3.2.1 Conventional Hydraulic Fracturing

Halliburton (2012) analyzed data from the past conventional hydraulic fracturing in the Sentous formation at the Inglewood Oil Field. The results of this analysis are summarized in this chapter to provide an indication of the feasibility and effectiveness of this technique at the Inglewood Oil Field.

Conventional hydraulic fracturing uses water, sand, and additives to fracture and stimulate the producing formation to a distance of up to several hundred feet from the well. This method is intended to affect the formation surrounding the perforated zone of the well, and enhance the hydrocarbon production of the target zone. It is typically applied in sandstone and some shale formations.

In this type of treatment, water is mixed with a polymer to increase the viscosity to the range of 10 to 40 centipoise (cp); for comparison, water viscosity is 1 cp. When ready to pump into the well, the water and polymer blend referred to as the "base gel" is blended further with a liquid additive that binds the polymer chains in the base gel increasing the viscosity to several thousand cp which aids in the suspension of the solids. This process is referred to as "cross-linking" the base gel. The cross-linked gel is mixed with the proppant and pumped into the well as slurry. The proppant, either natural (sand) or manmade (ceramic beads), is pumped along with the fluid and remains in the created fractures to hold it open. Additives designed to delay the degradation of the cross-linked gel are pumped along with the cross-linked gel and, in combination with the elevated temperature in the formation, return the cross-linked gel to a viscosity approaching that of water so that it can be recovered, or "flowed back" from the formation.

Conventional hydraulic fracturing has been used for every producing formation deeper than the Vickers and the Rindge at the Inglewood Oil Field. Most conventional hydraulic fracturing jobs were completed in the Sentous, the deepest producing formation at approximately 10,000 feet beneath the ground surface. Halliburton (2012) contains an analysis of the outcomes of hydraulic fracturing in the Sentous zone based on detailed analysis of two wells: TVIC-1033 and VIC2-1133. Figures 3-5A and 3-5B present different visualizations of the fracture geometries determined from the hydraulic fracturing treatments. The small rectangular area at the base of the diagram represents the calculated volume that received proppant. The figures include the relevant formation surfaces, ground surface, geologic structure, including major faults; water-bearing bodies near the surface are also depicted. The area affected by the conventional hydraulic fracturing remained in the Sentous formation, greater than 9,000 feet below the ground surface.

Figure 3-5B Side View Showing Modeled Fracture Geometries for Study Well in the Sentous Zone Together with Structural Features (Faults)

3.2.2 High-Volume Hydraulic Fracturing

PXP contracted Halliburton Energy Services to conduct two high-volume hydraulic fracture jobs at separate wells on the Inglewood Oil Field for the purposes of addressing feasibility and potential impacts of hydraulic fracturing. The first hydraulic fracture completion was conducted on September 15 and 16, 2011, at the VIC1-330 well. The second completion was conducted on January 5 and 6, 2012, at the VIC1-635 well.

Only one hydraulically fractured stage was completed on each well during the operations. Both of these operations were conducted in the Nodular Shale, a subunit of the Monterey Shale, approximately 8,000 to 9,000 feet below ground surface. Halliburton (2012) contains a full report of these operations.

The conditions of the hydraulic fracture jobs are the same as those expected for any other future high-volume hydraulic fracturing to be conducted at the field. Therefore, the applied pressure, water use, and monitored effects are expected to be similar between these two stages of high-volume hydraulic fracture jobs and any future stages of high-volume hydraulic fracture jobs.

Future high-volume hydraulic fracturing completions would likely utilize more than one stage per well in the future. That is, any single hydraulic fracture job in the future could consist of more than one individual fracturing event. In hydraulic fracture jobs that consist of more than one stage, each stage would be conducted one after the other, never simultaneously. Therefore, any one stage will be similar to those stages described in this section. Cumulatively, the amount of water and chemicals used would be greater for a multi-stage completion than for a single-stage completion. However, the volumes required are still much less than the overall water usage at the field.

Although VIC1-330 and VIC1-635 are both vertical wells, PXP reports that in the future, high-volume hydraulic fracturing may be conducted via horizontal wells. This difference would not lead to any variation in the hydraulic fracture stage, or to the monitored effects; the only difference would be the construction of the well itself. Although a horizontal well can be much longer than a vertical well in the same formation, the hydraulic fracture completion targets an individual zone, and so the amount of water, sand, and additives used would be the same, stage for stage. A longer, horizontal well would also result in more than one stage, which as described above, would result in the use of greater volumes of water and chemicals.

This section describes the conditions and results of high-volume hydraulic fracturing of the VIC1-330 and VIC1-635 wells. Both hydraulic fracturing events were in the Nodular shale, at depths in excess of 8,000 feet below ground surface. Microseismic data are fist used to describe the hydraulic fracturing. Next, water demand, water reuse, and chemical use are described for both jobs.

Microseismic Monitoring Methods

A hydraulic fracture job generates microseismic events when the rock develops cracks. During the hydraulic fracturing treatment, these microseismic events are measured with seismic receivers or geophones placed at depth within a nearby well or wells. The events are so imperceptible, even by this sensitive equipment, that it must be placed at or near the depth of fracturing to detect them. Figure 3-6 shows the locations of the four wells, and the nearby wells used for microseismic monitoring of VIC1-330 and VIC1-635.

Earthquakes and other seismic events are commonly measured using the Richter scale (Figure 3-7). The Richter scale is based on Magnitude; that is, an earthquake of Magnitude 6 is ten times stronger than an earthquake of Magnitude 5, as a result of the amplification of ground movements (e.g., soft soils overlying bedrock will strengthen the intensity of the ground movement). Events of Magnitude 3 to 4 are similar to vibrations caused by heavy traffic. Events of Magnitude 2 to 3 are typically not noticed by people. Events of Magnitude 1 to 2 are only detectable by seismographs and are not felt by people. For context, the Northridge earthquake of 1994 was Magnitude 6.4, and the San Fernando earthquake of 1970 was Magnitude 6.9.

During hydraulic fracturing, the microseismic events are generally less than Magnitude -2 or -3 on the Richter scale (Halliburton 2012). That is, they are about 1,000,000 times weaker than events that are typically felt by people. Although the pressures used in hydraulic fracturing are, by definition, high enough to fracture rock, the effects are very localized and do not induce further seismic effects. As discussed further in Section 4.5.6, recent studies by the U.S. Geological Survey and other organizations have consistently concluded that the forces generated by hydraulic fracturing do not cause earthquakes. These studies have shown that, under some conditions, injection of water or other fluids associated with wastewater disposal can, however, induce small tremors less than Richter Magnitude 3 or 4.

Figure 3-7 Graphical Representation of Seismic Events as Recorded on the Richter Scale

Microseismic monitoring was conducted during hydraulic fracturing treatments for both VIC1-330 and VIC1-635. The results are used to determine the extent of fractured rock resulting from the treatment by mapping the locations of induced microseismic events. Figure 3-8A presents a detailed earth model side view visualization showing the locations of microseismic events detected during the mainstage fracture treatment. Each dot shown is a microseismic event, corresponding to a fracture. The rectangular area within the microseismic events represents the calculated volume that received proppant. The color of the microseismic events represents the time that they occurred. Taken together, the area affected by the microfractures is the zone affected by high-volume hydraulic fracturing. As depicted in Figure 3-8A, a few microseismic events occurred in the underlying Sentous Formation. However, the rectangular areas indicate that the proppant remained in the Nodular Shale, so the deeper fractures would seal after the high-volume hydraulic fracturing. Descriptions of fracture height and fracture length refer to the overall zone affected by fracturing; these are not the heights and lengths of individual fractures.

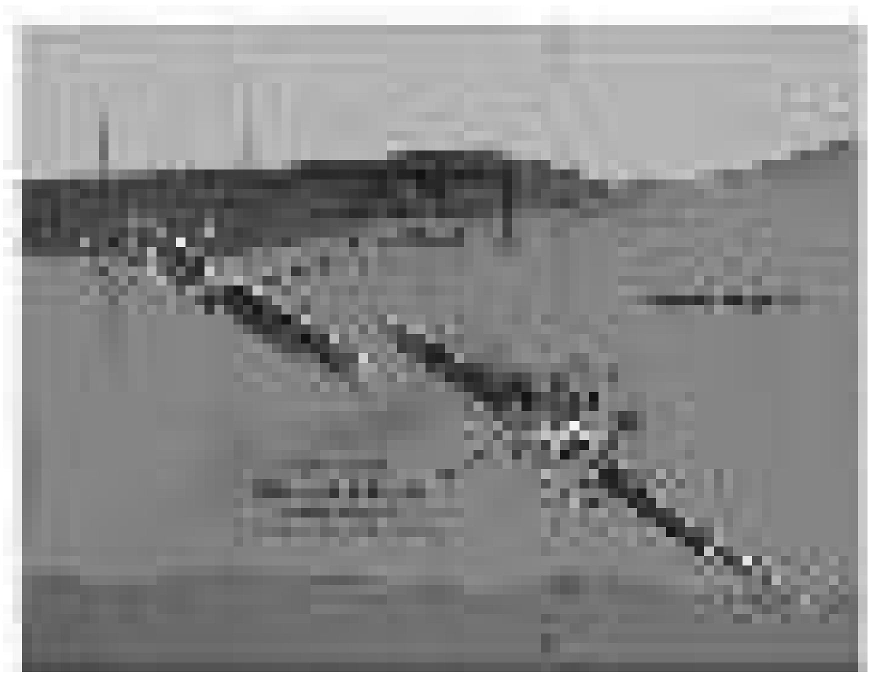

Figure 3-8A **Microseismic Events Detected During the Hydraulic Treatments in the Sentous Zone in Wells VIC1-330 and VIC1-635**

Figure 3-8B presents the 3-D model visualization of the microseismic events recorded during hydraulic fracture treatments in the Nodular Shale zone in wells VIC1-330 and VIC1-635. The distance between the top of the created fracture and the near-surface water bodies is approximately 7,700 feet. As shown in Figure 3-8B and described in the following sections, the fracture treatment stayed predominantly within the zone, and all proppant applied stayed within the zone (Halliburton 2012).

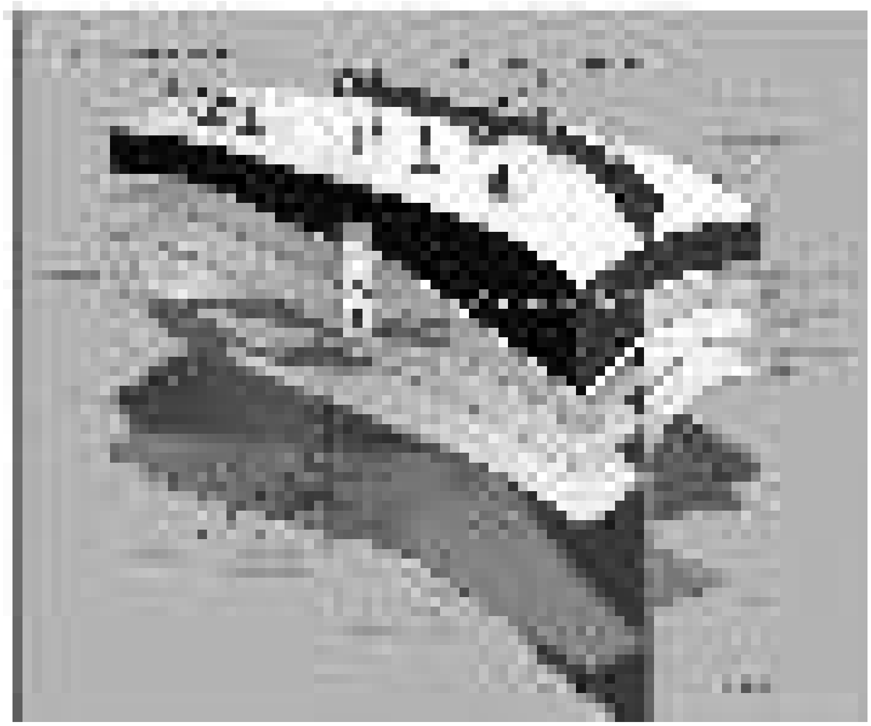

Figure 3-8B **Earth Model Visualization Showing the Microseismic Events Recorded during Hydraulic Fracture Treatment in the Nodular Shale Zone in Wells VIC1-330 and VIC1-635**

Well VIC1-330 Hydraulic Fracturing and Microseismic Monitoring

VIC1-330 well was hydraulically fractured between the depths of 8,030 to 8,050 feet below ground surface. The target formation was the Nodular Shale. The microseismic monitoring of VIC1-330 well was done from the VIC1-934 well using an array of geophones spaced 100 feet apart. The distance from the center of the geophone array to the perforations in the VIC1-330 treatment well is approximately 700 feet.

A total of 47 microseismic events were located during the hydraulic fracturing (Figure 3-9) operation. Based on the microseismic monitoring, the fractures are not radially distributed around the well, but follow three primary directions corresponding to the structure of the reservoir. Some fractures occur outside of the Nodular Shale, although most lie within the target unit (Schlumberger 2012b). Halliburton (2012) also models the distribution of proppant applied to the fractures in the target zone. Based on this model, all of the proppant stayed within the target zone of the Nodular Shale. The minor fractures that occurred outside the Nodular Shale did not receive proppant, and as such the minor fractures sealed based on the overburden pressure.

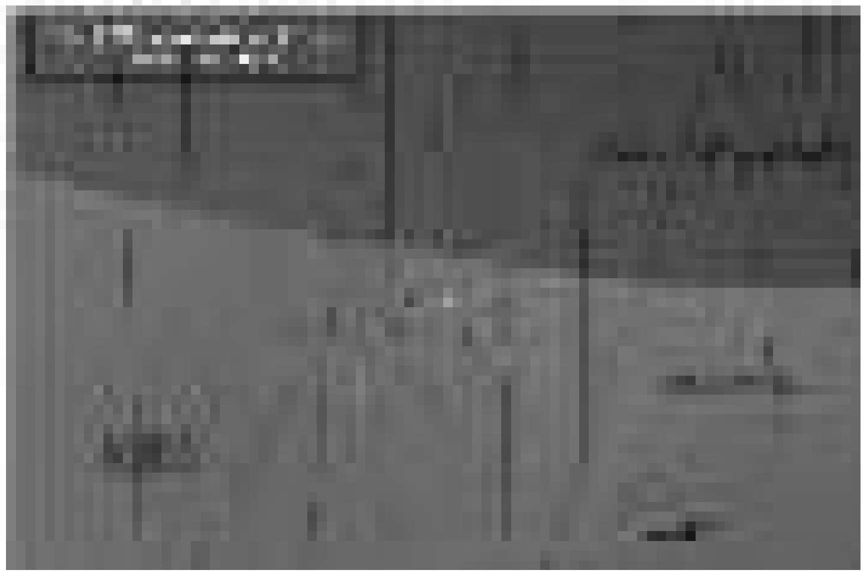

Figure 3-9 **Detailed Zoomed in Side View Visualization of the Microseismic Events Recorded during Fracture Treatment in the Sentous Zone in Well VIC1-330**

Well VIC1-635 Hydraulic Fracturing and Microseismic Monitoring

VIC1-635 well was hydraulically fractured between the depths of 8,430 to 8,450 feet below ground surface. The target formation was the Nodular Shale. The microseismic monitoring of VIC1-635 well was done from wells VIC1-735 and VIC1-935 using an array of geophones spaced 100 feet apart. Figure 3-10 depicts the microseismic events that were observed during the hydraulic fracturing treatment.

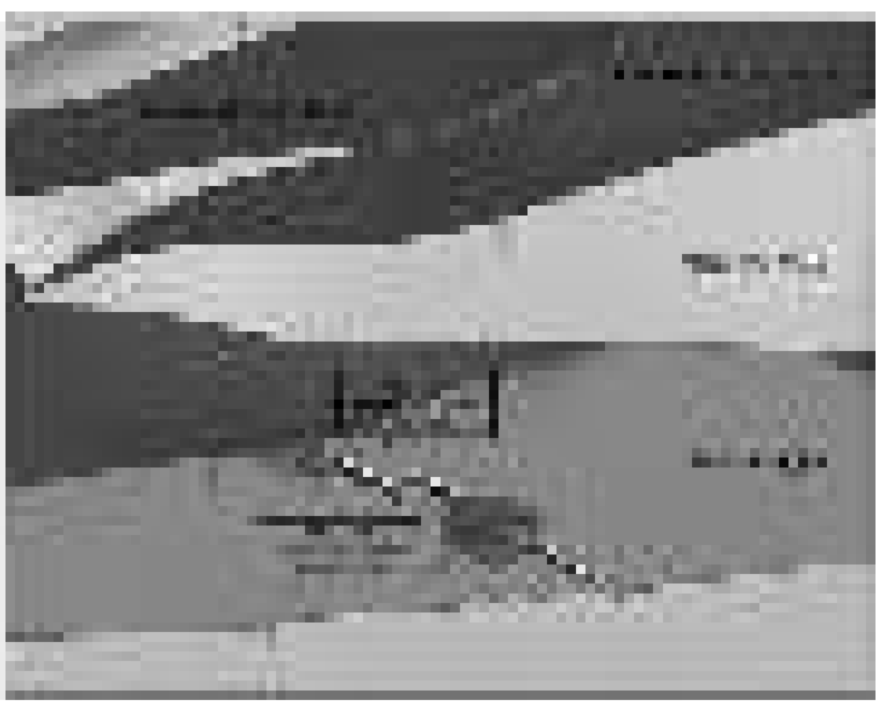

Figure 3-10 **Microseismic Events Detected during Mainstage Fracture Treatment, Top View**

Figure 3-11 shows the map view (left) and 2D Depth view (right) of the Mainstage high-volume hydraulic fracture treatment along with the microseismic events for the hydraulic fracture in well VIC1-635.

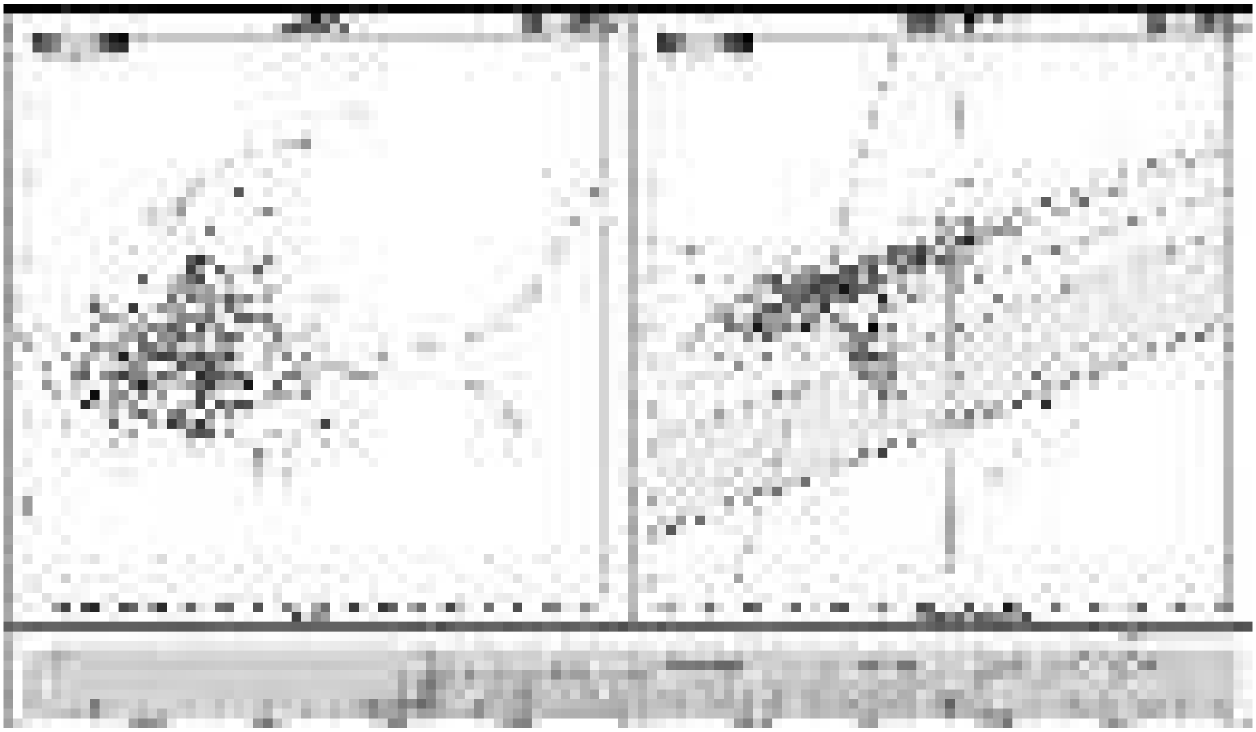

Figure 3-11 2D VIC1-635, VIC1-735 and VIC1-935 Surface Locations with Events Mapped

Earlier geologic control from well logs and structural mapping in the area indicated the Nodular Shale has dipping beds (~20°) from the northeast to the southwest. Based on the microseismic monitoring, the primary fracture network direction is considered east-west for the single stage mapped in the VIC1-635 well with a secondary fracture direction of N45°E. The microseismic mapping results indicate that the target zone of the Nodular Shale was effectively stimulated and fracture growth occurred along the formation dip of approximately 20 degrees. Growth appears to be asymmetric to the west based on the geophone array locations. The fracture network half-length was measured to be 750 feet. Fracture height was approximately 230 feet.

Almost all of the microseismic events occurred in the Nodular Shale; however, some microseismic events occurred outside the Nodular Shale and affected the Sentous Shale, underlying the Nodular. This appears to be related to pre-existing structure. Halliburton (2012) also models the distribution of proppant applied to the fractures in the target zone. Based on this model, all of the proppant stayed within the target zone of the Nodular Shale. Therefore the minor events (corresponding to microfractures) that occurred outside the Nodular Shale did not receive proppant, and as such they sealed based on the overburden pressure.

Water and Chemical Use during High-Volume Hydraulic Fracturing

Water Use and Source

Water for the hydraulic fracturing operations at the Inglewood Oil Field is provided from either produced water the field or, if a potassium chloride gel is used, fresh water provided by California American Water Company, the provider of all fresh water used at the Inglewood Oil Field. For both of the high-volume operations on the field, PXP used fresh water. Table 3-1 provides the volumes of water used during the high-volume hydraulic fracturing at the Inglewood Oil Field.

Table 3-1 Volumes of Water Used During High-Volume Hydraulic Fracturing Operations at the Inglewood Oil Field

Operation Type	Date	Well	Volume Water Used (gallons)	Water Source
High Volume	September 15-16, 2011	VIC1-330	123,354	Fresh Water
High Volume	January 5-6, 2012	VIC1-635	94,248	Fresh Water

Water Disposal

Water produced during hydraulic fracturing operations, known as flowback water and flush water, is transported by pipeline to the field water treatment plant where it is mixed with other produced water generated on the field. The treated water is then reinjected into the oil and gas producing formations as part of the waterflood process. This operation is in accordance with CSD Condition E.2.(i), which requires that all produced water and oil associated with production, processing, and storage be contained within closed systems at all times. The volume of water in the oil and gas producing zones is much greater than the volumes used for hydraulic fracturing and as such any residual additives are greatly diluted. In addition, many of the chemicals are soluble in oil and would be removed from the subsurface when the oil is sold.

Chemical Listing

Table 3-2 lists the additives that were mixed with the water and sand and injected into the formation during the two high-volume hydraulic fracture operations at the Inglewood Oil Field. Please refer to Appendix B for more detailed information regarding these additives, including volume injected and concentration.

Table 3-2 List of Additives Used During High-Volume Hydraulic Fracture Operations at the Inglewood Oil Field

Additive Type	Trade Name	Typical Main Compound Listed on Material Safety Data Sheet	Purpose
Water		Water	Base fluid carries proppant, also can be present in some additives
Biocide	BE-3S	Propionamide	Prevents or limits growth of bacteria which can cause formation of hydrogen sulfide and physically plug flow or oil and gas into the well
Gel	LGC-38 UC	Guar Gum	Thickens the water in order to suspend the sand
		Naptha hydrotreated heavy	
Breaker	SP Breaker	Sodium Persulfate	Allows for a delayed breakdown of the gel
Crosslinker	BC-140	Borate	Maintains fluid viscosity as a temperature increases

Table 3-2 List of Additives Used During High-Volume Hydraulic Fracture Operations at the Inglewood Oil Field

Additive Type	Trade Name	Typical Main Compound Listed on Material Safety Data Sheet	Purpose
pH Adjusting Agent	MO-67	Sodium Hydroxide	Adjusts pH to proper range for fluid to maintain the effectiveness of other fluid components
Surfactant	Losurf-300M	Ethanol	Aids in recovery of water used during fracturing operation by reducing surface tension
Clay control	Clayfix II Plus	Alkylated quaternary chloride	Clay-stabilization additive which helps prevent fluid interaction with formation clays
		Potassium chloride	
Proppant		Silica	Holds open fracture to allow oil and gas to flow to well

3.2.3 Images from January 2012 Completion Operations

This section presents photographs taken during high-rate gravel packing and high-volume hydraulic fracturing operations conducted at the Inglewood Oil Field in January 2012. The first photo above shows the overall requirements for a high-rate gravel pack completion; they are setting up near the wellhead.

After bringing the vehicles and equipment to the wellhead, hoses and pipes are connected to the various components of the test. The hydraulic fracturing is conducted at elevated pressure, so all components that bear pressure are steep pipes with wall thickness that provides a margin of safety. Hoses are used to connect water, sand, and chemicals prior to mixing and injection.

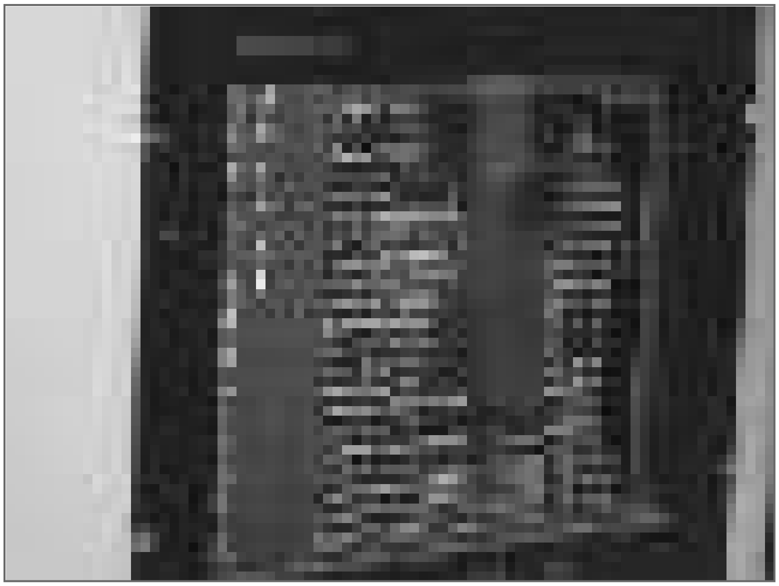
The blender unit is located behind the trailers in this image. The blender mixes the water, sand, and additives prior to introduction into the well for the completion process.

This is an image of the mixture of water, sand and additives used for the high-volume hydraulic fracturing at VIC1-635. This sample of the proppant/gelled water mixture is used to test for consistency with project specifications; samples are taken frequently during the course of the hydraulic fracture treatment for quality control purposes. Note that the food-grade gelling agents hold the sand in suspension, allowing the sand to be introduced into the fractures away from the well. Without the gel, the sand would settle out and not prop open the fractures formed by the completion process. The compound that causes this thickening, guar gum, is an additive used to thicken ice creams for human consumption (Halliburton 2012).

This image shows the VIC1-635 wellhead with a device for isolating the wellhead from the hydraulic fracturing equipment, set up to begin hydraulic fracturing. The green vertical pipe is the wellhead, and the two red pipes attached to the wellhead deliver the water-sand-additive fluid mixture down the well under pressure.

This image shows the VIC1-635 wellhead set up to begin hydraulic fracturing, looking the other direction from the previous image. The water-sand-additive fluid mixture is delivered down the well through the red pipes connected to the top of the well. The image shows the above-ground pumping unit to be connected after the well completion process (hydraulic fracturing), and the amount of equipment needed at the wellhead for hydraulic fracturing job.

A mobile Control Room is placed on site adjacent to the well to be hydraulically fractured at the Inglewood Oil Field. The control room has connections to all of the monitoring, allowing real-time adjustment of the hydraulic fracturing conditions as the job progresses. This control ensures that well integrity, pressures, proppant delivery, and all other attributes of the process can be adjusted to meet downhole conditions. The control room also has a small lab for testing the samples of gelled water and proppant material that are collected for quality control.



This image depicts a screen in the on-site mobile control room, monitoring downhole characteristics of the early stages of the VIC1-635 hydraulic fracture job in progress.

This image shows a graphical display of part of the VIC1-635 hydraulic fracture job in the mobile control room. The image on the screen shows the progress of adding the water-sand-additive mixture; the real-time monitoring using both numerical and graphical displays allows for modification or cessation of the hydraulic fracturing job if the performance does not meet the project design specifications.

3.3 Gravel Packs at the Inglewood Oil Field

In addition to hydraulic fracturing, the Settlement Agreement requires that gravel packing also be described and evaluated in this study. High-rate gravel packing uses water, gravel, and additives to limit entry of formation particles and sand into the wellbore. High-rate gravel packing is a technique that is used for sand control. High-rate gravel packing is ideal in formations that are already permeable. The gravel pack method uses a metal screen placed in the wellbore. The surrounding annulus, or the space between the well and the outer casing, is packed with gravel, water, and additives to limit entry of formation fines and sand into the wellbore. In this process, the space between the formation and the outer casing is packed, at a high-rate, with gravel that is sized small enough to prevent formation grains and fine particles from mixing and entering the wellbore with the produced fluids, but large enough to be held in place by screens. Sand and finer particles reduce the life of surface equipment such as valves, pipelines, and separators. In addition, produced sand can reduce oil production and impair the performance of injection wells.

3.3.1 Past Gravel Packs

Gravel packing is a completion approach that is specifically designed to prevent non-consolidated formation sands from flowing into the wellbore and preventing hydrocarbon production. In gravel packing operations, a steel screen is placed in the wellbore and the surrounding annulus packed with prepared gravel of a specific size designed to prevent the passage of formation sand. The primary objective is to stabilize the formation while causing minimal impairment to well productivity (Schlumberger 2012a). The gravel is circulated into place rather than pumped in under high pressure. Gravel packing does not exceed the fracture gradient.

The process of introducing a gravel pack has gone through several changes over time at the field. Prior to 2003, all of the gravel packs were conducted at pressures below the fracture gradient of the formation. Open hole gravel packs were used until 2003 in the Vickers-Rindge formation and were never installed above the fracture gradient of the surrounding formation. From the mid-1990s to 2003 in the Vickers-Rindge, the technique was modified to a cased-hole gravel pack; this improvement allowed the completion to target the specific producing zone. This had the effect of isolating high saline water producing zones so that the more oil-rich zones could be targeted. This method was also used in the Vickers-Rindge, and was never installed above the fracture gradient of the surrounding formation.

High-rate gravel packs were first used in 2003. At that time, this technique used the cased hole as before, and was limited to a 200-foot target interval as before. This method, however, was the first to exceed the fracture gradient in the surrounding formation, as well as introducing the gravel pack. The fractures would typically be less than 250 feet from the well. Eleven of the initial completions in 2004 used produced crude oil in the fluids in order to be more consistent with the oil in the formation, and potentially yield better well performance; however, analysis of well performance indicated that this was not the case and the use of oil was subsequently stopped. The crude oil had been previously pumped from the formation, and was only used for high-rate gravel packs targeting the oil producing zones. That is, crude oil was never used above, or near, the base of fresh water, but only in oil-bearing formations.

Table 3-3 lists the primary differences between high-rate gravel packs and conventional and high-volume hydraulic fracturing.

Table 3-3 Comparison of High-Rate Gravel Packs to Conventional Hydraulic Fracturing

High-Rate Gravel Packs	Hydraulic Fracturing
Wire wrapped screen is installed in the well	No wire wrapped screen in the well
Goal is not to pump entire sand / proppant volume in the formation but to prevent the entrance of sand into the wellbore	Goal is to pump entire sand / proppant volume into the formation
Sand and water mixture is placed within a short radius of the wellbore (normally 10-50 feet but can reach 250 feet)	Sand and water mixture can be pushed out well in excess of 500 feet from the wellbore

Source: Halliburton 2012

In addition, high-rate gravel pack treatments are usually smaller in terms of sand and fluid volumes and require less time to pump than an average conventional hydraulic fracturing treatment. To illustrate this difference, Table 3-4 provides a comparison of actual sand and fluid volumes pumped in the Inglewood Oil Field during a high-rate gravel pack treatment and the high-volume hydraulic fracturing treatments that were the subject of this study.

Table 3-4 Comparison of Sand and Fluid Volumes between High-Rate Gravel Pack and High-Volume Hydraulic Fracturing at the Inglewood Oil Field

Parameters	High-Rate Gravel Pack	Hydraulic Fracturing
Pump Time (minutes)	27.68	141.87
Clean Volume (bbl)	418.45	2992.18
Slurry Volume (bbl)	458.89	3210.35
Average Treating Pressure (psi)	768	6914
Max Treating Pressure (psi)	1343	8,818
Proppant Mass (100* lb)	373.79	2013.48

Source: Halliburton 2012

Since 2003, PXP has conducted high-rate gravel pack completions on approximately 166 wells in the Inglewood Oil Field, all in the Vickers and the Rindge formation, with a single completion in the Investment Zone (Figure 3-12). Each high-rate gravel pack includes an average of five stages per well; therefore, approximately 830 stages have been completed at the Inglewood Oil Field since 2003.

Halliburton (2012) studied four recent high-rate gravel pack completions in the Vickers and Rindge formations to assess applicability and feasibility: VRU-4243, TVIC-274, Stocker 461, and BC-285. The wells were selected because of their location within the field, including presence on both sides of the Newport-Inglewood Fault. Twenty-one independent high-rate gravel pack treatments from the four wells selected in the Vickers and Rindge zones were analyzed (Halliburton 2012).

PLAINS EXPLORATION & PRODUCTION COMPANY

Figure 3-12
High-Rate Gravel Pack Completions
at the Inglewood Oil Field

10 | 01 | 12

The results of the analysis showed the following:

- The fracture height created by the high-rate gravel packs in the Vickers and Rindge formations was, on average, in the range of 100 to 170 feet for the majority of the stages. The fracture height in several stages was around 200 to 240 feet.
- Fracture height is very small in relation to the depth of the fracture.
- The top of the created fracture is at least 1,000 feet below the bottom of the deepest perched water zones in the area that includes the Inglewood Oil Field.

Figures 3-13A and 3-13B present different visualizations of the fracture geometries produced by the high-rate gravel packs. The figures also show the relevant formation surfaces, ground surface, geologic structure including major faults, and groundwater-bearing bodies near the surface.

Figure 3-13A Side View Showing Modeled Fracture Geometries in the Vickers Zone

Figure 3-13B Side View Showing Modeled Fracture Geometries in the Vickers Zone and Structure (Faults)

3.3.2 Recent High-Rate Gravel Pack Completions

PXP also conducted high-rate gravel pack jobs at two wells on the Inglewood Oil Field to assess feasibility and potential impacts. The first high-rate gravel pack involving a five-stage completion was conducted on January 9, 2012, at the TVIC-221 well. The second high-rate gravel pack involved a six-stage completion and was conducted on the same day at a different well, TVIC-3254. Both of these operations were conducted in the Vickers and Rindge formations. The high-rate gravel pack operations were conducted by Halliburton with PXP oversight. The conditions of the high-rate gravel packs are similar to the well completions previously conducted across the field, and are also similar for any future high-rate gravel pack jobs that would be expected to be conducted at the oil field.

The maximum applied pressure during both high-rate gravel packs was 1,900 psi. In comparison the high-volume hydraulic fracturing projects had an average treatment pressure of 2,971 psi (VIC1-330) and 6,914 psi (VIC1-635). The high-rate gravel pack fracturing influences the zone within 100 to 250 feet of the well within the target oil-producing zone, compared to in excess of 500 feet for hydraulic fracturing.

Water and Chemical Use during High-Rate Gravel Pack

Water Demand/Source

Water for high-rate gravel packs at the Inglewood Oil Field has been provided either from produced water at the field or, if a potassium-chloride gel is used, fresh water provided by California American Water Company (the water service provider for all fresh water on the oil field). The majority of the high-rate gravel pack operations that have occurred since April 2011 have used produced water from the lease, including the two high-rate gravel pack examined in this study. Table 3-5 provides the volumes of water used during the two high-rate gravel pack fracture jobs at the Inglewood Oil Field.

Table 3-5 Volumes of Water Used During High-Rate Gravel Pack Hydraulic Fracturing Operations at the Inglewood Oil Field

Operation Type	Date	Well	Volume Water Used (gallons)	Water Source
High-rate gravel pack	January 5-6, 2012	TVIC 3254	33,357	Produced Water
High-rate gravel pack	January 5-6, 2012	TVIC 221	55,247	Produced Water

Chemical Listing

Table 3-6 below, lists the materials that have been injected into the formation during the high-rate gravel pack operations at the Inglewood Oil Field.

Table 3-6 List of Additives at Used During High-Rate Gravel Pack Operations at the Inglewood Oil Field

Additive Type	Trade Name	Typical Main Compound	Purpose
Water		▪ Water	Base fluid carries proppant, also can be present in some additives
Buffering Agent	BA-40L	▪ Potassium carbonate	pH buffer
Gel	LGC-36 UC	▪ Guar Gum ▪ Naphtha hydrotreated heavy	Thickens the water in order to suspend the sand
Breaker	SP Breaker	▪ Sodium Persulfate	Allows for a delayed breakdown of the gel
Crosslinker	K-38	▪ Disodium octoborate tetrahydrate	Maintains fluid viscosity as a temperature increases
pH Adjusting Agent	MO-67	▪ Sodium Hydroxide	Adjusts pH to proper range for fluid to maintain the effectiveness of other fluid components
Activator	CAT-3	▪ Copper chelate	Reduces viscosity
Surfactant	Losurf-300M	▪ Ethanol	Aids in recovery of water used during fracturing operation by reducing surface tension
Clay control	Clayfix II Plus	▪ Alkylated quaternary chloride ▪ Potassium chloride	Clay-stabilization additive which helps prevent fluid interaction with formation clays
Proppant		▪ Silica	Holds open fracture to allow oil and gas to flow to well

Water Reuse

As described for the high-volume hydraulic fracture operations, water produced during high-rate gravel pack operations is transported by pipeline to the field water treatment plant where it is mixed with other produced water generated on the field. The treated water is then reinjected into the oil and natural gas producing formations as part of the waterflood process. This operation is in accordance with CSD Condition E.2.(i) which requires that all produced water and oil associated with production, processing, and storage are contained within closed systems at all times. The volume of water in the oil and gas producing zones is much greater than the volumes used for hydraulic fracturing and as such any residual additives would be greatly diluted. In addition, many of the chemicals are soluble in oil and would be removed from the subsurface when the oil is sold.

3.4 Anticipated Future Use of Hydraulic Fracturing and Gravel Packing at the Inglewood Oil Field

PXP expects that, in the future, high-volume hydraulic fracturing and conventional hydraulic fracturing may be conducted in the relatively deep Rubel, Moynier, Bradna, City of Inglewood, Nodular, and Sentous zones (all located deeper than 4,000 feet below ground surface).

It is anticipated that high-rate gravel packing operations may be conducted on as many as 90 percent of all future production wells drilled in the Vickers and Rindge formations on the Inglewood Oil Field, as well as other permeable sandstone completions. This procedure results in less formation sand being drawn into the well during pumping, thus, the amount of formation sand that requires management at the surface is reduced and the procedure provides a longer life to the well.

Chapter 4

Environmental Effects Monitored in Conjunction with Hydraulic Fracturing Tests

4.1 Introduction

As described in Chapter 4, the Inglewood Oil Field has an ongoing program of environmental monitoring and reporting for environmental factors such as water quality, air quality, and others. As part of this Hydraulic Fracturing Study, these ongoing monitoring programs were augmented to include other monitoring of environmental factors of importance. This chapter summarizes the results of this comprehensive environmental monitoring, as follows:

- Hydrogeology, Water Quantity and Quality
- Containment of Fractures to the Desired Zone
- Well Integrity
- Slope Stability, Subsidence, Ground Movement, Induced Seismicity
- Methane
- Other Emissions to Air
- Noise and Vibration
- Los Angeles County Department of Public Health Study

In addition, since high-volume hydraulic fracturing was first used for shale gas development in the northeastern United States and tight sands development in the Intermountain West, there has been extensive coverage of controversies surrounding its use. Although most of the news has been about the development of shale gas, tight sands and coalbed methane deposits rather than the type of oil and natural gas development that occurs at the Inglewood Oil Field, community outreach conducted as part of this study indicated that many of the concerns surrounding shale gas development are shared by the local community. Therefore, in this chapter we present the methods and results of environmental monitoring conducted at the Inglewood Oil Field, and we provide context by describing how these issues have been described as they relate to shale gas development. Although the focus of this chapter is the Inglewood Oil Field, the issues have been framed by the national attention given to shale gas development elsewhere in the country; thus, the context is relevant to the Inglewood Oil Field.

4.2 Hydrogeology, Water Quantity and Quality

4.2.1 Geologic Control on the Distribution of Groundwater-Bearing Zones

The geology of the Baldwin Hills constrains the occurrence and movement of groundwater, as described in the USGS groundwater model of the Los Angeles Basin (USGS 2003), the California Department of Water Resources groundwater assessment of the Los Angeles Basin

(DWR 1961), and studies specific to the Inglewood Oil Field summarized in this study. The USGS excludes the Baldwin Hills from the model domain, separating it by a no-flow boundary. The no-flow boundary condition means that groundwater neither flows in to or out of the Baldwin Hills; it is isolated from the remainder of the Los Angeles groundwater basin (Figure 4-1). In the definitive account of the groundwater geology of the Los Angeles Basin, the Department of Water Resources concludes that "the Baldwin Hills form a complete barrier to groundwater movement, where the essentially non-water bearing Pico Formation crops out" (DWR 1961). The results of the extensive site-specific study of the Baldwin Hills, including a groundwater monitoring array that traverses the entire zone of potential fresh water, summarized in this section, are in complete agreement with the findings of the USGS and DWR.

Figure 4-2 presents the standard model of the geology of the Baldwin Hills (Wright 1991), from the surface to a depth in excess of two miles. The center of the figure has a small area labeled "*See Figure 4-3C*" which represents the uppermost 500 feet at the Baldwin Hills; this area will be magnified in stages from Figure 4-3B to 4-3C.

Figure 4-3A shows the locations of all of the groundwater monitoring wells installed on the Inglewood Oil Field. All the oil producing formations, from the Investment Zone downwards, contain water too saline for direct use at the surface. Only the upper 500 feet, above the top of the Pico Formation, has any fresh water, albeit limited in extent and yield. For this reason, the top of the Pico Formation is known as the base of fresh water.

Figure 4-3B is the first level of magnification and shows the freshwater zones. In all parts of the world, fresh (not salty) groundwater lies at relatively shallow depths. At greater depths the water is saline, not drinkable, and is sometimes called formation water. The USEPA makes this distinction in the Safe Drinking Water Act by protecting the shallow, fresh water from contamination by deeper, saline formation water. In most of the Los Angeles Basin, the base of the fresh water zone, below which saline formation water is found, is defined by a geological unit called the Pico Formation, a marine unit shown in Figure 4-3B (developed from USGS 2003). Overlying the Pico Formation are the aquifer systems in the Los Angeles Basin located away from the Baldwin Hills: the Inglewood Formation, the Silverado Formation, and the Lakewood Formation. In many parts of the Los Angeles Basin, these formations are aquifers for water supply wells. The box labeled "*See Figure 4-3C*" depicts how these formations became folded and faulted in the geological uplift of the Baldwin Hills (within the labeled box). As a result of this uplift, these formations are not water-bearing beneath the Baldwin Hills, and are in fact exposed at the surface. Their disruption by the uplift of the Baldwin Hills has disconnected them from the groundwater-bearing formations of the Los Angeles Basin (USGS 2003, DWR 1961).

Finally, Figure 4-3C shows the uppermost 500 feet beneath the Baldwin Hills. The ground surface is shown as the undulatory line at the top of the figure. The vertical black lines represent groundwater wells drilled at the Inglewood Oil Field from 1993 to present. Although they are shown along a single line in the figure, the wells are distributed across the oil field; their locations have been projected to a single line to aid in the presentation of the results. The length of the line shows the depth of drilling. If any groundwater was detected, the depth is shown with an upside-down triangle and the estimated extent of the groundwater is shown with the blue color surrounding the well (black line). If no groundwater was detected, that observation is noted with an upside-down triangle with a red circle around it, and a red cross-out.

Figure 4-3C

Groundwater Beneath the Oil Field

10 | 01 | 12

Figure 4-3C is based on measured conditions beneath the field, with 15 groundwater monitoring wells and four deep supply wells that were attempted by PXP, but that did not encounter water and were abandoned. Note that the same characteristics shown in Figure 4-3C are also shown in more detail by the 3-D model prepared by Halliburton in Figure 2-8H. The data show that the water bearing zones are not continuous across the field because they occur at different depths, or do not occur at all.

All of the wells have very low yield; the shallow wells and all but two of the deeper wells pump dry in less than 30 minutes at low pumping rates. The two that can sustain higher initial pumping rates show declining yields when pumped for more than a day, indicating that the water bearing zone from which they draw is limited in extent. None of the units show evidence of a connection to the aquifers of the Los Angeles Basin (shown in Figure 4-3C).

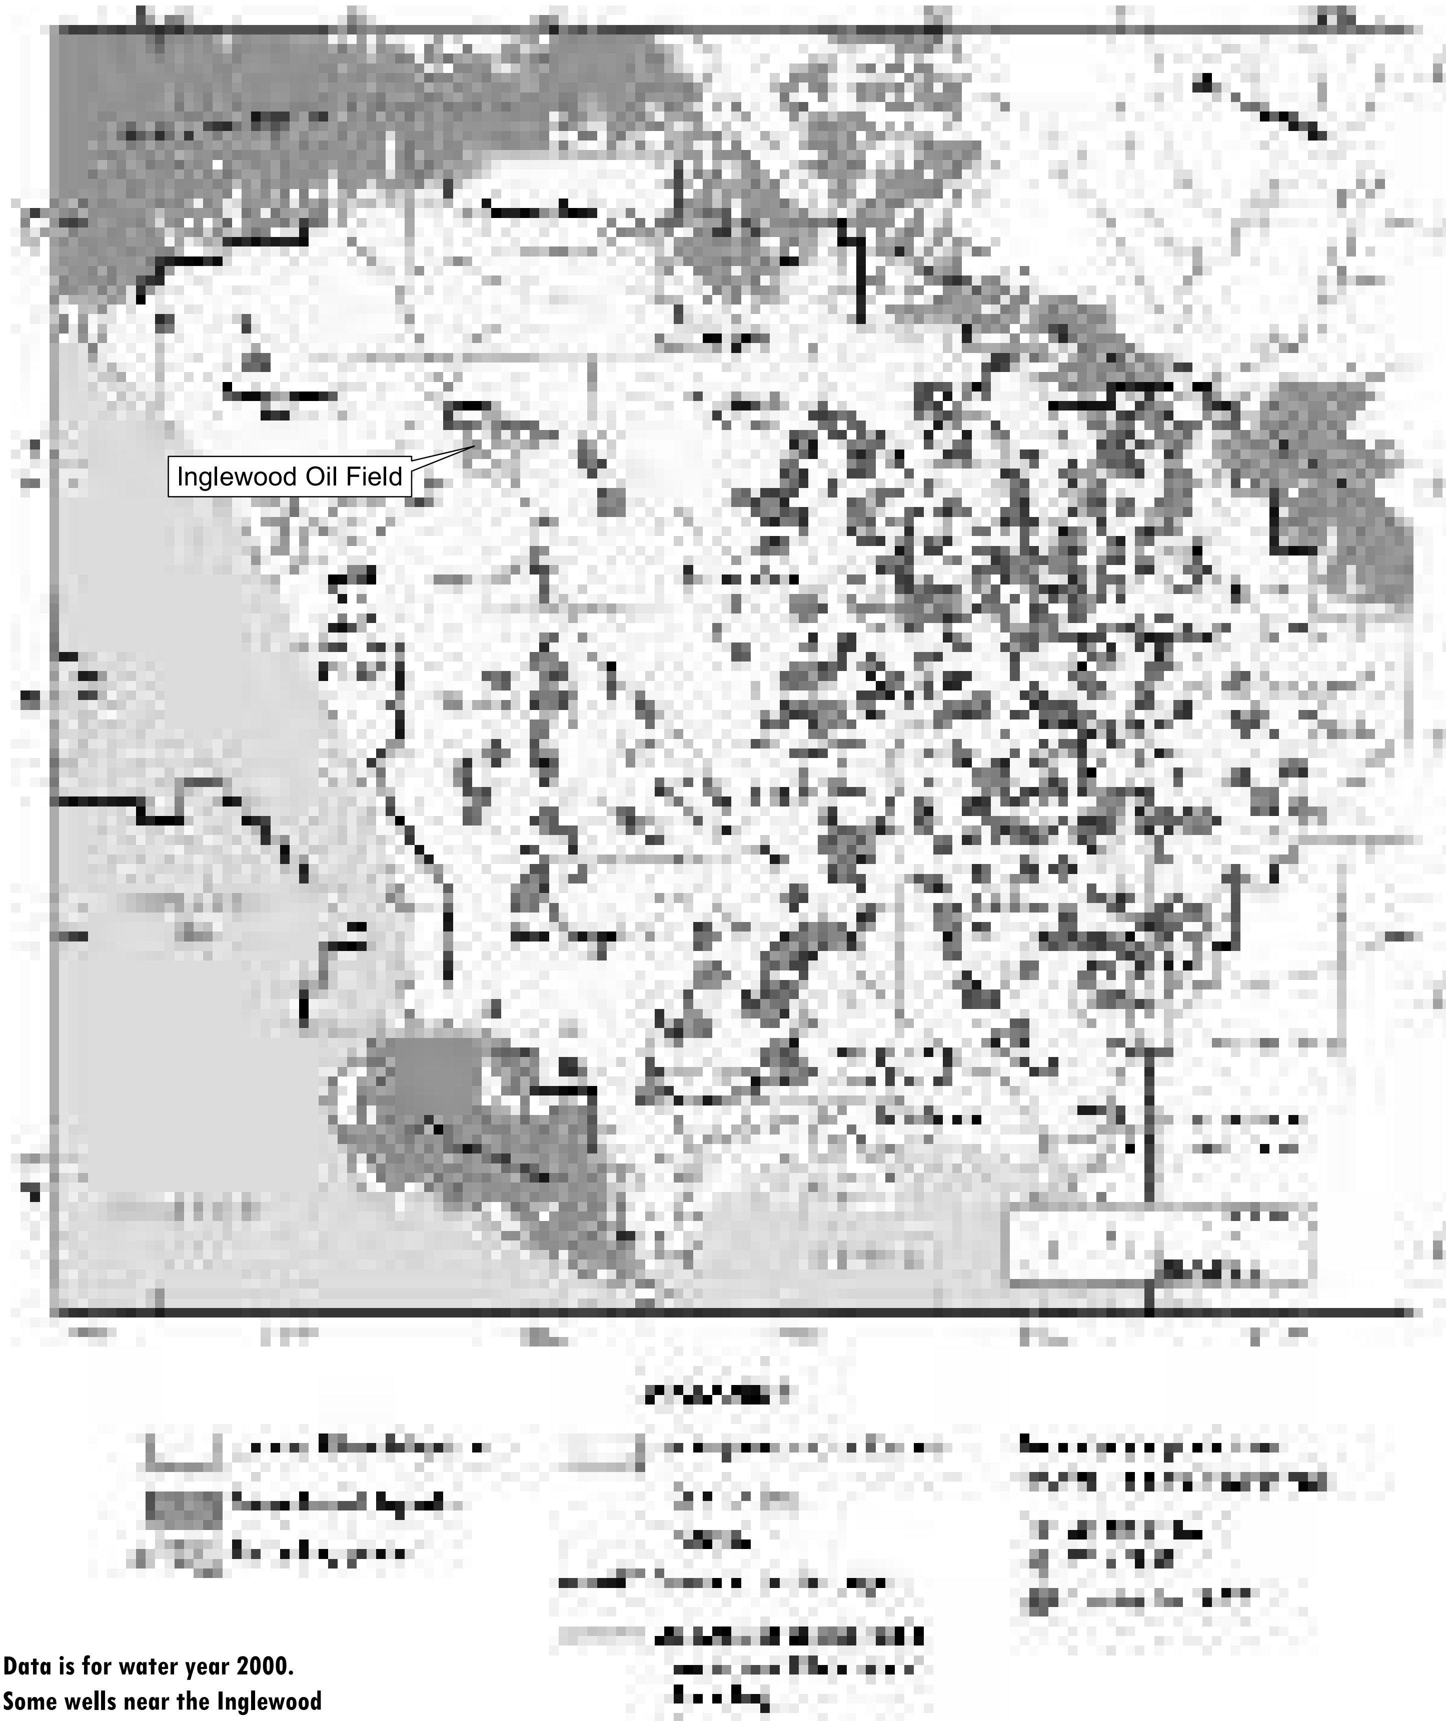
4.2.2 Hydrogeology

The description of conditions beneath the Inglewood Oil Field depicted in Figure 4-3C and described in the previous section is based on data collected from 15 groundwater monitoring wells installed to test for the presence and quality of groundwater beneath the site, ranging in depth from 30 feet to 500 feet beneath the ground surface. The four deepest wells were installed to reach the "base of the fresh water zone", that is, the top of the Pico Formation. As such, the understanding of groundwater hydrogeology and water quality is based on investigation of the *entire* zone beneath the surface that has any potential to contain fresh water.

The Baldwin Hills are generally comprised of non-water-bearing rock layers that straddle the West Coast, Central, and Santa Monica groundwater basins (Figure 4-4). As shown in this figure, where groundwater is pumped for groundwater supply, it is principally in areas to the east of the Baldwin Hills. The data used by the USGS to construct this figure were based on water year 2000; currently, the only wells in the vicinity of the Inglewood Oil Field are either no longer active (Environmental Data Resources, Inc. 2012) or located greater than 1.5 miles from the field boundary.

Studies of the Baldwin Hills have concluded that the tectonic uplift of the Baldwin Hills by folding and faulting has disconnected water-bearing sediments from groundwater supplies in the Los Angeles Basin (USGS 2003, DWR 1961). The geological formations that may produce usable quantities of groundwater from aquifers elsewhere in the Los Angeles Basin are folded, faulted, and either dry or have practically no water supply potential beneath the Baldwin Hills. Because of a lack of water, the geological formations beneath the Baldwin Hills are not suitable for water supply (DWR 1961, USGS 2003, County of Los Angeles 2008).

For example, the prominent aquifers in some portions of the Los Angeles Basin, which lie greater than 100 feet below the surface in the flat portion of the Los Angeles Basin (refer to Figure 4-1, Figure 4-3B), have been brought to the surface by folding and faulting of the Baldwin Hills. The units are exposed at the surface, do not contain water, and are not connected to the surrounding basin. In groundwater models of freshwater flow in the Los Angeles Basin aquifer systems recently prepared by the U.S. Geological Survey (USGS 2003), the Baldwin Hills is modeled as a "no flow" zone; that is, since the sediments beneath the Baldwin Hills are disconnected from the regional aquifers, groundwater flow is discontinuous across the Baldwin Hills.



Data is for water year 2000.
Some wells near the Inglewood Oil Field are no longer active.

Source: USGS 2003

The five water wells (MW-10, MW-11A, MW-11B, MW-12, and MW-13) drilled down to the base of fresh water in 2012 are intended to provide data for the deepest freshwater zones in the Baldwin Hills. Only two encountered water at the deepest levels, and were completed in the only zones containing water. Maps showing the top of the Pico used for oil exploration defined the top of the Pico Formation, and drilling progressed to that depth, in some places up to 500 feet below the ground surface. In addition, geophysical logs were run after drilling to thoroughly search for water. Two of the locations had only a single thin water-bearing zone, and the wells quickly pumped dry at low flow rates. One location had water near the top of the Pico Formation and was initially capable of sustaining pumping rates of eight gallons per minute. Over three days of pumping the yield diminished significantly, indicating a limited areal extent of the water-bearing zone. The fourth location of the deep water wells identified two thin water-bearing zones. One pumped dry readily, while the other well initially sustained pumping rates of one gallon per minute. Over three days of pumping the yield diminished significantly indicating a limited areal extent of the water-bearing zone.

At the Inglewood Oil Field perched groundwater (groundwater that is discontinuous and occurs in small pores within the rock layers) has been measured at depths ranging from approximately 45 to 500 feet below ground surface (Figure 4-3C). Groundwater monitoring on the field suggests that rainfall and irrigation water from nearby residences appear to be the only source of this groundwater because water levels respond to the presence of water in catch basins.

4.2.3 Water Quality

Regulatory Limits

The LARWQCB Water Quality Control Plan, or Basin Plan, establishes beneficial uses of surface and groundwater in the Los Angeles Basin. Based on the State Board Resolution No. 88-63, "Sources of Drinking Water Policy", all groundwater in the state must be considered a potential source of drinking water, and carry a beneficial use designation of Municipal Supply (or MUN). The only exceptions are as follows:

- Total Dissolved Solids (TDS) exceeds 3,000 mg/l (5,000 µS/cm electrical conductivity);
- Contamination exists, that cannot reasonably be treated for domestic use; and
- The source is not sufficient to supply an average sustained yield of 200 gallons per day.

The LARWQCB would also require that, for any groundwater to have the MUN designation removed that there be a formal process to de-designate the aquifer. There are only two de-designated areas in the LARWQCB jurisdiction: limited coastal areas beneath the Port of Los Angeles and the Port of Long Beach, and a limited area of El Segundo seaward of a series of injection wells to limit saltwater intrusion. Because the Inglewood Oil Field has not gone through a de-designation process, any water that may be encountered beneath the field has the beneficial use designation of MUN, and the drinking water standards are applied regardless of the low yield.

Chemical Disclosure and Environmental Effects of Chemical Additives

When new oil and natural gas development using high-volume hydraulic fracturing was initially introduced in the northeastern United States (areas dependent on shallow groundwater resources or water from relatively pristine watersheds), public concern was initially related to the policy of oilfield service companies to maintain confidentiality of the precise chemical names and concentrations used in hydraulic fracturing fluids. The initial lack of full disclosure on the part of the oilfield service companies increased public concerns about the chemicals. As a result of these concerns, several states initiated independent reviews of the environmental impacts of hydraulic fracturing with an emphasis on water quality and chemical disclosure. In addition, USEPA initiated two ongoing reviews, one focused on the potential effects of hydraulic fracturing on drinking water supplies, and the other focused on the definition of "diesel fuel" as part of a review of the 2005 EPAct provisions (USEPA 2011c, USEPA 2011d). The 2005 EPAct reaffirmed that hydraulic fracturing is a well completion process regulated at the state level, and therefore does not require an underground injection control permit under the Safe Drinking Water Act. The 2005 EPAct did require a UIC permit in cases where diesel fuel is used in hydraulic fracturing fluid.

Since the passage of the EPAct, many states have adopted regulations or passed legislation requiring operators to disclose the composition of the fluids used in the hydraulic fracturing process. In California, legislation (AB 591 - Wieckowski) requiring operators to post a complete list of the chemical constituents used in the hydraulic fracturing process was introduced during the 2011 – 2012 legislative session but failed to pass. The bill would have required that operators involved in hydraulic fracturing provide a complete list of the chemical constituents used in the hydraulic fracturing fluid, as well as the following additional information to DOGGR:

- the source and amount of water used in the exploration or production of the well;
- data on the use, recovery and disposal of any radiological components or tracers injected into the well; and
- if hydraulic fracturing is used, disclosure of the chemical information data described above.

The chemical additives used in hydraulic fracturing, typically 0.5 percent of the total fluids, are necessary to ensure that the fracturing job is as effective and efficient as possible. The various chemicals are used as friction reducers, biocides to prevent microorganism growth, oxygen scavengers and other stabilizers to prevent corrosion of metal pipes, and acids to remove drilling mud damage. The consequences of not using additives in the fluids include higher engine emissions as a result of greater loads, increasing pipe corrosion (and, in turn, compromised integrity of the well), increased water use, and decreased hydrocarbon recovery.

PXP reported the full chemical listing of the two recent high-volume hydraulic fracture operations on the FracFocus.org website. This website offers the opportunity to comply with the standard chemical disclosure regulations in effect in other parts the country. The level of disclosure used in this Hydraulic Fracturing Study would comply with the terms of AB 591 as drafted at the time this study was prepared. Diesel fuel is not used as a chemical additive for the hydraulic fracturing conducted at the Inglewood Oil Field; therefore, a UIC permit is not required.

Quarterly Water Quality Testing Prior to High-Volume Hydraulic Fracturing

Fifteen groundwater wells to test for the presence and quality of groundwater beneath the Inglewood Oil Field have been drilled since 1993. These vary in depth from 30 feet to 500 feet below the ground surface. In addition to the 15 groundwater monitoring wells, four wells were drilled as potential water supply wells for the oil field, but because they were dry, the wells were abandoned and sealed. Of the fifteen wells, six did not encounter groundwater but the wells remain in place. Four were installed in 2012 and were drilled to the base of fresh water in order to characterize the entire fresh water zone. The remaining five all sample the shallowest water on the field and are monitored on a quarterly basis, in accordance with CSD Condition 19.

Quarterly monitoring reports for 2010 and 2011 provide a baseline indication of existing groundwater quality. Prior to the hydraulic fracturing operations of January 2012, a total of nine monitoring wells were tested as part of the groundwater monitoring effort that took place on November 22, 2011. Specifically, the monitoring effort involved wells MW-2, MW-3, MW-4A, MW-4B, MW-4C, and MW-5, MW-6, MW-7, and MW-8 as part of the monitoring program. The sampling involved the collection of depth-to-water measurements and groundwater samples from monitor wells MW-2, MW-6, MW-7, and MW-8. Monitor wells MW-3, MW-4A, MW-4B, MW-4C and MW-5 were not sampled since they were dry or contained insufficient water at the time the monitoring was conducted.

Groundwater analytical results indicated no results were above the California Maximum Contaminant Level (MCL), with the exception of arsenic. Arsenic levels are believed to correspond to naturally occurring arsenic found in soil and rock formations throughout the Los Angeles Basin. As documented by USEPA, when "compared to the rest of the United States, western states have more systems with arsenic levels greater than the [US]EPA's standard of 10 parts per billion (ppb)" (USEPA 2012a). Arsenic delineation maps produced by the USGS in 2011 have documented increased levels of arsenic in both Los Angeles County and Southern California as a whole (Gronberg 2011). These data are also consistent with soils data from the 2008 California Department of Toxic Substance Control (DTSC) memo "Determination of a Southern California Regional Background Arsenic Concentration in Soil" (Chernoff et al. 2008). Areas in Southern California have been shown to have higher than average levels of arsenic present in soil and thus, through the release of naturally occurring arsenic in sediments, levels can be inferred to also be higher than average in groundwater resources throughout Southern California.

A summary of the baseline groundwater analytical results is as follows:

- TDS was measured at 590 mg/L in MW-2, 2,000 mg/L in MW-6, 2,500 mg/L in MW-7, and 1,500 mg/L in MW-8.
- pH was measured at 7.5 in MW-2, 7.0 in MW-6, 7.0 in MW-7, and 7.0 in MW-8.
- BOD_5 was measured at 38.5 mg/L in MW-2, 30.4 mg/L in MW-6, 25.6 mg/L in MW-7, and 15.7 mg/L in MW-8.
- Low levels of TPH in MW-2, MW-6 and MW-7. The silica gel filtering method, which removes nonpetroleum materials such as fats, was run on all groundwater samples. Results indicate TPH concentration of 0.35 mg/L in MW-2, and below the detectable limit of

0.10 mg/L in wells MW-6 and MW-7. These levels are within the range of drinking water standards for taste and odor commonly applied for TPH (between 0.050 and 1 mg/L).

- TRPH were below the detection limit of 0.50 mg/L in all samples.
- BTEX and MTBE were below detection limits in all samples.
- Nitrate was detected at a concentration of 0.34 mg/L in MW-2 and 3.8 mg/L in MW-7, both below the state MCL of 45 mg/L.
- Barium was detected in MW-6 at a concentration of 56 µg/L, MW-7 at a concentration of 60 µg/L, and in MW-8 at a concentration of 170 µg/L. These levels are all below the state MCL of 1,000 µg/L.
- Arsenic was detected at a concentration of 37 µg/L in MW-2 and 4.2 µg/L in MW-8. The concentration of arsenic in MW-2 is above the state MCL of 10 µg/L and is likely due to naturally occurring arsenic found in soil and rock formations as described previously in this section.

4.2.4 Groundwater Monitoring Associated with High-Volume Hydraulic Fracturing

The groundwater monitoring wells have been sampled twice since the high-volume hydraulic fracturing was completed. Results from baseline (pre-hydraulic fracturing) groundwater sampling are compared with results of sampling the same wells after hydraulic fracturing. Since the deep wells do not have a baseline, the results of two rounds of sampling the deep wells are compared to the same two rounds of the pre-existing wells.

The Inglewood Oil Field is required to sample and analyze groundwater on a quarterly basis in compliance with CSD Section E.19. This sampling will continue irrespective of whether hydraulic fracturing operations are conducted in the future, but this study focuses on the sample rounds at the end of 2011 (pre-hydraulic fracturing) compared to the two rounds of samples collected so far in 2012 (post-hydraulic fracturing).

Comparison of Baseline to Post-Hydraulic Fracturing Operation Water Quality

The monitoring wells with sample results prior to 2012 were sampled for the same analytes after the occurrence of hydraulic fracturing in January. The water was analyzed for the following constituents: pH, TPH, benzene, toluene, ethylbenzene, total xylenes, methyl-tributyl ethylene (MTBE), total recoverable petroleum hydrocarbons (TRPH), total dissolved solids (TDS), nitrate, nitrite, metals, and biological oxygen demand (BOD_5). These chemicals include compounds in the hydraulic fracturing fluids.

Analysis of samples taken post-fracturing (April and August 2012) indicated no results above the state MCL for any constituents, with the exception of arsenic, which is likely due to naturally occurring arsenic found in soil and rock formations that was present prior to fracturing. These results are consistent with earlier, pre-hydraulic fracturing sample results from these wells.

In most cases there were either no changes in the concentrations of the analytes sampled for, or there was a decrease in concentration after hydraulic fracturing. One of the wells, MW-7, had an increase of one compound, chromium, in the samples after the hydraulic fracturing (2.7 µg/L to

3.0 µg/L, both results well below the 50 µg/L state standard). Chromium is not associated with hydraulic fracturing additives.

The following analytes showed no major changes in concentration when comparing the data that was obtained prior to and after hydraulic fracturing:

- pH
- TPH-DRO[1]
- TRPH
- TDS
- Nitrite
- Cobalt

The following analytes were below detection prior to the hydraulic fracturing, and then showed concentrations above the detection limit in January 2012, with levels returning to below detection in April 2012 and remaining below detection in August 2012. All analytes were below the state MCL.

- MW-6 and MW-7 TPH-DRO (with Silica Gel)
- MW-3 Benzene, Toluene, Ethylbenzene, Total Xylenes, and MW-8 Toluene
- MW-2 and MW-6 Zinc

The following analytes showed an instance where there was a slight concentration increase after the hydraulic fracturing:

- MW-7 Chromium showed an increase from 2.7 to 3.0 µg/L. Both results are well below the 50 µg/L state standard. Chromium is not associated with hydraulic fracturing additives.

The following analytes showed a decrease after hydraulic fracturing:

- MW-2 and MW-6 Nitrate
- MW-7 Barium
- MW-8 Arsenic
- MW-7 Copper showed below detection limit immediately after wells were installed, then had a slight increase in concentration 6 months later, before returning to below the detection limit.
- MW-8 Lead showed below detection limit immediately after wells were installed, then had a slight increase in concentration 6 months later before returning to below the detection limit.

In summary, the hydraulic fracturing did not have a detectable change to groundwater quality based on the comparison of baseline results to post-hydraulic fracturing results. Any variations are within the ranges detected over the course of the monitoring. Figure 4-5 summarizes the monitoring results. The horizontal axis lists any detected compounds. The vertical axis divides the amount detected by the drinking water standard for that compound; a value of 1 means that the detected amount equaled the drinking water standard. The horizontal line corresponding to 1 on the vertical axis divides the chart between detections that meet the drinking water standard

[1] With the exception of MW-8, which showed below the detection limit after the well was installed in February 2012 then a slight increase to .34 mg/L in April 2012, before returning to below the detection limit in August 2012.

(all compounds except arsenic) from arsenic, which has a high background in Southern California that exceeds the drinking water standard.

Comparison of New Wells to Pre-Existing Wells

In addition to the existing monitor well array prior to hydraulic fracturing, five new wells (MW-10, MW-11A, MW-11B, MW-12, MW-13) were installed at the field in order to fully investigate the occurrence and quality of groundwater from the base of fresh water (the top of the Pico Formation at approximately 500 feet below ground surface) to the shallowest occurrence of water (approximately 30 feet below ground surface).

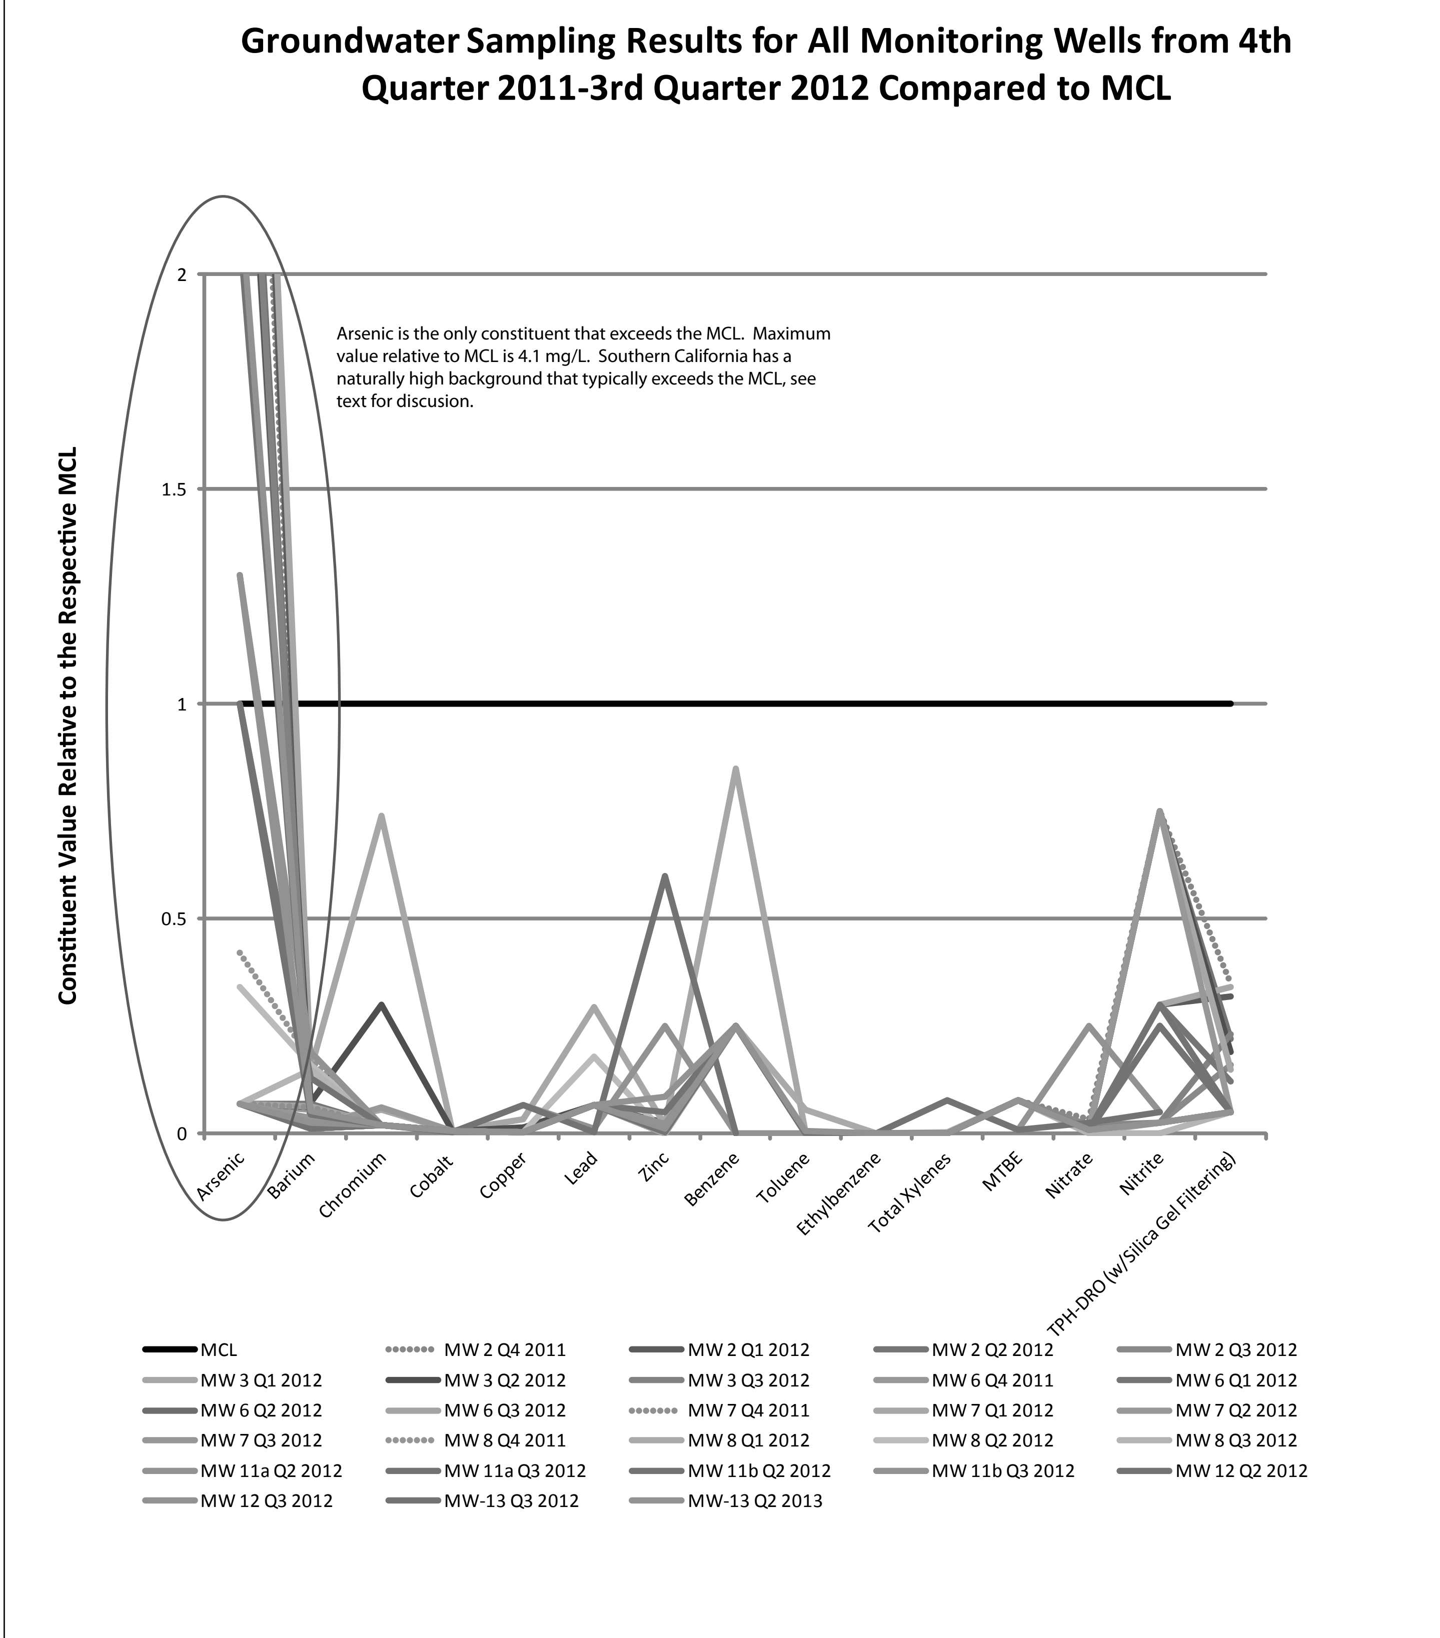
Groundwater sampled from these wells was analyzed for the following constituents: pH, TPH, benzene, toluene, ethylbenzene, total xylenes, MTBE, TRPH, TDS, nitrate, nitrite, metals, and BOD_5. A comparison of the sample results from the pre-existing wells to the new deeper wells show generally consistent results. In most cases, the results for the new deeper wells were within the ranges found at the pre-existing wells. All analytes were below the state MCL for Drinking Water Standards, with the exception of arsenic, which is likely due to naturally occurring arsenic found in soil and rock formations as described previously in this section.

The following analytes showed no major changes in concentration:

- pH
- Benzene, toluene, ethylbenzene, total xylenes, MTBE
- TRPH
- Nitrate and nitrite
- Cobalt
- Lead
- Barium
- Copper, below detection in most cases, but had similar ranges for those analytes that showed above detection.

The following analytes showed ranges that were greater in the new deep wells in comparison to pre-existing wells; all ranges were below the state MCL:

- TDS in the shallow wells showed a concentration range of 510 to 2,500 mg/L vs. 1,400 to 3,900 mg/L for deep wells.
- Zinc in the shallow wells showed a concentration range of 18 to 120 µg/L vs. 20 to 280 µg/L for deep wells.
- BOD in the shallow wells showed a concentration range of 9.91 to 43.4 mg/L vs. 11.5 to 92.6 mg/L for deep wells.



PLAINS EXPLORATION & PRODUCTION COMPANY

Cardno ENTRIX

Figure 4-5

Comparison of Baseline to Post-Hydraulic Fracturing Operation Water Quality

09 | 14 | 12

The following chemical concentrations in the new deep wells were lower than the concentration in the pre-existing wells. As a note, all ranges were below the state MCL with the exception of arsenic, which is likely due to naturally occurring arsenic found in soil and rock formations:

- Arsenic in the shallow wells showed a concentration range of up to 37 µg/L vs. 21 µg/L for deep wells.
- TPH DRO in the shallow wells showed a concentration range of up to 2.1 mg/L vs. 0.77 mg/L for deep wells.
- Chromium in the shallow wells showed a concentration rage of up to 32 mg/L vs. 12 mg/L for deep wells.

In summary, the new wells, intended to investigate the deepest zones of fresh water beneath the Baldwin Hills, had similar groundwater quality results compared to the pre-existing wells that have been sampled on a quarterly basis prior to high-volume hydraulic fracturing. Accordingly, the new wells do not show a detectable environmental effect of high-volume hydraulic fracturing. The values are within the ranges detected over the course of the monitoring (Cardno ENTRIX 2012).

4.2.5 Surface Water

No perennial or intermittent streams as defined by the USGS are present at the Inglewood Oil Field (County of Los Angeles 2008), although Ballona Creek lies to the north and west. Surface runoff occurs primarily as sheet flow across the land surface, eventually flowing into ephemeral gullies and drainage ditches to six surface water detention basins. Runoff from these basins is discharged to the Los Angeles County stormwater system near the boundaries of the field in accordance with protections, sampling and analysis, and monitoring overseen by the LARWQCB (NPDES No. CA0057827). No discharge of surface water occurred during hydraulic fracturing operations; thus, there was no effect on surface waters draining from the oil field.

4.2.6 Sources of Drinking Water to the Local Community

West Basin Water District (District) provides water to the City of Inglewood, Culver City, and the unincorporated communities of South Ladera Heights, Lennox, Athens, Howard and Ross-Sexon, View Park, Windsor Hills, and others near the Inglewood Oil Field, either itself or through sale of water to retail service provides such as California American Water Company, California Water Service Company, and Golden State Water Company, among others.

Approximately 66 percent of the District's water supply is imported from either the Colorado River or from the San Joaquin Delta in Northern California. Approximately 20 percent of the District's supply is from groundwater; however, the nearest active supply well is 1.5 miles from the Inglewood Oil Field, and most of the groundwater supply is from significantly further than 1.5 miles from the Inglewood Oil Field (USGS 2003, West Basin Municipal Water District 2011).

Among the other communities in the vicinity of the Baldwin Hills, the City of Culver City relies on imported sources of water and does not have a groundwater supply (Culver City 2010). The City of Inglewood has four groundwater supply wells in the West Basin, all of which are greater than 1.5 miles from the oil field. None of these wells serve the community around the field (City of Inglewood 2010). Golden State Water Company has 13 wells within the West Basin groundwater basin with the closest one located 1.5 miles from the Inglewood Oil Field (Golden

State Water Company 2011). California American Water Company which services the Baldwin Hills provides water purchased from West Basin Water District as well as groundwater pumped from the Central Basin (California American Water 2011b).

All of the water service providers to the communities surrounding the Baldwin Hills must test their water at least 4 times a year and report the results to the water users. The constituents that are tested include, but are not limited to, the following:

- Turbidity
- Aluminum
- Arsenic
- Fluoride
- Nitrate
- Gross Alpha Activity
- Gross Beta Activity
- Uranium
- Color
- Chloride
- Odor
- Specific Conductance
- Sulfate
- Total Dissolved Solids
- N-nitrosodimethylamine
- Alkalinity
- Calcium
- Hardness
- Magnesium
- pH
- Potassium
- Sodium
- Total Coliform Bacteria
- Bromate
- Chlorine Haloacetic acids
- TTHMs
- Copper

A review of the 2011 Annual Water Quality Reports for the local community (which includes testing in the 4th quarter following the high-volume hydraulic fracture of VIC1-330), indicate that the community receives water that meets USEPA and California drinking water standards. The continued monitoring four times per year ensures that the water supply will continue to meet these standards (California American Water 2011a, Golden State Water Company 2012). The data for 2012 has not yet been posted as of the time of this study, and is expected to be posted in January 2013.

There are no domestic or industrial water supply wells located within the active surface oil field boundary. Potable water aquifers nearest to the Baldwin Hills include the Silverado Aquifer, which is located along the north-northwest boundary of the Baldwin Hills and extends to depths between 200 and 450 feet below ground surface, and several aquifers to the east of the Field including (in descending order) the Exposition, Gage, Lynwood, Silverado, and Sunnyside aquifers that extend to depths of approximately 800 feet. These aquifers are underlain by the non-water-bearing Pico Formation (see Figure 4-3C, DWR 1961). As described in Section 4.2.1, the USGS (2003), DWR (1961) and this study have determined that because the Baldwin Hills are uplifted, the formations do not allow groundwater to flow in to or out of the Baldwin Hills; it is isolated from the remainder of the Los Angeles groundwater basin and are considered to form a complete barrier to groundwater movement. The groundwater monitoring and analysis has shown that hydraulic fracturing did not have a discernible effect on groundwater quality beneath the Baldwin Hills; the isolated nature of this groundwater further indicates that there would be no effect on the groundwater in surrounding aquifers of the Los Angeles Basin.

In summary, over much of the Baldwin Hills there is limited or no groundwater within the freshwater interval above the Pico Formation, and where groundwater does occur, it is not connected to the aquifers of the Los Angeles basin. The groundwater is not used for water supply of any type, nor is it present in sufficient quantity to provide a water supply. The local community receives most of its water from sources in northern California (the Delta) or the Colorado River. Therefore, activities associated with oil and gas development in the Baldwin Hills do not affect the community's drinking water supply. The water supplied to the local community (as well as any community in California) must be sampled on a quarterly basis, with the results reported to the community.

4.2.7 Water Supply Concerns Related to Shale Gas Development Elsewhere in the United States

National Issue

There have been several studies published in 2011 and 2012 that examine the potential effects of hydraulic fracturing and shale gas development on private water wells in their respective study areas. Specific concerns with regard to groundwater contamination include: risk of migration and contamination from fracturing fluids; and, risk of migration and contamination from gas, oil, or other compounds (e.g., arsenic, methane).

2011 Duke Study: Methane Contamination of Drinking Water

The first Duke University study was conducted in response to the widespread public concern in Pennsylvania about drinking water contamination from drilling and fracturing, and lack of scientific evidence as to whether these activities posed an actual risk. The study described itself as the first scientific review of water contamination near hydraulic fracturing operations. The study, which collected and analyzed samples from 68 drinking water wells in the Marcellus and Utica formations in Pennsylvania and New York, aimed to evaluate the potential impacts of natural gas drilling and hydraulic fracturing on shallow groundwater quality by comparing areas with active drilling and fracturing to areas that are not currently being drilled. This study found that methane contamination in private drinking wells systematically occurred in areas where hydraulic fracturing of shale gas takes place (Osborn et al. 2011).

The study also indicated that methane was detected in 85 percent of the drinking water wells across the region, regardless of gas industry operations, thus demonstrating a regional background in this area of natural gas. The concentration of methane in water collected from the drinking water wells in areas with active natural gas drilling and extraction were approximately 17 times higher on average than those further away. Average and maximum methane concentrations were found to be higher in wells located within approximately 1,000 meters (3,280 feet) of active drilling sites. Although methane gas is known to occur naturally in shallow groundwater aquifers in both of these regions, the testing determined that the gas found in the wells was consistent with methane gas that originated at depths associated with the reservoirs that were drilled. However, although the testing showed elevated methane levels in the wells, isotopic analyses conducted on the same wells did not find any indication that hydraulic fracturing fluids or saline produced water had polluted the groundwater aquifers (Osborn et al. 2011).

Critiques of the study cite the lack of baseline data. While the study finds higher methane concentrations near active wells and concludes that these increases are the result of hydraulic fracturing operations, it does not compare its data to wells sampled prior to the occurrence of hydraulic fracturing. Other criticisms have asserted that the data set is not large enough to draw any definitive conclusions, and that the results are likely to vary regionally. Furthermore, critiques point to areas without drilling where methane was detected in wells, suggesting that claims that hydraulic fracturing caused methane contamination are not scientifically supportable (Bauers 2011).

2012 Duke Study: Natural Migration of Brines

Researchers at Duke University published a second study in response to continued concerns related to reports of potential drinking water contamination related to hydraulic fracturing in Pennsylvania. The study aimed to examine hydraulic conductivity between shale gas formations and the shallower drinking water aquifers in Pennsylvania.

The study analyzed the chemical content of 426 groundwater samples collected from six counties in Northeastern Pennsylvania that did not have links to drilling activities. The study then compared the salts present in the samples to the salts present in brine water from the Marcellus Shale. For some samples, they found that the salts in the groundwater had the same chemical composition as the salts in the Marcellus Shale brine, suggesting that there are naturally occurring hydrogeological pathways in the Marcellus shale that could allow migration from the shale to shallower aquifers. The authors report that there is no link between the salinity of the samples and proximity to Marcellus Shale gas wells, stating that "it is unlikely that hydraulic fracturing for shale gas caused this salinization and that it is instead a naturally occurring phenomenon that occurs over longer timescales." The report speculates that "these areas could be at greater risk of contamination from shale gas development because of a preexisting network of cross-formational pathways that has enhanced hydraulic connectivity to deeper geological formations" (Warner et al. 2012).

2011 Pennsylvania Methane Study

Cabot Oil and Gas Corporation (Cabot) conducted baseline "pre-drill" groundwater sampling and analysis throughout Susquehanna County, PA for various water quality parameters, including dissolved gases and other water quality parameters related to drinking water standards. The baseline analysis was performed in advance of proposed drilling in accordance with Pennsylvania regulations or anticipated regulations. The study concluded that (1) there is consistent evidence of elevated methane in shallow groundwater, (2) concentrations of methane seem to correlate with surface topography (i.e. more methane was found in wells that were in lowland valleys than on hilltops), (3) there was no relationship between methane concentrations in non-productions areas versus historical gas production areas (i.e. higher methane concentrations were not related to gas well drilling) (Molofsky et al. 2011).

In addition, a smaller subset of wells was sampled to conduct an isotope analysis, which helps distinguish between sources of natural gas. This portion of the study was initiated by the Pennsylvania Department of Environmental Protection (DEP) and Cabot. The study concluded that the methane is naturally occurring, unrelated to gas drilling, and not from the shale gas-producing Marcellus shale (Molofsky et al. 2011).

Finally, the report criticized the 2011 Duke study of methane contamination, arguing against the conclusion by the Duke researchers that the thermogenic methane identified in their water samples was consistent with the Marcellus shale. Instead, the isotopic fingerprints of the Duke samples, and other hydrogeological evidence, suggested that the methane found may have been from shallower sources rather than the deeper Marcellus formation and are not related to hydraulic fracturing activities (Molofsky et al. 2011).

2012 Dimock Study

Dimock, Pennsylvania was portrayed in the 2010 movie "Gasland," and included interviews with residents who feared their water was contaminated by natural gas drilling. In early January 2012, USEPA responded to complaints of drinking water quality in Dimock. Residents complained of cloudy, foul smelling water since 2009 after Cabot Oil & Gas Corporation began hydraulic fracturing operations to extract natural gas from reserves near the Marcellus Shale. The USEPA sampled waters from 64 homes in Dimock and concluded the set of samples did not indicate levels of contaminants that would foster further action by USEPA. The USEPA released the final data set on May 11, 2012, of 59 homes. Since USEPA sampling began, contaminants were found in some wells, but USEPA stated the levels of contamination in the wells were considered safe and did not pose a threat to human health. The USEPA also resampled four wells where previous data showed contamination. At one of those wells, USEPA found elevated levels of manganese (a naturally-occurring substance) in untreated well water, but the two homes serviced by that well had water treatment systems the reduced the level of manganese to sage levels. None of the other wells contained levels of contaminants that would require action. The USEPA did find one well containing hits for methane, but USEPA declined to verify the source of pollution, as methane is documented to be a naturally occurring gas in the surrounding area. USEPA has released all sampling results to residents in Dimock and has no further plans to conduct additional sampling (USEPA 2012b). Representatives for Cabot have publicly contended the contaminants found in some of the wells are likely from background levels or other activities unrelated to hydraulic fracturing activities (Gardner 2012).

2008 Bainbridge Township, Ohio Study

In December 2007, the Ohio Department of Natural Resource, Division of Mineral Resources Management (DMRM) initiated an investigation after there was an explosion at a house. Responders quickly recognized that natural gas was entering homes through water wells; either unvented water wells located in basements, abandoned and unplugged water wells in basements, or wells with indoor well pumps. The Ohio Valley Energy Systems Corp, which had recently completed a nearby oil and gas well, English No. 1, assumed responsibility for the natural gas contamination and resulting explosion.

Further investigation by DMRM concluded that three factors were likely to have contributed to the gas invasion of the shallow aquifers: (1) inadequate cementing of the production casing around that well, (2) proceeding with hydraulic fracturing without addressing the casing deficiencies, and (3) the month long period after hydraulic fracturing during which the annular space between the surface and the production casing was shut in, confining high-pressure gas in the restricted space. The over-pressurized condition cause the migration of natural gas from the well annulus into the natural fractures in the bedrock located below the base of the cemented surface casing. It is believed that the natural gas traveled vertically through the fractures into overlying aquifers and into local water wells (ODNR 2008).

2011 Pavilion Study

The USEPA released a draft report in December 2011 examining the potential of a link between groundwater contamination in Pavillion, Wyoming and local hydraulic fracturing operations. The USEPA's draft report found that groundwater samples taken from two deep test wells contained benzene and at least 10 other compounds known to be used in hydraulic fracturing fluid. The draft report theorized that the fluids seeped up from improperly sealed gas wells. Several months after the USEPA issued its draft report, reviews by both critics and proponents of hydraulic fracturing provided additional expert opinion on the draft. The critical reviews contend that the data collection processes were faulty and accordingly no valid conclusions could be drawn from USEPA's study. Notable criticisms of USEPA's draft report are as follows:

- The pollution detected by USEPA that was linked to hydraulic fracturing was found in deep water monitoring wells, not the shallower monitoring wells that are more comparable to the drinking water supply wells. The link between pollution in deep monitoring wells and shallow water wells is uncertain.
- Contamination in shallow monitoring wells was strongly linked to contamination from waste disposal pits, rather than migration of deeper sources of contamination.
- USEPA's monitoring wells were drilled directly into gas bearing zones; approximately 200 to 275 meters bgs (656 to 902 feet); therefore, reviewers suggest that it is not unusual that elevated levels of methane, hydrocarbons, and benzene were detected (Petroleum Association of Wyoming 2011). Along the same line, methane is naturally occurring near the surface of the Wind River Formation and many residents recall the presence of methane in well water prior to the occurrence of energy production activities in Pavillion (EnCana Oil & Gas Inc. 2009)
- To the extent that drilling chemicals were detected in deep monitoring wells, USEPA acknowledges the possibility of poor wellbore design and integrity, resulting in vertical and lateral movement of contaminants to surrounding groundwater. The study stated that only two gas production wells in the Wind River Formation have surface casings that extend below the depth of domestic wells. Shallow surface casings in conjunction with little or no cement or sporadic bonding of production casings can facilitate upward gas and fluid migration. In addition, poorly sealed domestic water wells are a known concern in Pavillion and an improper seal can create a migration pathway for gas and fluids into domestic wells.

Another subsequent study of USEPA's draft report commissioned by NRDC, the Wyoming Outdoor Council, Sierra Club and the Oil and Gas Accountability Project largely supported the agency's findings. The report, by Nevada-based hydrologic consultant Tom Myers, was careful to state that more testing is needed, though he said USEPA's preliminary conclusion that hydraulic fracturing had polluted the area's groundwater was sound. Myers said hydraulic fracturing fluids could move up a number of ways in the region — from compromised gas wells, past thin layers of sandstone, or through out-of-formation rock fissures. The natural gas wells in the area, he stated, often lack metal casings or cement, allowing natural gas and fluids to travel up into groundwater. The USEPA, Myers said, also found a number of compounds during testing that aren't found naturally, including isopropanol and diethylene glycol. "*The [US]EPA is correct in its conclusion that there is no acceptable alternative explanation and the most likely source of these contaminants is fracking fluid*," Myers wrote. Myers also disputed that cement and drilling mud contaminated water samples, stating that neither could raise the pH level to the range found — between 11.2 and 12.0. Myers recommended that USEPA should continue collecting data, including from new and deeper monitoring wells, to try to replicate and verify its findings (Myers 2012b).

While USEPA's draft report identified potential links between hydraulic fracturing and contamination in the Pavillion water wells, the report remains a draft and USEPA is continuing its review. At a hearing before the House Subcommittee on Energy and Environment, in February 2012, USEPA Region 8 administrator Jim Martin stated the following in response to mischaracterizations of the draft report: "*We make clear that the causal link [of water contamination] to hydraulic fracturing has not been demonstrated conclusively,*" adding that USEPA's draft report "*should not be assumed to apply to fracturing in other geologic settings*" (Martin 2012).

In March 2012, USEPA agreed that additional testing was needed in the Pavillion before a final report could be issued. The USEPA in conjunction with the State of Wyoming is currently conducting further sampling of water wells in the area. In a joint statement, USEPA Administrator Lisa Jackson, Wyoming Governor Matt Mead, and the Northern Arapaho and Eastern Shoshone Tribes said: "*The USEPA, the State of Wyoming, and the Tribes recognize that further sampling of the deep monitoring wells drilled for the Agency's groundwater study is important to clarify questions about the initial monitoring results*" (USEPA 2012c).

2012 Myers Model Study of the Marcellus Shale

Tom Myers, a Nevada-based hydrologic consultant, published a study in spring 2012, which uses a model to characterize the risks associated with contaminants travelling through natural vertical pathways from fractured shale to shallower drinking water aquifers. The study analyzes two potential hydrogeological pathways – advective transport through bedrock and preferential flow through fractures. Myers assigned various factors to model contaminant flow including groundwater flow, conductivity of the substrate, and changes in conductivity of the substrates based on regional shale hydrogeology, high density fracturing, and faulting; and high-volume injection.

The study acknowledges that the model simplifies a complex underground system, but the results suggest that a combination of the factors described above could decrease transport times from the Marcellus Shale to shallower aquifers from geological times scales to only tens of years, and that preferential flow through natural and hydraulic fracturing induced fractures could further reduce transport times to as little as just a few years (Myers 2012a). However, the study is a modeling exercise that is theoretical in nature and specific to contaminant transport in the Marcellus shale. Following publication of this study, Syracuse University hydrogeology Dr. Don Siegel released a critique of its assumptions and conclusions. Myers developed "an implausible model" that produced "completely wrong results," Siegel wrote. According to Siegel, the Myers model is based on mistaken assumptions about the kind of rock that lies above the Marcellus Shale, the way groundwater moves through sedimentary basins, and the length of the fissures created by hydraulic fracturing (Siegel 2012).

Relevance to Inglewood Oil Field

Of the studies noted above, USEPA's ongoing study of Pavillion, Wyoming has received the most media attention nationally and continues to be the subject of varying interpretations. In evaluating the draft report it is important to note that hydraulic fracturing operations and geology at the Pavillion Natural Gas Field are distinctly different from those under consideration at the Inglewood Oil Field. For comparison purposes, the drinking water aquifer sits directly atop the production zone at the Pavillion Natural Gas Field and high-volume hydraulic fracturing is used to extract gas from as shallow as 372 meters (1,220 feet) bgs, in close range to the domestic water wells that are screened as deep as 244 meters (800 feet) bgs. Consequently, there is a negligible separation between the hydraulic fracturing operations and groundwater. In contrast, the high-volume hydraulic fracturing jobs PXP conducted occurred over 2,500 meters (8,202 feet) bgs to retrieve shale oil, while the perched water formation is located approximately 120 meters (393 feet) bgs, a separation of over one mile.

Furthermore, as noted in Section 4.2.1, there is no groundwater that can sustain a water supply beneath the Baldwin Hills. The supply to the local area is primarily from sources outside of Los Angeles, whereas in Pavillion groundwater is integral to the community's water supply. The water supply in Los Angeles is subject to quarterly testing and public reporting. Due to uplift in the Baldwin Hills and associated folding and faulting, water tables are sporadic and shallow throughout the production zone on the oil field itself and there is no sustainable groundwater resources located within perimeters of the oil field. In groundwater models of freshwater flow in the Los Angeles Basin aquifer systems (USGS 2003), the Baldwin Hills is modeled as a "no flow" zone; that is, since the sediments beneath the Baldwin Hills are disconnected from the regional aquifers, groundwater flow is discontinuous across the Baldwin Hills (see Figures 4-1 and 4-3C).

4.3 Containment of Hydraulic Fractures to the Desired Zone

A significant amount of discussion has taken place about the vertical growth of hydraulic fractures, particularly in gas shales, tight sands, and shallow reservoirs in regards to whether these hydraulic fractures can create pathways for the fracturing fluids or hydrocarbons to migrate upward and contaminate groundwater supplies.

The vertical extent that a created fracture can propagate is controlled by the upper confining zone or formation, and the volume, rate, and pressure of the fluid that is pumped. The confining zone will limit the vertical growth of a fracture because it either possesses sufficient strength or elasticity to contain the pressure of the injected fluids or an insufficient volume of fluid has been pumped. This is important to note because the greater the distance between the fractured formation and the groundwater or water-bearing zones, the more likely it is that multiple formations will possess the qualities necessary to impede the growth of hydraulic fractures.

Microseismic and micro-deformation mapping has been conducted on thousands of hydraulic fracturing jobs nationwide (Fisher and Warpinski 2011) and indicate that the growth of fractures vertically is relatively well-contained. Figure 4-6 is taken from Fisher and Warpinski (2011) and depicts the depth and vertical height affected by hydraulic fracture jobs conducted in the Barnett Shale of Texas (inclined multi-colored lines), compared to the depth of water (blue horizontal line at top of chart). This relationship was validated during observations of microseismic results at the Inglewood Oil Field (see Figure 3-11).

Fracture lengths of a typical hydraulic fracture operation can sometimes exceed 1,000 feet when contained within a relatively homogenous layer, but fracture heights, because of the layered geological environment and other physical parameters are typically much smaller, usually measured in ten-foot or hundred-foot intervals (Warpinski et al. 2011).

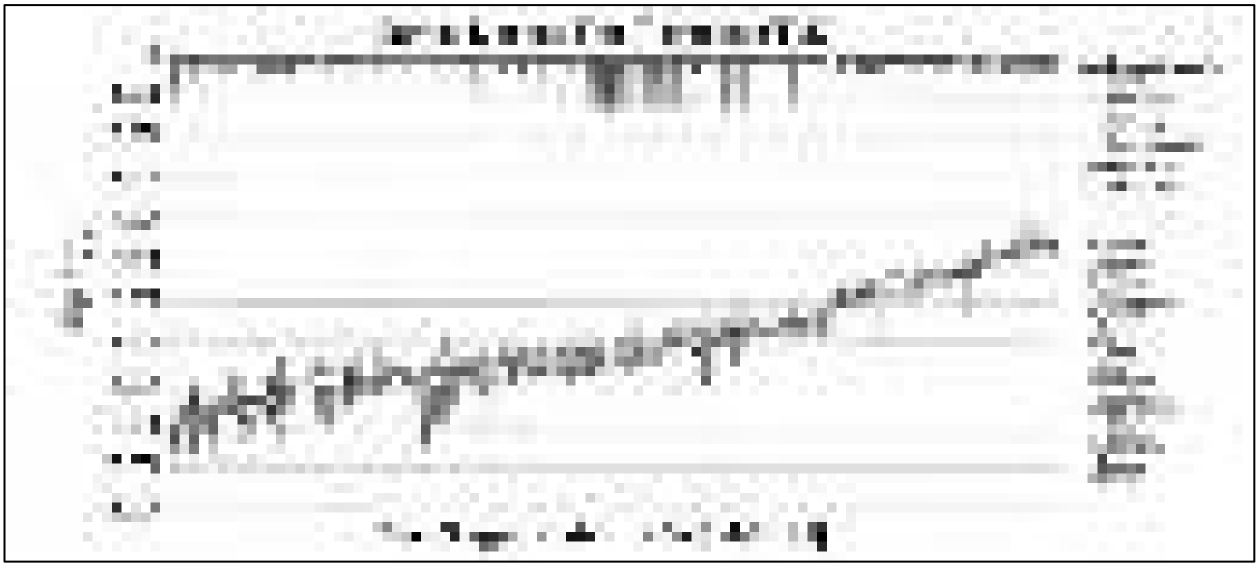


Figure 4-6 Barnett Mapped Frac Treatments/TVD

Similar results have been found by Fisher and Warpinski (2011) in their study of the real fracture growth data mapped during thousands of fracturing treatments in tight sands and shales. They supplemented their data with an in-depth discussion of fracture-growth limited mechanisms augmented by mine back tests and other studies. They also note that fractures and fracture networks tend to be complex; the complexity tends to shorten the network as the energy dissipates.

At the Inglewood Oil Field, the measured distribution of fractures caused by the hydraulic fracture completions at VIC1-330 and VIC1-635 were less than 1,000 feet horizontally from the well, and were almost entirely within the target zone with limited vertical fracture growth (less than 250 feet). Fractures grew either horizontally from the well or at angles less than 20 degrees depending on the local dip angle of the geological formations. The high-volume hydraulic fracture completions were conducted between 8,000 and 9,000 feet below the ground surface and microseismic analysis of the operations indicate that fractures did not form at shallower depths than approximately 8,000 feet below the ground surface (see Section 3.2.2). By comparison, the deepest groundwater encountered that had relatively low salinity was at a depth of 500 feet below the ground surface, corresponding to the base of fresh water beneath the Inglewood Oil Field.

During hydraulic fracturing, the pressure applied to the rock by the water/sand/additive mixture exceeds the fracture strength of the rock, and portions of the rock fractures. As measured by the microseismic data in Section 3.2.2, the induced fractures follow the bedding planes at approximately 20-degree angles. Halliburton (2012) also models the distribution of proppant applied to the fractures in the target zone. Based on this model, all of the proppant stayed within the target zone of the Nodular Shale. The minor fractures indicated by the microseismic data that occurred outside the Nodular Shale were in the underlying, oil-bearing Sentous Formation. These fractures did not receive proppant, and as such they sealed based on the overburden pressure.

4.4 Well Integrity

The proper construction of active oil wells and the condition of idle, plugged, and abandoned wells ensures that protections to fresh water-bearing zones are intact. As described in Section 4.2.1, the water-bearing zones above the base of fresh water beneath the Baldwin Hills do not have sufficient yield to support a water supply, and the local community receives their water supply primarily from sources that are distant from the Los Angeles Basin. However, well integrity was still investigated as part of this study at the scale of the wells subject to hydraulic fracturing, as well as at the scale of the entire oil field.

The term "well integrity" refers to the containment of hydrocarbons within a well from the producing formation all the way to the surface. The rock formations that lie between the hydrocarbon producing formations and the groundwater have isolated the groundwater over millions of years. The well construction process uses a combination of steel casing, cement sheaths, and other mechanical isolation devices to prevent the migration and transport of fluids between these subsurface layers. These construction and engineering controls provide multiple layers of groundwater protection throughout the life of the well. The wells within injection zones at Inglewood Oil Field are constructed in accordance with API guidelines, ensuring that all Federal and State regulations are met and groundwater is protected (API 2009).DOGGR well integrity regulations require a facility to keep records of the size, weight, grade, and condition of all casings and any equipment attached to the casing, pursuant to California Code of Regulations (CCR), Chapter 4, Article 3, §1724.

To supplement more broadly applicable statutory and regulatory requirements, the State Oil and Gas Supervisor may establish Field Rules for any oil and gas pool or zone in a field when sufficient geologic and engineering data are available from previous drilling operations, pursuant to CCR Title 14, Division 2, Chapter 4, § 1722 (k). Each Field Rule is specific to a field, and in many cases, specific to Areas and Zones or Pools within a field. DOGGR has established Field Rules for those fields where geologic and engineering information is available to accurately describe subsurface conditions. These Field Rules identify downhole conditions and well construction information that oil and gas operators should consider when drilling and completing onshore oil and gas wells. Field Rules have been established for the Inglewood Oil Field in two areas – west of the Newport-Inglewood fault and east of the Newport-Inglewood fault (DOGGR 2007).

With regard to abandoned wells, Term 10 of the Settlement Agreement requires PXP to install a 150-foot cement plug at the surface of the well, which exceeds DOGGR standards 6-fold (DOGGR requires only installation of a 25-foot plug). This supplemental requirement provides enhanced protection of any surface resources.

Based on review of records maintained by PXP, the active wells at the Inglewood Oil Field meet modern well construction and casing standards, which protect against releases to the environment, pursuant to State Regulations and Field Rules. Idle wells are tested annually and reports are submitted to DOGGR, in accordance with CCR, Chapter 4, Article 3, §1723.9.

Prior to commencing injection operations, each injection well must pass pressure tests to confirm the integrity of the casing. A Mechanical Integrity Test (MIT) must be performed on all injection wells to verify that injected fluid is confined to the approved zone(s). California regulations mandate that "data shall be maintained to show performance of the project and to establish that no damage to health, life, property, or natural resources is occurring by reason of the project. Injection shall be stopped if there is evidence of such damage, or loss of hydrocarbons. All project data shall be available for periodic inspection by Division personnel" (CCR 1724.10 (h)).

Active injection wells at the Inglewood Oil Field are surveyed annually (and pressure tested after each well work) per DOGGR requirements pursuant to CCR, Chapter 4, Article 3, §1724.10(j)3. In addition, PXP monitors active injection wells weekly for injection rates and pressures (what also indicates the integrity of the wellbore and confinement of fluids to the injection zone) and reports to DOGGR on a monthly basis, pursuant to CCR Chapter 4, Article 3, §1724.10(c).

PXP also measures the pressure of the annulus after they idle production or injection at a well and reports this data to DOGGR, as required by Chapter 4, Article 3, §1724.1. Each idle well (production or injection) is subject to DOGGR Idle Wells Testing program according to California Code of Regulations. The testing is done in two parts. Initially it is determined if wellbore fluids (i.e. formation fluids) are above or below the designated base of fresh water. If the fluids are below, then no further testing is required until the next testing cycle. If the fluid in the wellbore is at or above the designated base of fresh water, thus creating a potential for migrating into the designated fresh water formation, then the next part of testing takes place. The integrity of the casing (steel pipe and cement) at this time is evaluated by one of the following methods: running static temperature and spinner surveys, pressure testing the casing, or a nitrogen fluid level depression tests. Both fluid level in the wellbore location determination, and subsequent (if needed) integrity testing are subject to DOGGR witnessing. Any problems determined during an annual Idle Wells Testing are addressed by either repairing or abandoning the well.

Additional well integrity monitoring is provided through PXP's active production well monitoring. In accordance with Public Resources Code Division 3, Article 1, Section 3227, PXP provides monthly production reports that indicate the amount of oil/gas produced from each well, composition of produced water (e.g., salinity), amount of injection fluid, and any other information requested by the Division. While reports are only produced on a monthly basis, PXP monitors active production wells daily for oil and water production rates and pump behavior. Although PXP reports that this is not intended to be a well integrity monitoring program, PXP notes that this monitoring allows them to quickly identify, isolate, and correct any potential problems.

Well integrity is further monitored prior to and during each stage of the hydraulic fracturing operations. The well casing of the subject well is tested to ensure integrity prior to injection of fracturing fluids (Halliburton 2012). This is accomplished by pressure testing the well up to 70 percent of the strength of the casing. Offset wells, production wells, and injection wells are also tested for proper zonal isolation (i.e., annular cement) prior to any hydraulic fracturing operations. Halliburton's post-job reports for hydraulic fracturing operations indicate that all measurements of well integrity conducted for this study show that there were no losses in pressure. Furthermore, as shown in the microseismic results (see Section 3.6), none of the fractures encroach on nearby wells. The applied energy of the hydraulic fracturing rapidly decreases away from the completed well, and as such, surrounding wells would not be adversely affected by the operation.

Prior to issuing a permit for any new injection well, or converting an existing production well to an injection well, DOGGR conducts an Area of Review (AOR) as required by the Underground

Injection Control Program (see Section 5.4.1 for greater discussion of this program). The AOR investigates the condition of every well within one-quarter mile radius of the proposed new injection well. The AOR includes all active, idle, plugged, and abandoned wells and determines the casing and cement intervals. The purpose of the review is to ensure that all wells in the area are completed or abandoned in such a way as to contain injected fluids within the zones that are approved for injection and isolate freshwater zones from the injected fluids.

4.5 Slope Stability, Subsidence, Ground Movement, Seismicity

4.5.1 Slope Stability

Slope stability is a primary geologic concern in the Baldwin Hills. The California Department of Conservation, Division of Mines and Geology, has previously reported on slope stability and geological issues of the Baldwin Hills (CDMG 1982). The purpose of the program was to identify the nature and cause of slope failures across the state, and to provide the information to local governments within whose jurisdictions the failures occurred so that they can plan action to mitigate the problems. The 1982 study was solely focused on the Baldwin Hills and included investigations starting in 1969. The study included detailed mapping of areas with slope instability in the Baldwin Hills, investigation into the causes of the failures, and recommended mitigation.

The study notes widespread damage from slope failures caused by rains in 1969, 1978, and 1980, and less widespread damage in other years. The study concludes that there are two reasons why slope stability is a substantial problem in the Baldwin Hills:

- The terrain that has been developed consists mostly of steep natural slopes underlain by soft sedimentary rocks. This combination will lead to slope instabilities. The result is that graded and natural slopes with slope angles up to 45 degrees or steeper occur without proper drainage devices and retaining walls.
- Much of the Baldwin Hills were developed prior to the enactment of strict grading codes by local government, and as such lack adequate protections. These protections include lower slope angles, requirements for compaction of fills, and structural requirements.

The study notes that the Inglewood Formation is susceptible to slope instability because the surficial soils developed on the formation are clay-rich, while the Culver Sands are particularly susceptible to erosion. The study also notes the presence of ancient, apparently large, landslides. Most of the mapped slope failures damaged more than one property.

The study also notes that in the three most densely developed portions of the Baldwin Hills, approximately 21 percent of the properties have been damaged by rainfall-induced slope failures. As described in the CDMG report, approximately 93 percent of the residential properties have the potential for at least minor damage from slopes failure during or after large storms in the future (CDMG 1982).

Monitoring for vibration and subsidence did not detect a change due to hydraulic fracturing. As such, hydraulic fracturing would not affect surface slope stability.

4.5.2 Subsidence

Subsidence is another geological concern in the Baldwin Hills. As described in the Baldwin Hills CSD EIR, prior to 1971 the maximum cumulative subsidence of any of the areas along the Newport-Inglewood fault zone was centered over the Inglewood Oil Field, where 67,000 acre-feet of oil, water, and sand had been withdrawn from shallow production horizons. Water injection into the shallow production horizons began in 1957 and as of 1971, effectively eliminated subsidence associated with oil and gas production (County of Los Angeles 2008). The Inglewood Oil Field has an ongoing program of annual subsidence monitoring that is reported in the framework of the CSD. To date, although minor subsidence has been detected, no changes in ground surface are attributed to oil and gas production activities (Fugro Consultants 2012). Measurements of subsidence before and after high-volume hydraulic fracturing did not detect a measurable change.

Subsidence has also been theorized to be one factor associated with the failure of the former 20-acre Baldwin Hills Reservoir in 1963. The north embankment of the Baldwin Hills Reservoir failed causing property damage and loss of life. One of the leading theories for the reservoir's failure is that it was undermined by seepage along a fault which was known prior to construction of the reservoir, and which is related to the active Inglewood fault system. The dam's failure has been attributed to different causes: oil-field subsidence (Castle and Yerkes 1969); tectonic faulting (Hudson and Scott 1965); water injection in the nearby oil field (Hamilton and Meehan 1971); and construction related factors (Wright 1987). An innovative design was intended to prevent tectonic subsidence and water injection from jeopardizing the reservoir. In a study of the reservoir failure, Wright (1987b) presents records that document that a field change to the design during construction undermined most of the features intended to accommodate the original design protections. As such, it has been theorized that the design changes also played a role in the dam's eventual collapse (Casagrande et al. 1972).

4.5.3 Monitoring of Ground Movement

The CSD requires an annual ground movement survey at the Inglewood Oil Field. Surveying for both vertical and horizontal ground movement is accomplished using satellite-based Global Positioning System (GPS) technology. Accumulated subsidence or uplift is measured using repeat pass Differentially Interferometric Synthetic Aperture Radar (inSAR) technology. The data are then evaluated to determine whether Inglewood Oil Field operations are related to any detected ground motions or subsidence. According to the ground movement survey covering the 2011/2012 monitoring period there is no correlation between measured elevation changes and field activities (Fugro Consultants 2012, Fugro NPA 2012, Psomas 2012). For this period, inSAR imagery was collected on January 15, 2012, and elevation data at each survey location was collected in February 2012. Note that hydraulic fracturing operations occurred in September 2011 and January 5-6, 2012, and were captured in this survey period. Fugro Consultants compiled a list of the Inglewood Oil Field production and injection wells within a 1,000-foot radius of each survey location and PXP supplied the annual production and injection volumes from all active wells across the field. The database included 456 production wells and 213 waterflood injection wells. Some stations recorded settlement where the injected fluid exceeded the produced volume, some monuments recorded elevation gains where the produced water volume exceeded injected volume, and others showed changes where no active wells are within a 1,000-foot radius. The majority of movements is less than the 0.05 foot measurement threshold and, therefore, at or less than the limit that can be detected (Fugro Consultants 2012, Fugro NPA 2012, Psomas 2012). None of the ground movement was attributable to high-volume hydraulic fracturing.

4.5.4 Vibration and Seismicity During Hydraulic Fracturing

PXP retained Matheson Mining Consultants, Inc. to conduct vibration and ground surface monitoring during the high-volume hydraulic fracturing operations at the VIC1-330 well on September 15 and 16; the VIC1-635 well on January 5 and 6; and at TVIC-221 and TVIC-3254 high-rate gravel pack operations on January 7, 9, 10, and 11.

Vibration records for the VIC1-330 and VIC1-635 wells were collected using four and eight seismographs, respectively, installed at different locations in relation to the high-volume hydraulic fracture operations. The TVIC-221 and TVIC-3254 wells are directly adjacent to one another; therefore, the same seismographs were used to monitor the high-rate gravel pack operations at these wells. Vibration records for these wells were collected using eight seismographs installed at different locations between 218 and 1,000 feet from the wells. Seismographs were placed near the subject wells. All of the seismographs were put in place early enough to allow the collection of 24 hours of baseline data prior to recording vibrations of the hydraulic fracturing operation and high-rate gravel pack operation. Each device was set to the lowest trigger level possible (0.005 in/sec) in order to detect all vibrations.

Seismic events (imperceptible to humans and below the limit which could cause any structural damage) caused by vehicles and other oil field activities at the surface were noted during the baseline period conducted prior to each hydraulic fracture event. These events were then compared to events recorded during both the pumping test and hydraulic fracturing time periods. Table 4-1 displays the highest level vibration recorded during the baseline period and each hydraulic fracture operation. Based on this comparison, Matheson Mining concluded that no seismic activity was produced by any of the high-volume hydraulic fracturing or high-rate gravel pack operations for which seismicity was recorded (Matheson Mining 2012a, b, c).

Table 4-1 Comparison of Vibration Levels Recorded During Baseline Monitoring and Hydraulic Fracturing Operations

Subject Well	Maximum Vibration Record (in/sec)	
	Baseline Monitoring	During Hydraulic Fracturing Operation
VIC1-330	0.0062	0.0119
VIC1-635	0.0075	0.0162
TVIC-221 and 3254	0.025	0.0194

4.5.5 Induced Seismicity and Additional Seismic Monitoring During Hydraulic Fracturing

Microseismicity was measured directly during and after the hydraulic fracturing. However, the public has expressed concern related to induced seismicity along the Newport-Inglewood Fault potentially resulting from hydraulic fracturing or water injection. This section addresses this topic using data from the Newport-Inglewood Fault across southern California, and measurements made at the field as part of the California Institute of Technology's monitoring program for the region.

The Newport-Inglewood Fault is discernible at the surface by the chain of low hills extending from Culver City (the Baldwin Hills) to Signal Hill. According to the Southern California Earthquake Center (Petersen and Wesnousky 1994), the fault is not marked by a sharp zone, but instead is marked by a broad zone of seismicity centered on the fault trace. Faults of the Newport-Inglewood zone of deformation are predominantly defined in the subsurface from oil-well data and groundwater data. Petersen and Wesnousky (1994) evaluated all seismic events greater than Magnitude 2 in the Newport-Inglewood Fault zone, and determined that most epicenters are located at depths between 3.5 miles and 12 miles below ground surface (Petersen and Wesnousky 1994, Hauksson 1987).

In comparison, the waterflood operation at the Inglewood Oil Field extends to depths of up to 3,000 feet (0.57 mile) and the deepest hydraulic fracturing occurs at less than 10,000 feet depth (1.9 miles). The very small, not discernible, microseismic effects of fracturing are located 1.6 miles above the zone where most epicenters are located, and the waterflood is 2.9 miles above this zone. Based on distHance alone, there would be little or no relationship between the location of Inglewood Oil Field activities and the much deeper epicenters of most earthquakes along the Newport-Inglewood fault zone.

In addition to the seismic monitoring conducted by Matheson Mining Consultants, Inc., seismic data collected by the permanently installed California Institute of Technology (Cal-Tech) accelerometer (seismometer) at the CI.BHP Baldwin Hills location (adjacent to the PXP field office at 5640 South Fairfax Avenue, approximately 6,300 feet southeast of VIC1-635 and 7,806 feet southeast of VIC1-330, and 9,620 feet from the TVIC wells) was reviewed for the time periods before and during the hydraulic fracturing and high-rate gravel pack operations. The data collected from the seismograph during the VIC1-635 operation showed two minor spikes during the time period reviewed (the largest of which measured 0.0012 inch per second). Analysis of the data by Dr. Hauksson, a Senior Research Associate in Geophysics with the Cal-Tech Seismological Laboratory indicates that no seismic events above background levels (0.0003 to 0.0006 inch per second) were recorded. These spikes tend to occur randomly every two or three hours and could be related to local traffic. According to Dr. Hauksson, these spikes are common in urban areas and not considered significant (Matheson Mining Consultants, Inc. 2012a). No data above background levels was recorded on the Cal-Tech seismograph during the VIC1-330 operation (Matheson Mining Consultants, Inc. 2012b). The data collected from the seismograph during the TVIC high-rate gravel pack operations showed some spikes during the time period reviewed but no significant signals above the background levels. As with the VIC1-635 operation, analysis of the data by Dr. Hauksson indicates that the noise recorded on the seismograph during the time period of the hydraulic fracturing operation, even the spikes, did not exceed background levels (Matheson Mining Consultants, Inc. 2012a).

The utilization of these data is relevant in addressing public concerns about the potential for ground movement triggered through induced seismicity as a result of hydraulic fracturing and high-rate gravel pack operations at the Inglewood Oil Field. Based on an analysis of the data, all tests indicate that the hydraulic fracturing analyzed in this study did not induce seismic activity. Any microseismicity as a result of the hydraulic fracturing was imperceptible at the surface. In addition, any effects of oil field operations are much shallower than the zones typically associated with earthquake epicenters along the Newport-Inglewood Fault zone. The Baldwin Hills CSD includes provisions that address the effects of earthquakes on the field. These include construction provisions, and provisions to cease operations after large earthquakes and conduct inspections. For example, the Magnitude 6.4 Coalinga earthquake of 1983, in the San Joaquin Valley of California, caused damage to some oilfield facilities. Most of the damage was to surface facilities, with very minor subsurface damage. Fourteen of 1,725 active wells had some damage (Hughes et al. 1990). This event led to enhanced safety measures. The Baldwin Hills CSD requires an accelerometer on the field for purposes of monitoring seismic activity and triggering inspections.

4.5.6 Potential for Induced Seismicity at Other Areas in the United States

National Issue

Several earthquakes in Mahoning County, Ohio (an area that is not historically seismically active) prompted Ohio's Department of Natural Resources to shut down five deep underground injection wells in January 2012, due to concerns that wastewater injected into the wells under pressure triggered the earthquakes. Similarly, a 5.6-Magnitude earthquake shook Oklahoma in November 2011, following a series of smaller quakes over the preceding months that may also have been attributed to wastewater injection.

All agencies that have reviewed the question have determined that hydraulic fracturing itself is not the cause and is likely not capable of producing an earthquake event of any notable size. Seismologists at the U.S. Geologic Survey have found that hydraulic fracturing "itself probably does not put enough energy into the ground to trigger an earthquake" (USGS 2012). Review of the source studies for the articles found that many point to energy-related activities other than hydraulic fracturing (e.g., injection for waste disposal) as the source of induced seismicity.

As recently as June 2012, the National Research Council, a division of the National Academies of Science, released a report titled *Induced Seismicity Potential in Energy Technologies.* The report found that only one felt event in England had been confirmed and attributed to hydraulic fracturing globally. This case, caused by Cuadrilla in England in 2011, recorded two earthquakes (one Magnitude 2.3 and one Magnitude 1.5) that Cuadrilla believes was due to hydraulic fracturing. These are below a level that would be felt. The cause was thought to be injection of large volumes of sand and proppant.

Of the 35,000 shale gas wells that had been hydraulically fractured, only one case was suspected, but not confirmed, to be attributed to hydraulic fracturing connected to shale gas development. Two other cases connected to conventional oil and gas development were associated with, but never confirmed to stem from, the application of hydraulic fracturing technologies. The report found that, "the very low number of felt events relative to the large number of hydraulically fractured wells for shale gas is likely due to the short duration of injection of fluids and the limited fluid volumes in a small spatial area" (NRC 2012).

Seismic activity as a result of energy-related activities is not a new phenomenon. According to the USDOE Lawrence Berkeley National Laboratory, energy-related activities have been linked to isolated events of induced seismicity since the 1930s, which marks the start of large-scale fluid extraction (USDOE 2012). USDOE has found that hydraulic fracturing is known to cause slight tremors when fluid is injected into the ground under high pressure, but these are on the order of Magnitude -3 and -4 and are practically imperceptible.

Most of the USDOE research conducted to date however has pointed to the injection of fluids into deep wells for waste disposal as a cause of induced seismicity, as well as the use of reservoirs for water supplies, carbon sequestration, and geothermal energy operation. Injection into deep wells could cause seismic events capable of being felt if fluids migrate into neighboring rock formations. The deep, old rocks that surround injection wells have many faults that have reached equilibrium over hundreds of millions of years, but migrating fluid due to wastewater injection could disrupt this equilibrium and trigger shaking (de Pater and Baisch 2011).

Similarly, USGS studies have indicated that hydraulic fracturing did not cause increased seismicity in the midcontinent United States. As part of an effort to understand the potential impacts from U.S. energy production, the USGS has been investigating the recent increase in the number of earthquakes in the midcontinent United States with a Magnitude of three or greater on the Richter scale. Scientists looked carefully at regions where energy production activities have changed during recent years. The results of the studies suggest that hydraulic fracturing has not caused the increased frequency of earthquakes; however, in some instances, the increase in seismicity was linked to deep underground injection wells. The USGS indicates that it is still unclear whether the increased seismic activity is related to changes in production methodology or the increased rate of oil and gas production. For example, the USGS has previously reported that oil and gas extraction can cause earthquakes when removal of large quantities of oil, gas, or water changes underground stresses. The studies also note that not all underground injection causes earthquakes and that there have not been conclusive examples that underground injection may trigger large, major earthquakes even if located near a fault (Hayes 2012).

The recent National Resource Council study of induced seismicity (NRC 2012) finds that many factors are important in the relationship between human activity and induced seismicity: the depth, rate, and net volume of injected or extracted fluids, bottom-hole pressure, permeability of the relevant geologic layers, locations and properties of faults, and crustal stress conditions. Moreover, in a recent survey of earthquake activity and injection wells in Texas, the results suggested that injection rates, pressures, geological substrate permeability as well as fault location and underlying fault stress could influence the probability of fluid injection creating earthquakes (Frohlich 2012). In the siting of many injection wells, these factors are not well known. At the Inglewood Oil Field however the geological conditions are well known and there is a long history of successful waterflood operations.

Ohio Case Study

Although Mahoning County, Ohio, is historically not a seismically active area, nine low-Magnitude earthquakes were observed beginning in early 2011. Initial media coverage following the earthquakes pointed to hydraulic fracturing as the cause (Fountain 2011, Palmer 2012). Seismologists later plotted the quakes however and determined that their epicenters corresponded to Northstar 1, a 9,000-foot deep Class II injection well used to dispose of brine and wastes from natural gas hydraulic fracturing operations. The state shut down four deep disposal wells in January 2011, after a Magnitude-4 earthquake occurred. The Ohio Department of Natural Resources concluded that the earthquakes were caused by deep underground injection at Northstar 1, not the hydraulic fracturing operations, for the following reasons: injection operations began at Northstar 1 shortly before the first seismic events were recorded in the area; seismic events were clustered around the wellbore (the focal depths of the events were 4,000 feet laterally and 2,500 vertically from the well bore terminus); and there is evidence of fractures and permeable zones in the surrounding formation. Further modeling and analysis of the Northstar 1 well and the surrounding geology are required to establish a better understanding of what happened. Additional studies are underway by ODNR and cooperating agencies (ODNR 2012).

Texas Case Study

In 2011 and 2012, a retrospective survey was conducted near the Dallas-Fort Worth area in Texas. The study's intent was to review the relationship between detectable earthquakes and the characteristics of nearby injection wells. The study reviewed earthquake activity between November 2009 and September 2011 over a 70-km area of the Barnett Shale using temporary seismographs installed under the National Science Foundation's funded EarthScope U.S. Array program. It identified that there were a sizable number (67) of earthquakes Magnitudes 1.5 and higher that could be identified under the U.S. Array program. Only one-eighth of these were reported by the National Earthquake Information Center, however.

The earthquakes identified seemed to have varying relationships with the surrounding injection wells. The rates of injection wells nearest the strongest cluster of earthquakes typically exceeded 150,000 barrels of water per month. However, 90 percent of wells that had injection rates exceeding 150,000 barrels of water per month did not have related earthquakes. The study suggested that earthquakes may more likely be triggered if the injection reaches a critical rate, but that the rate could depend on localized geologic conditions. The geological substrate permeability as well as fault location and underlying fault stress could influence the probability of fluid injection triggering earthquakes (Frohlich 2012).

Oklahoma Case Study

In January 2011, the Oklahoma Geologic Service was contacted with reports of multiple earthquakes observed in the Garvin County area within a 24-hour period. Following the reports, the Oklahoma Geologic Service confirmed that in fact, over 50 earthquakes ranging in Magnitude 1.0 to 2.8 were recorded in this area. A review of activity in the area also confirmed that a hydraulic fracturing event had taken place that day at the nearby Eola field. This area of south-central Oklahoma has historically been seismically active; therefore, a network of seismic stations was installed in 1977 which allowed for the accurate reporting and determination of epicenters for this series of quakes. The Eola field is located in an area where several fault blocks are located between major faults (the Eola, Reagan, and Mill Creek faults). The Oklahoma Geologic Survey conducted its own study to determine if the reported earthquakes were in fact induced by the hydraulic fracturing that had taken place on the field. The study involved a series of model simulations and statistical analyses using the data records by the seismic monitors as well as data collected from the field operator regarding the hydraulic fracturing event itself. The Oklahoma Geologic Service found that there was a clear correlation between the hydraulic fracturing event and the observed seismicity, and that all of the epicenters of the seismic events were within 5 km (3.1 miles) of the Eola field and that some of the earthquakes occurred at similar depths as the reservoirs which were fractured (approximately 630 meters or 2,066 feet). However, the service could not confirm that the fluid pressure at the hypocentral location of the earthquakes was enough to generate seismicity and given the extensive seismic history in the area, the Service could not determine if the hydraulic fracturing had actually induced the earthquakes. The study also noted that the earthquakes observed were extremely low Magnitude in nature and were felt by only one individual (Holland 2011).

Basel, Switzerland Case Study

One of the most publicized instances of induced seismicity that is cited by critiques of hydraulic fracturing occurred at a geothermal project in Basel, Switzerland. In 2006, during the course of the development of an enhanced geothermal reservoir at a depth of about 5 km (3.1 miles) underneath the city, a Magnitude 3.4 earthquake was triggered. The earthquake occurred after 11,500 cubic meters of liquid (3.03 million gallons) were injected into a 5-km (3.1 miles) deep injection well. A steady increase in seismicity was detected in response to a gradual increase in flow rate and wellhead pressure. Monitors recorded more than 10,000 seismic events during the injection phase. After water had been injected for about 16 hours, a Magnitude 2.6 event occurred within the reservoir, which exceeded the safety threshold for continued well stimulation. In response, injection was halted prematurely. Two additional seismic events of Magnitude-2.7 and 3.4 occurred several hours later. At that point, the well was opened and the water was allowed to flow back. The seismic activity declined quickly thereafter. The well was officially shut down in 2009 (Deichmann and Giardini 2009).

A study was commissioned by the Canton of Basel-Stadt and the Swiss federal government to assess the seismic risk resulting from continued development and operation of the geothermal system. The study addressed the effect of continued development and operation of the geothermal facility and its effect on induced seismicity, as well as the effects of operations on natural seismicity in the Basel Region; i.e., “triggered seismicity.” A 3-D geological model was used to map eight relevant faults in the vicinity of the Basel geothermal reservoir. The seismic activity (time intervals when large earthquakes could be expected) of each fault was estimated, and it was determined that the presence of the geothermal reservoir could have a direct impact on the recurrence time of these natural earthquakes by modifying subsurface stresses but that variation would be small. The study also found that there is a possibility that earthquakes exceeding the strength of previous seismic activity would occur during continued development and operation of the facility. Based on model simulations, the largest “triggered” seismic event was predicted to have a Magnitude 4.5 (Baisch et. al 2009).

Rocky Mountain Arsenal

One of the first records of induced seismicity linked to deep underground injection was at the Rocky Mountain Arsenal, where a deep injection well constructed in 1961 was used to dispose of wastes from the U.S. Army’s chemical weapon testing operations. The well was drilled to a depth of 12,045 feet. It was cased and sealed to 11,975 feet, and the remaining 70 feet were left as an open hole for fluid injection. 165 million gallons of Basin F liquid waste, consisting of salty water that includes some metals, chlorides, wastewater and toxic organics was injected into the well from 1962–1966. During that time period, there were several small earthquakes in the area, and in 1966 a correlation was noticed between the frequency of earthquakes and the volume of water being pumped. Pumping was halted in 1966 due to the possibility that the fluid injection was triggering the earthquakes in the area. Over the next two years earthquakes continued to occur as far as 6 km (3.7 miles) from the injection well as the pressure front caused by injection dissipated (Nicholson and Wesson 1990). The well remained unused for almost twenty years until the army permanently sealed it in 1985.

Relevance to Inglewood Oil Field

The studies of the potential link between hydraulic fracturing and earthquakes have all concluded that the hydraulic fracturing produces small, imperceptible microseismic events (like dropping a milk bottle on the floor according to Stanford geophysicist, Mark Zoback [COGA 2012]) as part of the process itself. These microseismic events were recorded by the microseismicity monitoring conducted during the VIC1-330 and VIC1-635 hydraulic fracturing operations completed as a part of this study, and most were restricted to the target oil producing zone. These microseismic events did not cause any recordable event at the surface, based on two types of vibration monitoring and the Cal-Tech accelerometer.

The Inglewood Oil Field does not inject wastewater in the manner where small (Magnitude 3 or 4) earthquakes have been detected in Ohio and elsewhere. In those cases, the wastewater is injected into a formation other than the gas-producing zone. At Inglewood, the waterflood operation injects treated produced water into the depressurized oil-bearing formation. The waterflood therefore does not increase the subsurface pressure. The waterflood has been conducted waterflood operations since 1954, and since 1971 at a rate to halt subsidence. No earthquakes on the Newport-Inglewood Fault zone, or any other fault zone, have been attributed to the waterflood operation. This history is validated by the National Research Council study which found, “the potential for felt induced seismicity due to secondary recovery and EOR is low” (NRC 2012). As part of the CSD conditions, ground motion, vibration, and seismicity are monitored to determine whether there is a connection. In the two years of monitoring so far, there has been no connection between oil field operations, including the waterflood, high-rate gravel pack, or high-volume hydraulic fracturing operations, and seismicity, vibration, or ground movement.

Petersen and Wesnousky (1994) evaluated all seismic events greater than Magnitude-2 on the Newport-Inglewood Fault zone, and determined that most epicenters are located at depths between 3.5 miles and 12 miles depth (Petersen and Wesnousky 1994, Hauksson 1987). In comparison, the waterflood operation at the Inglewood Oil Field extends to depths of up to 3,000 feet (0.57 mile) and the deepest hydraulic fracturing occurs at less than 10,000 feet depth (1.9 miles). Therefore, any effects of oil field operations are much shallower than the zones typically associated with earthquake epicenters along the Newport-Inglewood Fault zone.

4.6 Methane

4.6.1 Subsurface Occurrence of Methane

As described in Chapter 2, the Los Angeles Basin is the richest oil basin in the world based on the volume of hydrocarbons per volume of sedimentary fill (Biddle 1991). Most of the oil and gas lies trapped beneath both shales and faults, allowing it to accumulate at depth. However, some surface seeps do occur, as at the La Brea Tar Pits, and methane also migrates to the surface.

There are three types of gases that may exist within the geological and soil units underlying the active surface of the Inglewood Oil Field, including biogenic (swamp or sewer) gas, thermogenic (field) gas, and processed natural (or piped) gas.

Biogenic gas is primarily methane with carbon dioxide and sulfide gases that result from decomposition of organic material, such as from former marshy areas or from sewers. Although biogenic gas contains of mostly methane and carbon dioxide, these gases also consist of lesser amounts of ethane, propane, and butane, as well as trace amounts of hydrogen sulfide and ammonia. In the active surface field area, marshy areas were formerly present immediately north of the Baldwin Hills, in the former floodplain of Ballona Creek (Hsu et al. 1982). In addition, the large-diameter (approximately 15-foot) City of Los Angeles North Outfall Replacement Sewer underlies the active surface field boundary. Both of these features are potential sources of biogenic gas.

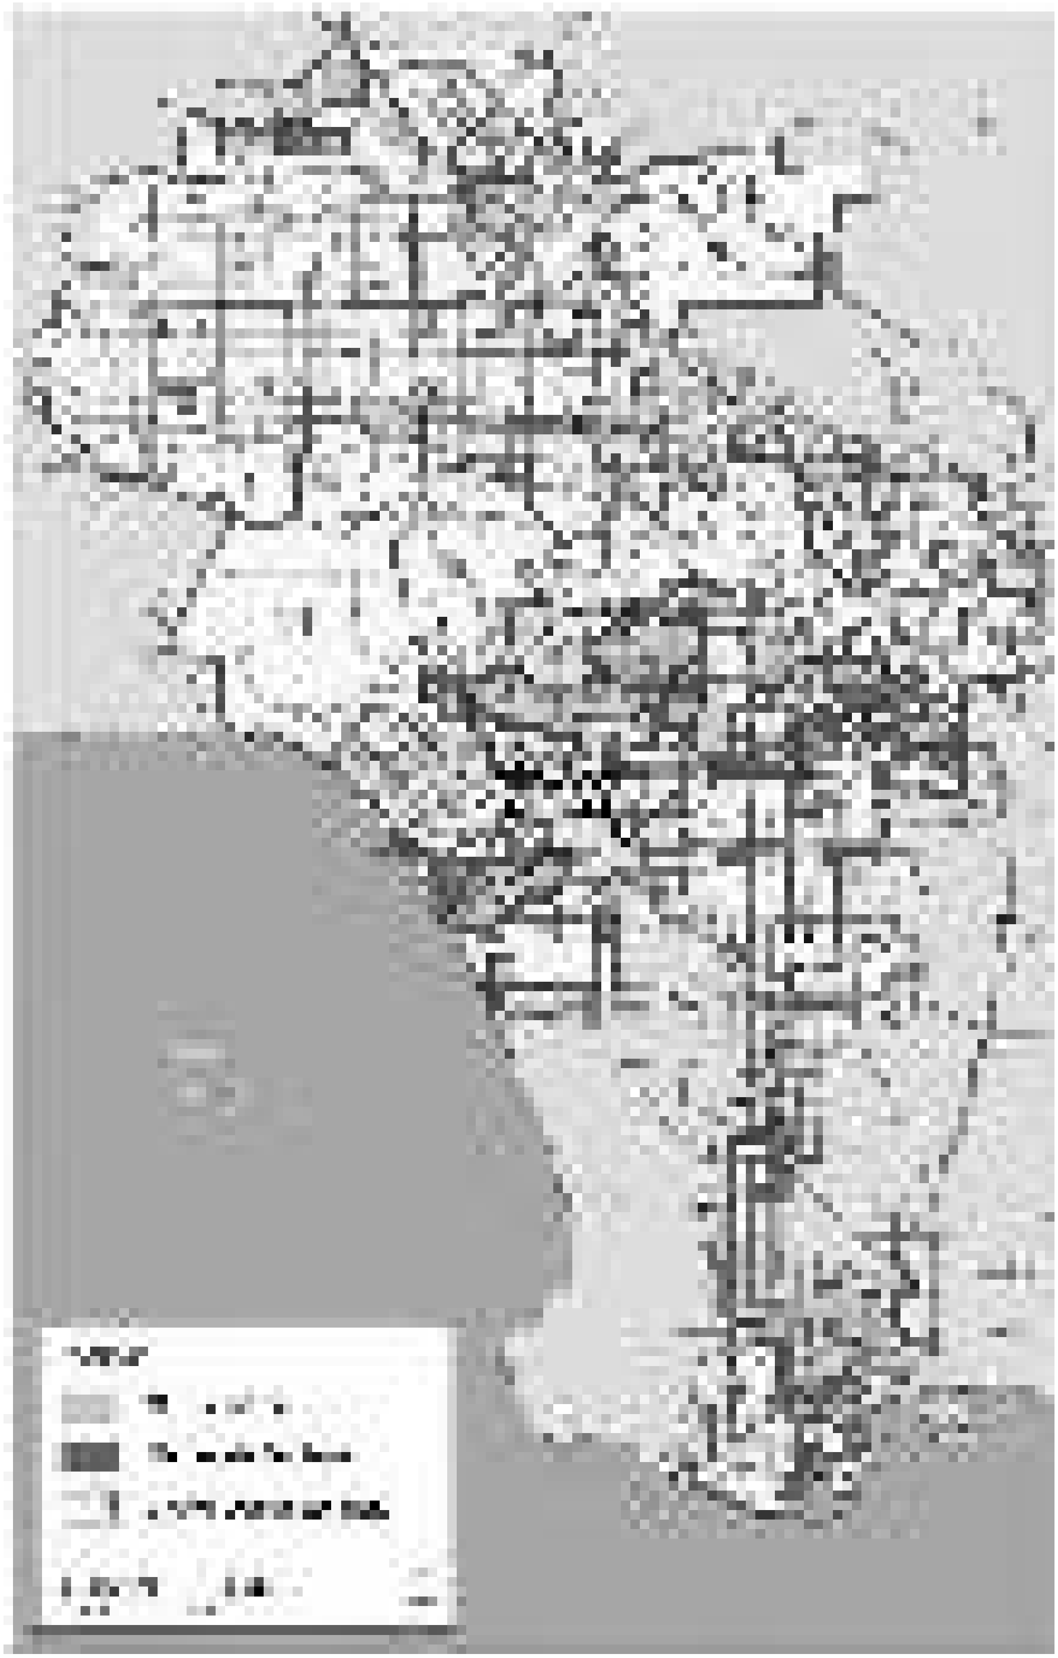
Thermogenic gas is generated at depth when increased temperatures and pressures alter organic material to form gases. Similar to biogenic gas, thermogenic gas contains a broad range of gas components including methane, ethane, propane, and butane, as well as trace amounts of toxic gases, including hydrogen sulfide. Activities at the Inglewood Oil Field produce oil and associated thermogenic gas.

Natural gas at the field is processed and sold to the BP Carson refinery, sold to Southern California Gas Company, or utilized for field use. Processed natural gas began as thermogenic gas derived from the oil and gas producing zones, and then had most non-methane components removed and reused.

These various types of gases exhibit distinct chemical characteristics, which permits "finger-printing" of gases, or differentiation between gas types (California Public Utilities Commission 2004).

4.6.2 Regulatory Framework for Methane

Due to the probability of methane gas releases from naturally occurring thermogenic and biogenic sources in this prolific oil and gas province, the City of Los Angeles has established a zoning ordinance identifying two zones, a Methane Zone and a Methane Buffer Zone (Figure 4-7). Special requirements for new construction, existing construction, and monitoring for methane have been established for these zones. The Baldwin Hills are not in the City of Los Angeles, and therefore are not classified on the methane map. However, the field is surrounded by such zones, and there is likelihood that methane conditions beneath the field are consistent with the relatively high background levels of methane in the Los Angeles Basin.



Source: City of Los Angeles 2004

Figure 4-7 Methane Zone Map

Following an explosion at the Ross Department Store in the Wilshire-Fairfax district of Los Angeles, and in an effort to avoid land use conflicts between oil field operations and urban environments, Senate Bill 1458 (Roberti) in 1986 directed the Department of Conservation and DOGGR to identify areas with the greatest potential for gas migration into structures, which could cause potential health and safety issues. A *Study of Abandoned Oil and Gas Wells and Methane and Other Hazardous Gas Accumulations* (Geoscience Analytical, Inc. 1986) identified eight high risk areas in the Southern California region that have the potential to cause a health and safety issue. These areas are categorized based on their locations within urban areas, having a history of seeps, and history of having plugged and abandoned wells within their boundaries. The Inglewood Oil Field was not identified as a high risk area in the study. The areas identified include: Salt Lake Oil Field (City of Los Angeles – Fairfax/Wilshire District); Newport Oil Field (City of Newport Beach); Santa Fe Springs Oil Field (City of Santa Fe Springs); the Rideout Heights area of the Whittier Oil Field (City of Whittier); Los Angeles City Oil Field (City of Los Angeles); Brea-Olinda Oil Field (City of Brea); Summerland Oil Field (City of Summerland); and Huntington Beach Oil Field (City of Huntington Beach) (Geoscience 1986).

Gas samples were collected at all high risk locations in the DOGGR study and analyzed to determine the hydrocarbon gas content and the origin of the soil gases. Of all the samples collected and indicating gas seepage, only two had the potential of originating from old oil and gas wells. In these two locations (Newport Beach and Huntington Beach) it was suspected that structures were built over old wells that were not plugged and abandoned to current standards. Although these old wells could have been the cause of the gas seepage, gas analysis indicated that the gas was biogenic in nature (i.e., not related to the oil and gas productive zone in the wells) and therefore the wells may have only been a conduit for the shallow biogenic gas (DOGGR, personal communication 2008 reported in CSD EIR).

Hamilton and Meehan (1992) also examined the causes of methane migration and the explosion in the Ross Store, as well as another natural gas vent in the Fairfax District near the La Brea Tar Pits. They reported that the methane was thermogenic in origin (that is, from the underlying oil-producing zone), but proposed that an additional scenario could account for the subsurface migration of methane: overpressuring of the oil-producing zone, leading to fracturing of the surrounding rocks and movement of methane along those newly-formed fractures. They recommended that DOGGR monitor injection operations to ensure that injection above the fracture pressure during produced water injection not exceed the formation fracture stress.

Chilingar and Endres (2005) have also evaluated methane migration in oil and gas producing areas, principally the many urban oil fields in Southern California. They conclude that "virtually all leaks can be traced to the poor well completion and/or abandonment procedures (i.e., poor cementing practices)." They advocate the evaluation of the integrity of old wells in the urban setting as a means to reduce this risk.

DOGGR reviews all applications for water injection wells under the authority of the UIC program. Injection wells for oil and gas development are Class 2 wells in this program, and DOGGR must evaluate the proposed injection pressures, the surrounding geology, and the well integrity of wells within one-quarter mile of any new proposed injection well. Because the field is contiguous and not interspersed with urban and residential development, the active Inglewood Oil Field is well positioned to address these issues in the Baldwin Hills. Because the field is active, it ensures that any unidentified issues will be addressed during field development, in comparison to orphan wells elsewhere in the state for which there is no identified owner.

4.6.3 Gas Monitoring Prior to Hydraulic Fracturing at the Inglewood Oil Field

Background soil gas methane concentrations throughout Southern California are typically 50 parts per million volume (ppmv) or less, although in Los Angeles certain areas are known to have higher background concentrations and have been identified on City Methane Zone Maps.

Since 2007, PXP has conducted annual soil gas surveys throughout the Inglewood Oil Field to test for methane concentrations and potential gas leaks from abandoned and idle wells. In 2007, GeoScience Analytical, Inc. sampled 94 locations, probing soil to a depth of four feet. The majority of these sampling locations were in the vicinity of idled or abandoned wells. Soil gases were extracted from each of the soil probes and transported to the laboratory for analyses of C_1 (methane) up to C_7 hydrocarbons, and hydrogen sulfide. The same 94 sample locations were tested in 2008 and 2009, with the addition of two other sites (GeoScience Analytical, Inc. 2009). Figure 4-8 depicts the sampling locations.

Methane concentrations detected in 2007 ranged from 1.0 ppmv to a high of 981,400 ppmv in the case of location #7, located near well LAI 1-130, which was an idled well. Given the high value for this location, additional soil gas vapor testing was done at 12 sites located around well LAI 1-130. The results of this additional sampling indicated that the source of the gas was most likely well LAI 1-130. The well was subsequently abandoned to the current DOGGR standards.

4.6.4 Gas Monitoring After High-Volume Hydraulic Fracturing

Soil gas testing was conducted again in 2011, following the high-volume hydraulic fracture operation of VIC1-330 in early September. During this sample event, 31 soil samples were taken and tested for C_1 to C_7 hydrocarbons and hydrogen sulfide. Of the samples tested, only two had readings greater than 500 ppmv (1,346 and 551 ppmv); both of which were well under the level for concern (12,500 ppmv) (GeoScience Analytical, Inc. 2011). GeoScience Analytical, Inc. concluded that the soil gases detected on the field were most likely the result of bacterial decomposition of crude oil in the near surface soils, i.e. biogenic (GeoScience Analytical, Inc. 2011). Isotopic analysis of three of the shallow soil gas samples was conducted to validate this finding. Carbon and hydrogen isotopic ratios were measured, and the results confirm a biogenic source for shallow soil gas (Figure 4-9).

There was no detected correlation between the hydraulic fracturing operation and the detected soil gas on the field.

4.6.5 Groundwater Monitoring for Methane after Hydraulic Fracturing

Methane in groundwater was tested during the quarterly sampling conducted on the Inglewood Oil Field (see Section 4.2). Groundwater was never measured for methane prior to high-volume hydraulic fracturing. Samples collected after high-volume hydraulic fracturing detected dissolved methane in all but one well (MW-7), at concentrations ranging from 0.01 to 9.7 mg/L. Wells MW-8, MW-11A, MW-11B, and MW-13 are located across the center of the field, and had concentrations ranging from 3.5 to 9.7 mg/L methane; all other concentrations were below 0.190 mg/L. Methane in water is not toxic and therefore, there is no drinking water standard (MCL) established. The City of Los Angeles methane zoning ordinance does not address methane in groundwater; the ordinance only addresses levels in soil gas and applies construction standards (Ordinance No. 175750). In water supplies, methane volatilizes from water, and at very high concentrations can displace oxygen. The U.S. Office of Surface Mining considers 28 mg/L in a water supply well as indicative that action be taken to reduce the concentration before use. Concentrations below 10 mg/L are considered safe, and between 10 and 28 mg/L the U.S. Office of Surface Mining suggests monitoring. The U.S. Bureau of Land Management also lists 10 mg/L as a safe concentration (U.S. Office of Surface Mining 2001). Therefore, all methane detections noted in groundwater samples within the oil field were within the level considered safe for any conditions. None of the water beneath the Baldwin Hills is used as a water supply, nor does it supply water at a yield suitable for a water supply.

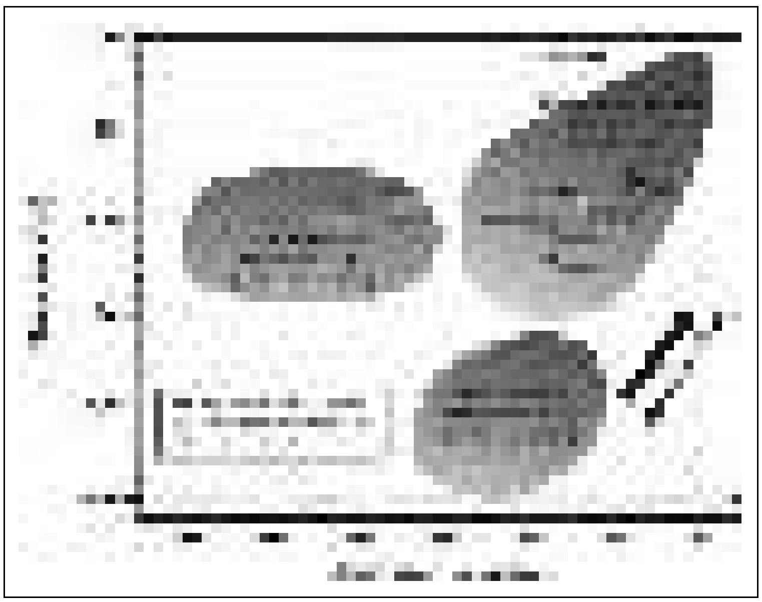

Figure 4-9 Methane Isotopic Results

Based on isotopic analysis of the dissolved methane in groundwater, it is thermogenic (from the oil-bearing formation) in origin, whereas detections in shallow soil gas are biogenic in origin (Figure 4-9). Therefore the methane in water and the methane in soil gas at the Inglewood Oil Field have different sources and are not in continuity. There are shallow occurrences of oil in the Investment Zone, within the Pico Formation, that are not commercially produced. Since these untapped zones are in closest proximity to the water-bearing zones, and the occurrence of methane is pervasive in the monitoring results, it does not appear to be related to oil and gas production activity. The occurrence is also not correlated to the locations of high-volume hydraulic fracturing. None of the levels detected are at concentrations that exceed levels considered safe, and none trigger further action under current regulations.

4.6.6 Methane Emissions and Climate Change

National Issue

Methane is the simplest hydrocarbon (alkane), consisting of one carbon and four hydrogen atoms. Methane is the main component of natural gas, typically over 90 percent by volume, and is one of the most abundant naturally-occurring organic compounds on earth. Pure methane is colorless, odorless, and nontoxic, but highly flammable, which makes it an attractive clean-burning fuel with a "carbon footprint" about 50 percent lower than coal when used to generate electricity. Since methane is 44 percent lighter than air, it dissipates upward when released. However, although nontoxic, methane is a simple asphyxiant and may displace oxygen in enclosed spaces and may also form explosive mixtures with air under certain conditions, thus presenting hazards. Methane is a greenhouse gas with an IPCC GWP coefficient of 21 relative to carbon dioxide. This means that methane has 21 times the averaged relative radiative forcing effect of CO_2 (USEPA 2011a, CCAR 2009).

A public concern related to hydraulic fracturing deals with methane gas that can escape into the atmosphere as a result of hydraulic fracturing operations and contribute to climate change. It is commonly recognized that methane gas can potentially escape as fugitive emissions during well completion. Large volumes of water are forced under pressure into the ground to fracture a rock formation and increase gas flow. A large portion of this water returns to the surface as flowback water within the first several days to weeks after injection. The flowback water is accompanied by quantities of methane that exceed the amount that can be dissolved within the flowback fluids. To assist in minimizing fugitive emissions at the Inglewood Oil Field, all flowback water accompanied by methane gas is piped to portable 500 bbl tanks connected to a South Coast Air Quality Management District (SCAQMD) permitted vapor control system. This is standard practice for oil operations throughout the Los Angeles Basin but differs from the air quality policies in shale gas producing states where in most cases, until recently, emissions from the flowback operations were largely unregulated. The rate of methane released with flowback fluid corresponds to the initial production rate and pressure of a well. Methane is also released during "drill-out," which is the stage of developing shale gases and oil in which the plugs that are set to separate fracturing stages are drilled out to release gas and/or oil for production. Fugitive methane emissions might result from equipment leaks and routine venting from pressure relief valves that are designed to purposefully vent gas (Howarth et al. 2011).

Untreated raw gas can contain some hydrogen sulfide (H_2S) which is highly odorous – the "rotten egg" smell – and the H_2S is toxic in high enough concentrations. Other natural sources of hydrogen sulfide include decaying organic matter under anaerobic (oxygen deprived) conditions. While hydrogen sulfide presents risks to oilfield workers, it is not considered a public safety risk due to safety zones between drilling activities and the general public which provide adequate distances for atmospheric dispersion in the event of leaks.

Relevance to Inglewood Oil Field

The Inglewood Oil Field operates in compliance with the requirements of the SCAQMD pursuant to Rules 463, 1148.1, 1173, and 1176 as applicable, which effectively control emissions of methane and other hydrocarbons into the atmosphere. In this regard emissions regulations relevant to the Inglewood Oil Field are significantly advanced compared to most shale gas producing states where, until recently, emissions from the flowback operations were predominantly unregulated. The Inglewood Oil Field is in the development stage rather than the exploration stage, so natural gas and produced water are contained in pipelines or enclosed tanks. Most concerns expressed regarding methane emissions to air and their effect on climate change are from natural gas fields in the exploration phase, where piping and gas treatment and sale facilities are not yet in place, as it is at Inglewood. As required by SCAQMD, there is an ongoing program of monitoring and repairing fugitive sources of hydrocarbon emissions. On a general comparative basis, air quality regulations in many oil and gas producing states are less comprehensive than the regulations adopted by the SCQAMD and apply to oil and gas activities at the Inglewood Oil Field.

The “carbon footprint” concern has been minimized at the Inglewood Oil Field as a result of its historic, stable long-term operation, and extensive local regulatory compliance framework for air quality including greenhouse gases. Unlike drilling operations in other less-regulated western states, current SCAQMD regulations prohibit uncontrolled venting of gas to the atmosphere which effectively mitigates the effects of hydraulic fracturing during well completion.

4.7 Other Emissions to Air

In compliance with SCAQMD Rules 463, 1148.1, 1173 and 1176 as applicable, hydrocarbon emissions at the Inglewood Oil Field are controlled and also monitored as described in an Air Monitoring Plan in accordance with Section E.2(d) of the Baldwin Hills CSD. This plan requires monitoring for hydrogen sulfide and total hydrocarbon vapors. It also requires that drilling or completion operations shut down if monitoring detects concentrations of hydrogen sulfide greater than 10 ppmv or hydrocarbon concentration of 1,000 ppmv or greater. Construction equipment and vehicles used for on-road and off-road purposes are also regulated by the CSD under Sections E.2(j) through E.2(n).

The following analyses focus on how the new USEPA hydraulic fracturing rules mesh with current SCAQMD rules, whether SCAQMD compliance comprises “de facto” USEPA compliance, or whether additional measures (activities, equipment) will be required to comply with USEPA notwithstanding SCAQMD. Applicable SCAQMD rules which prohibit uncontrolled emissions of VOC/GHG (e.g., raw untreated natural gas, tank headspace vapors, fugitive hydrocarbon leaks, etc.) are identified below:

- **Rule 463.** Organic Liquid Storage
- **Rule 1148.1.** Oil and Gas Production Wells
- **Rule 1173.** Control of Volatile Organic Compound Leaks and Releases from Components at Petroleum Facilities and Chemical Plants
- **Rule 1176.** VOC Emissions from Wastewater Systems

40 CFR Part 63 – New Source Performance Standards (NSPS) for New Hydraulically Fractured Wells (drilled after August 23, 2011)

To ensure that smog-forming volatile organic compounds (VOCs) are controlled without slowing natural gas production, USEPA’s final NSPS for VOCs establishes two phases for reducing VOCs during well completion. This approach will provide industry time to order and manufacture enough equipment to capture natural gas using a process called *green completions,* also known as "reduced emissions completions."

USEPA established the phased approach to address concerns raised in comments related to the availability of equipment and operators to conduct green completions in time to meet compliance dates in the proposed rule.

Phase 1

In the first phase (before January 1, 2015), industry must reduce VOC emissions either by flaring using a completion combustion device or by capturing the gas using green completions with a completion combustion device (unless combustion is a safety hazard or is prohibited by state or local regulations).

- A completion combustion device burns off the gas that would otherwise escape during the well-completion period (combustion generally would occur through pit flaring). Industry may use completion combustion devices to reduce VOC emissions until January 1, 2015, unless state or local requirements prohibit the practice or require more stringent controls (e.g., SCAQMD Rule 1148.1). USEPA encourages industry to begin using green completions during this time.

Phase 2

Beginning January 1, 2015, operators must capture the gas and make it available for use or sale, which they can do through the use of green completions.

- A completion device which captures the gas that would otherwise escape during the well-completion period will be required. Industry must use completion devices to reduce VOC emissions beginning January 1, 2015. Captured gas must be sent to economic use, either as fuel gas, sales gas, or reinjection.
- USEPA estimates that use of green completions for the three- to 10-day flowback period reduces VOC emissions from completions and recompletions of hydraulically fractured wells by 95 percent at each well (USEPA 2012d)
- Both combustion and green completions will reduce the VOCs that currently escape into the air during well completion. Capturing the gas through a green completion prevents a valuable resource from going to waste and does not generate NO_X, which is a byproduct of combustion.
- Methane, a potent greenhouse gas, and air toxics, which are linked to cancer and other serious health effects, also would be significantly reduced as a co-benefit of reducing VOCs.

Exceptions for New Wells

Green completions are not required for:

- New exploratory ("wildcat") wells or delineation wells (used to define the borders of a natural gas reservoir), because they are not near a pipeline to bring the gas to market.

- Hydraulically fractured low-pressure wells, where natural gas cannot be routed to the gathering line. Operators may use a simple formula based on well depth and well pressure to determine whether a well is a low-pressure well.

Owners/operators must reduce emissions from these wells using combustion during the well-completion process, unless combustion is a safety hazard or is prohibited by state or local regulations.

SCAQMD Rule 1148.1 – Oil and Gas Production Wells (relevant excerpts below, see entire rule for details)

"(a) The purpose of this rule is to reduce emissions of volatile organic compounds (VOCs) from the wellheads, the well cellars and the handling of produced gas at oil and gas production facilities.

(b) This rule applies to onshore oil producing wells, well cellars and produced gas handling activities at onshore facilities where petroleum and processed gas are produced, gathered, separated, processed and stored. Natural gas distribution, transmission and associated storage operations are not subject to the requirements of this rule.

(d)(6) Effective January 1, 2006, the operator of an oil and gas production facility shall not allow natural gas or produced gas to be vented into the atmosphere. The emissions of produced gas shall be collected and controlled using one of the following:

- *A system handling gas for fuel, sale, or underground injection; or*
- *A device, approved by the Executive Officer, with a VOC vapor removal efficiency demonstrated to be at least 95% by weight per test method of paragraph (g)(2) or by demonstrating an outlet VOC concentration of 50 ppm according to the test method in paragraph (g)(1). If the control device uses supplemental natural gas to control VOC, it shall be equipped with a device that automatically shuts off the flow of natural gas in the event of a flame-out or pilot failure.*

(d (7) Except as Rule 1173 applies to components of produced gas handling equipment located within 100 meters of a sensitive receptor, the operator shall repair any gaseous leaks of 250 ppm TOC or greater by the close of the business day following the leak discovery or take actions to prevent the release of TOC emissions to the atmosphere until repairs have been completed.

(d (8) Effective March 5, 2004, unless approved in writing by the Executive Officer, CARB, and USEPA as having no significant emissions impacts, no person shall:

- *Remove or otherwise render ineffective a well cellar at an oil and gas production well except for purposes of abandonment to be certified by the California Department of Conservation, Division of Oil, Gas and Geothermal Resources; or*
- *Drill a new oil and gas production well unless a well cellar is installed for containment of fluids."*

Analysis

Until December 31, 2014, compliance with SCAQMD Rule 1148.1 subparts (d)(6)(A) – capture, or (d)(6)(B) – incineration, constitutes compliance with Phase 1 of the new USEPA rule. Beginning January 1, 2015, only capture pursuant to subpart (d)(6)(A) can be used for so-called "green completions" under Phase 2; incineration pursuant to subpart (d)(6)(B) will no longer be allowed by USEPA. Thus, subpart (d)(6)(B) will be superseded by 40 CFR 63 on January 1, 2015. Since PXP presently complies with Rule 1148.1, PXP is also presently in basic compliance with 40 CFR 63.

Other Equipment - NSPS Requirements for New & Modified Pneumatic Controllers

Pneumatic controllers are automated instruments used for maintaining a condition such as liquid level, pressure, and temperature at wells and natural gas processing plants, among other locations in the oil and natural gas industry. These controllers often are powered by high-pressure natural gas and may release gas (including VOCs and methane) with every valve movement, or continuously in many cases as part of their normal operations.

The final rule affects high-bleed, gas-driven controllers (with a gas bleed rate greater than 6 standard cubic feet per hour) that are located between the wellhead and the point where gas enters the transmission pipeline.

- The rule sets limits for controllers based on location. For controllers used at the well site, the gas bleed limit is 6 cubic feet of gas per hour at an individual controller.
- The final rule phases in this requirement over one year, to give manufacturers of pneumatic controllers time to test and document that the gas bleed rate of their pneumatic controllers is below 6 cubic feet per hour.
- Low-bleed controllers used at well sites (with a gas bleed rate less than 6 standard cubic feet per hour) are not subject to this rule.

The final rule includes exceptions for applications requiring high-bleed controllers for certain purposes, including operational requirements and safety. The rule also includes requirements for initial performance testing, recordkeeping and annual reporting.

Analysis

Since PXP presently complies with SCAQMD Rule 1173 (*Control of Volatile Organic Compound Leaks and Releases from Components at Petroleum Facilities and Chemical Plants; and Rule 466.1 – Valves and Flanges*) PXP is also presently in basic compliance with this section of 40 CFR 63, notwithstanding particulars and details. This topic will also require coverage in the MRRP discussed above.

Other Equipment - NSPS Requirements for Storage Vessels at the Well Site

Storage tanks at natural gas well sites are commonly used to store condensate, crude oil and produced water. These tanks may be subject to two standards: the NSPS for VOCs and the major source air toxics standards (NESHAP) for Oil and Natural Gas Production.

NSPS Requirements

New storage tanks with VOC emissions of 6 tons a year or more must reduce VOC emissions by at least 95 percent. USEPA expects this will generally be accomplished by routing emissions to a combustion device.

- To ensure enough combustion devices are available, the final rule provides a one-year phase-in for this requirement.
- After one year, owners/operators of new storage tanks at sites with wells in production must comply. Owners/operators at sites with no wells in production will have 30 days to determine the emissions from a tank; and another 30 days to install controls.

Air Toxics Requirements

In response to public comments, USEPA did not finalize proposed air toxics standards for storage vessels *without* the potential for flash emissions, which currently are not regulated under the NESHAP for Oil and Natural Gas Production. The agency determined that it needs additional data in order to establish emission standards for this type of storage vessel. The previous standards for storage tanks *with* the potential for flash emissions remain in place.

- The final rule amends the definition of “associated equipment, “ meaning that emissions from all storage vessels now will be counted toward determining whether a facility is a major source under the NESHAP for Oil and Natural Gas Production.

Analysis

Since PXP presently complies with SCAQMD Rule 1176 (*VOC Emissions from Wastewater Systems*), Rule 463 (*Organic Liquid Storage*), and Rule 1178 (*Further Reductions of VOC Emissions From Storage Tanks at Petroleum Facilities*) PXP is also presently in basic compliance with this section of 40 CFR 63, notwithstanding particulars and details.

In particular, during the hydraulic fracturing process, any fluid flowback is captured in a closed system diverted to a portable 500 bbl. tank connected to a SCAQMD-permitted hydrocarbon vapor control system (activated carbon canisters). While PXP currently logs and reports the performance of this system to SCAQMD pursuant to the rule, this topic also requires coverage in the MRRP discussed above. Also, all aboveground stationary tanks are vapor tight and connected to existing vapor recovery systems as required by Rule.

Construction Emissions Estimation for Off-road Equipment and On-road Vehicles

Cardno ENTRIX has estimated mass emissions of criteria pollutants and greenhouse gases (GHG) for off-road equipment and on-road vehicles using emission factors published by the SCAQMD (SCAQMD 2008) and USEPA (USEPA 2011e, 2011f). The project schedule and equipment/vehicle list provided by PXP and Halliburton served as the basis for the analysis. The results of the analysis are presented in the emissions thresholds and summary Tables 4-2, 4-3, and 4-4 contained in this section (SCAQMD 2011). As shown in the tables, the estimated emissions are well below the daily limits set by the SCAQMD.

Table 4-2 Emissions Thresholds – South Coast AQMD

Criteria Pollutant	Temporary Construction lbs/day	Permanent Operation[1] lbs/day
Volatile Organic Compounds (VOC as CH_4)	75	55
Carbon Monoxide (CO)	550	550
Oxides of Nitrogen (NO_X as NO_2)	100	55
Sulfur Dioxide (SO_X as SO_2)	150	150
Respirable Particulates (PM_{10})	150	150
Fine Particulates ($PM_{2.5}$)	55	55

Source: SCAQMD 2011

[1] Does not apply to this project (not a permanent stationary source)

Table 4-3 Estimated Emissions of Criteria Pollutants

Criteria Pollutants	Maximum lbs/day	Threshold lbs/day	Total tons
Volatile Organic Compounds (VOC as CH_4)	2.0	75	0.007
Carbon Monoxide (CO)	13.8	550	0.048
Oxides of Nitrogen (NO_X as NO_2)	13.8	100	0.048
Sulfur Dioxide (SO_X as SO_2)	0.01	150	0.000
Combustion Particulates (C-PM_{10})	0.7	150	0.002
Combustion Particulates (C-$PM_{2.5}$)	0.6	55	0.002

Table 4-4 Estimated Emissions of Greenhouse Gases

Greenhouse Gases	Daily lbs/day	Total Project	
		Tons[1]	Tonnes[2]
Carbon Dioxide (GHG - CO_2)	1,320	4.62	4.19
Methane (GHG - CH_4)	0.03	0.0001	0.0001
Nitrous Oxide (GHG - N_2O)	0.08	0.0003	0.0002
Carbon Dioxide Equivalents (CO_2 eqv)	1,344	4.71	4.27

Sources: USEPA 2011e, 2011f, CCAR 2009

[1] short ton = 2,000 lbs

[2] metric tonne = 1,000 kg or 2,204.6 lbs

Methodology

For general engine exhaust emissions, the pre-processed SCAQMD factors are outputs from the California Air Resources Board (CARB) EMFAC and OFFROAD software applications and are the same conservative factors used in the official statewide URBEMIS and CalEEMod software applications for general land use planning in all 58 counties. For federal relevancy in all 50 states, the on-road and off-road factors are consistent with 40 CFR Parts 9, 69, 80, 86, 89, 94, 1039, 1048, 1051, 1065, and 1068 as applicable. For diesel off-road equipment with specified Tiers (1, 2, 3 or 4), engine exhaust emissions are based on applicable standards pursuant to 40 CFR 89.112, 13 CCR 2423, and 69 FR 38957-39273.

SCAQMD on-road and off-road factors were used for volatile organic compounds (VOC), carbon monoxide (CO), nitrogen oxides (NO_X), sulfur oxides (SO_X), respirable particulate matter (PM_{10}), carbon dioxide (CO_2), and methane (CH_4). USEPA factors were used for nitrous oxide (N2O), which are not included in the SCAQMD factors. For specified off-road Tiers, USEPA factors for VOC, CO, NO_X, SO_X, PM_{10}, CO_2, CH_4 and N_2O were used. For estimation purposes, fine particulate matter ($PM_{2.5}$) was quantified as 92 percent of PM_{10} for consistency with the EMFAC software (SCAQMD 2008). Where applicable, off-road and/or on-road fugitive dust emissions were estimated using USEPA algorithms contained in Chapters 11 and 13 of AP-42 (USEPA 2011a, 2011b).

Global Warming Potential (GWP) coefficients developed by the Intergovernmental Panel on Climate Change (IPCC) were used to quantify the globally averaged relative radiative forcing effects of a given GHG, using carbon dioxide as the reference gas. Accordingly, GWP coefficients of 1 for CO_2, 21 for CH_4, and 310 for N_2O were applied to aggregate GHGs as CO_2 equivalents (CO_2e) (USEPA 2011e, CCAR 2009).

4.8 Noise and Vibration

Noise attenuation and noise limits for activities occurring on the Inglewood Oil Field are addressed in Section E.5 of the CSD. This regulation sets hours for quiet drilling on the oil field (as outlined in the associated Quiet Mode Drilling Plan) and time limits for construction and deliveries to the oil field. Vibration levels are addressed in Section E.6 and must not exceed a velocity of 0.25 mm/second over a range of 1 to 100 hertz (Hz) in any developed area. The CSD requires that noise and vibration levels be monitored on the oil field to ensure that oil operations do not exceed the set thresholds. Table 4-5 lists noise levels for various types of sources for reference (70 dB, which is an annoyingly loud noise level to some individuals is used as an arbitrary base of comparison).

Table 4-5 Noise Sources and Their Effects

Noise Source	Decibel Level	Human Effects
Jet take-off (at 25 meters)	150	Eardrum rupture
Aircraft carrier deck	140	
Military jet aircraft take-off from aircraft carrier with afterburner at 50 feet (130 dB).	130	
Thunderclap, chain saw. Oxygen torch (121 dB).	120	Painful. 32 times as loud as 70 dB.
Steel mill, auto horn at 1 meter. Turbo-fan aircraft at takeoff power at 200 feet (118 dB). Riveting machine (110 dB); live rock music (108 - 114 dB).	110	Average human pain threshold. 16 times as loud as 70 dB.
Jet take-off (at 305 meters), use of outboard motor, power lawn mower, motorcycle, farm tractor, jackhammer, garbage truck. Boeing 707 or DC-8 aircraft at one nautical mile (6080 feet) before landing (106 dB); jet flyover at 1000 feet (103 dB); Bell J-2A helicopter at 100 feet (100 dB).	100	8 times as loud as 70 dB. Serious damage possible in 8-hr exposure
Boeing 737 or DC-9 aircraft at one nautical mile (6080 feet) before landing (97 dB); power mower (96 dB); motorcycle at 25 feet (90 dB). Newspaper press (97 dB).	90	4 times as loud as 70 dB. Likely damage 8-hr exposure
Garbage disposal, dishwasher, average factory, freight train (at 15 meters). Car wash at 20 feet (89 dB); propeller plane flyover at 1000 feet (88 dB); diesel truck 40 mph at 50 feet (84 dB); diesel train at 45 mph at 100 feet (83 dB). Food blender (88 dB); milling machine (85 dB); garbage disposal (80 dB).	80	2 times as loud as 70 dB. Possible damage in 8 hr exposure.
Passenger car at 65 mph at 25 feet (77 dB); freeway at 50 feet from pavement edge 10 a.m. (76 dB). Living room music (76 dB); radio or TV-audio, vacuum cleaner (70 dB).	70	Arbitrary base of comparison. Upper 70s are annoyingly loud to some people.
Conversation in restaurant, office, background music, Air conditioning unit at 100 feet	60	Half as loud as 70 dB. Fairly quiet
Quiet suburb, conversation at home. Large electrical transformers at 100 feet	50	One-fourth as loud as 70 dB.
Library, bird calls (44 dB); lowest limit of urban ambient sound	40	One-eighth as loud as 70 dB.
Quiet rural area	30	One-sixteenth as loud as 70 dB. Very Quiet
Whisper, rustling leaves	20	
Breathing	10	Barely audible

Sources: Federal Interagency Committee on Noise 1974; 1992 *Federal Agency Review of Selected Airport Noise Analysis Issues*, Federal Interagency Committee on Noise (August 1992).

To address concerns regarding perceptible vibration and noise during high-volume hydraulic fracturing operations, PXP commissioned Behrens and Associates, Inc., a firm specializing in noise and vibration studies, to measure produced vibration during the VIC1-330 and VIC1-635 high-volume hydraulic fractures and the TVIC-221 and TVIC-3254 high-rate gravel pack events. The ground-borne vibration survey for each event was completed while all equipment was operated under normal loads and conditions.

The high-volume hydraulic fracturing treatment on September 16, 2011, was completed on the VIC1-330 well, located in the northwestern portion of the field. Ground-borne vibration levels were measured in one direction (west) at 10-foot intervals from the high-volume hydraulic fracture operation (Figure 4-10A). Measured levels indicate that the maximum ground-borne vibration produced during the operation was 0.006 inch per second (0.1524 mm/second), as measured 40 feet from the operation. At 160 feet from the operation, measured vibration was 0.001 inch per second (0.0254 mm/second). As shown on the Figure 4-10 below, both of these levels are imperceptible to humans (Behrens and Associates, Inc. 2011). These measurements are also below the limit set by the CSD. No noise monitoring was conducted during the VIC1-330 treatment.

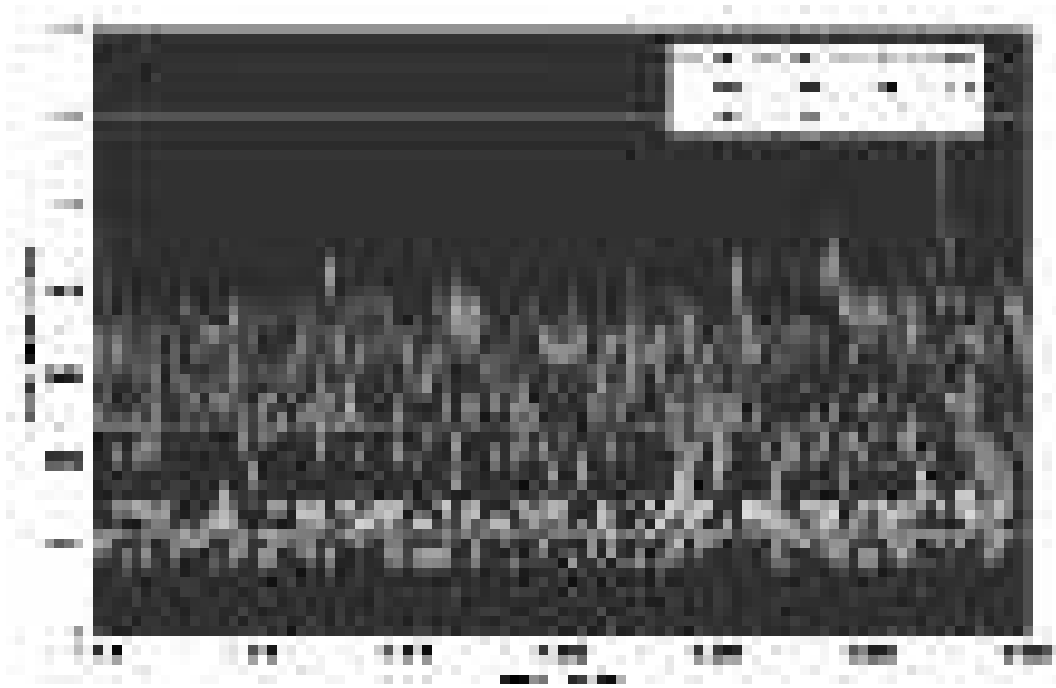

Figure 4-10A Ground Vibration Level Measurements from High-Volume Hydraulic Fracture at VIC1-330

The high-volume hydraulic fracture on January 6, 2012, was completed on the VIC1-635 well. Ground-borne vibration levels were measured to the south of the high-volume hydraulic fracture site at 50, 100, 150, and 200 feet from the well. Measured levels (Figure 4-10B) indicate that the maximum ground-borne vibration was 0.0012 inch per second (0.0305 mm/sec) as measured 50 feet from the operation. Similar to the measured level during the prior high-volume hydraulic fracture operation at VIC1-330, at 150 feet from the operation, measured vibration was 0.001 inch per second (0.0254 mm/second). These measured levels are imperceptible to humans.

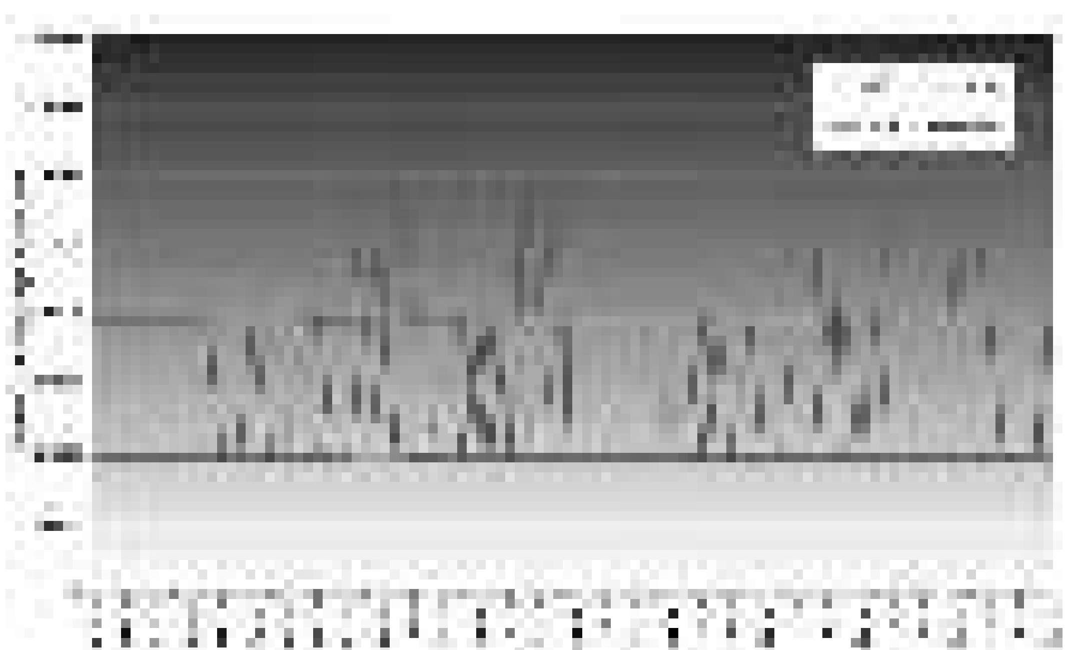

Figure 4-10B Ground Vibration Level Measurements from High-Volume Hydraulic Fracture at VIC1-635

In addition to ground-borne vibration measurements, Behrens and Associates, Inc. also took sound level measurements during the high-volume hydraulic fracturing operation at VIC1-635 using a calibrated sound level meter. The microphone was set at five feet above ground surface. The measured noise level at 100 and 200 feet from the operation was 68.9 and 68.4 decibels (dBA), respectively (Behrens and Associates, Inc. 2012a). These are within CSD limits.

The high-rate gravel pack treatments were completed on January 7 and 8, 2012, on the TVIC-221 and TVIC-3254 wells, which are located immediately adjacent to one another. The ground-borne vibration levels were measured during the high-rate gravel pack at TVIC-221 and TVIC-3254 at a distance of 50, 100, 200, and 300 feet to the east of the high-rate gravel pack operation site (Figure 4-10C).

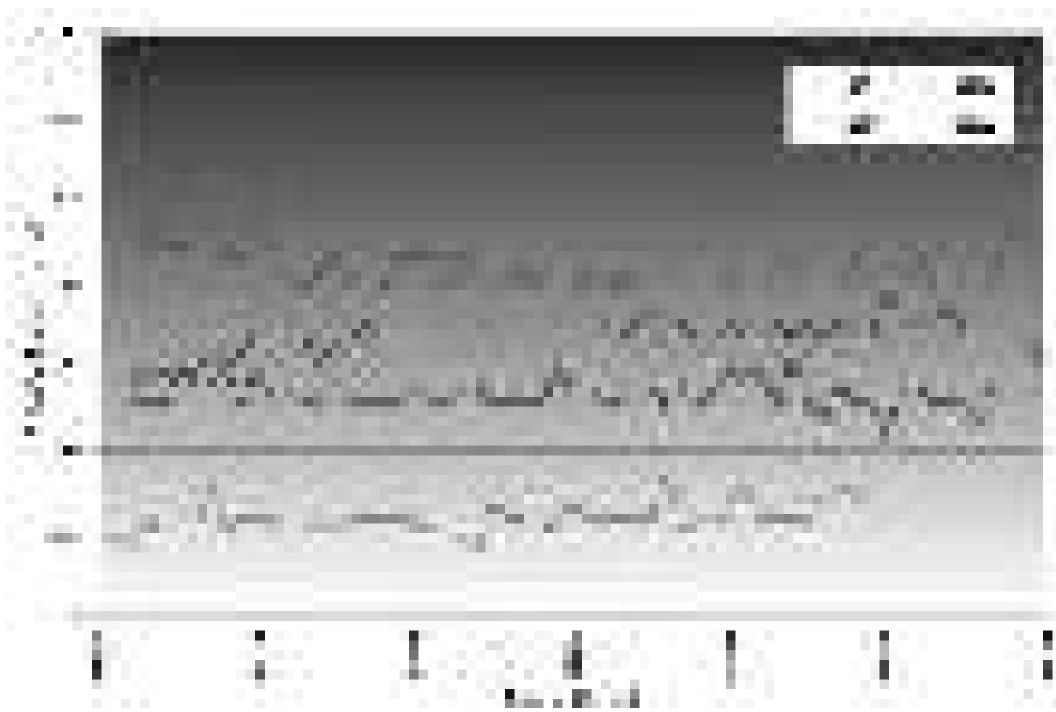

Figure 4-10C Ground Vibration Level Measurements from Gravel Pack Operations at TVIC-221 and TVIC-3254

Measured levels indicate that the maximum ground-borne vibration produced during the high-rate gravel pack operation was 0.012 inch per second (0.304 mm/second), as measured 50 feet from the operation. At 300 feet from the operation, measured vibration was less than 0.004 inch per second (0.102 mm/second). While 0.01 inch per second is the low threshold of vibration that may be perceptible to humans (see Figure 4-11), levels measured further from the site are imperceptible. Further, while the vibration level near the well is greater than the 0.25 mm/second CSD limit, the vibration is decreased to below the limit well away from any developed areas (Behrens and Associates 2012b).

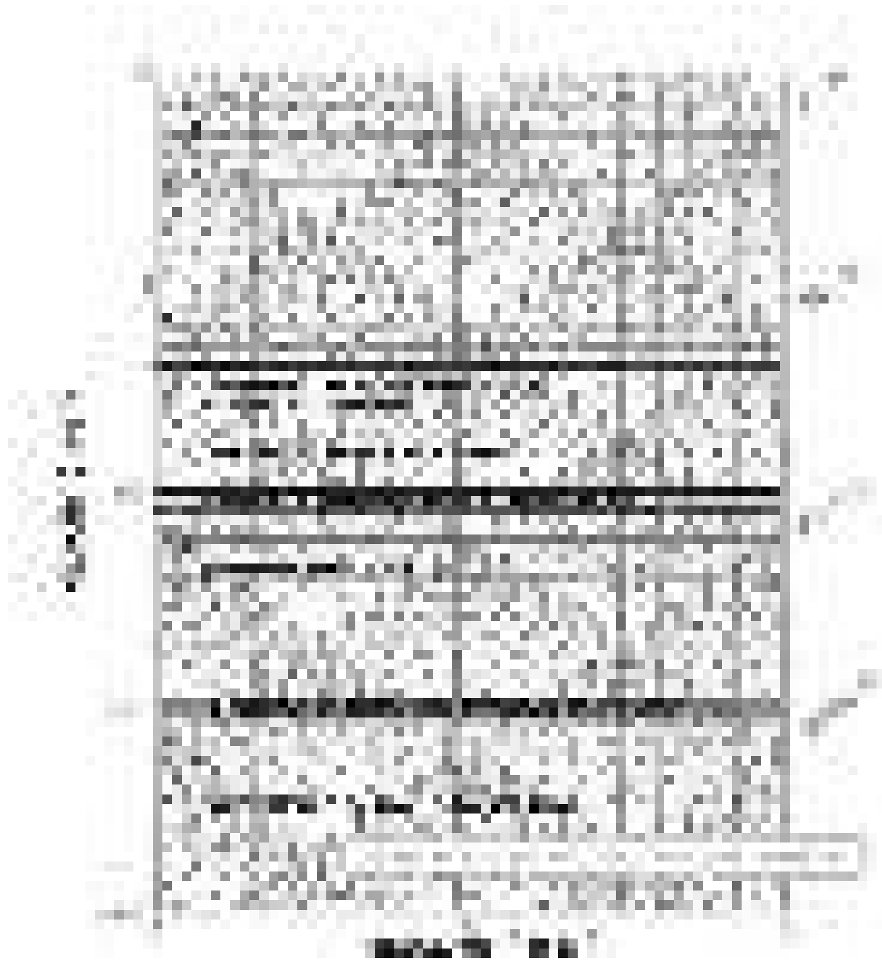

Figure 4-11 Vibration Sensitivity Chart

Sound level measurements were conducted at 100 feet and 200 feet from the TVIC-221 and TVIC-3254 high-rate gravel pack operations. The measured noise level at 100 feet was measured at 68.1 dBA and the noise level at 200 feet was 63.5 dBA (Behrens and Associates 2012b). These are within CSD limits.

4.9 Los Angeles County Department of Public Health Study

In response to health concerns expressed by residents in communities near the Inglewood Oil Field during the EIR process for the CSD, and at the request of the Second Supervisorial District, the Los Angeles County Department of Public Health (LAC DPH) conducted a community health assessment on the population living in communities surrounding the Inglewood Oil Field. The assessment was designed to determine if the health concerns reflect a higher than expected rate or an unusual pattern of disease in the concerned communities. The report was sent to three external peer reviewers who found it to be technically sound.

The conclusions of the health study indicate that there is not a detectable relationship between the activities at the Inglewood Oil Field and the health of the surrounding community. Five types of blood-related cancer (most common types of cancer associated with petroleum exposure) to determine if operations at the Inglewood Oil Field had any adverse impact on cancer rates in the surrounding community. The study found there was no conclusive evidence or link between Inglewood Oil Field activities and cancer rates in the community. The report acknowledges that the data cannot determine whether there is a small adverse health effect, nor can the data address the contribution of other, non-quantifiable health-related issues such as smoking, lack of exercise, and social determinants of health (LAC DPH 2011). As described in Chapter 7, conventional hydraulic fracturing and high-rate gravel pack operations have occurred at the field for several years along with other oil and gas development activity. Any prospective impact from these operations would have contributed to the assessment's baseline findings. The Health Study indicates that operations at the field have not had an adverse effect on the health of the local community.

The Health Assessment included five components, each of which is summarized below:

- An analysis of mortality (death) rates based on data reported on death certificates;
- An analysis of rates of low-birth-weight births based on data reported on birth certificates;
- An analysis of rates of birth defects based on data collected by the California Birth Defects Monitoring Program;
- An analysis of cancer rates based on data compiled by the University of Southern California (USC) Cancer Surveillance Program; and
- A community health survey of self-reported illness, including asthma and other health concerns.

The report of the Health Assessment (LAC DPH 2011) included conclusions for the first four components. The community health survey of self-reported illness was postponed to allow enough time to evaluate the effects of continuous drilling and released in April 2012.

4.9.1 Mortality

From 2000 to 2007, the mortality rate for all causes of death was 731.9 deaths per 100,000 persons in the Inglewood Oil Field communities and 751.7 deaths per 100,000 persons in Los Angeles County, after adjusting for age and the racial/ethnic distribution of the underlying populations. Although the mortality rate appears lower in the Inglewood Oil Field communities, there was no statistically significant difference in the mortality rates for all causes of death, after adjusting for age and race/ethnicity.

The differences in mortality rates for the leading causes of death and premature death do not appear to be related to the geographic location of the Inglewood Oil Field communities. Many of the differences observed within these communities are common in Los Angeles County and represent a significant public health challenge throughout the county. The disparities in mortality rates can best be addressed by targeting the underlying causes of these disparities.

4.9.2 Low Birth Weight

After adjusting for race/ethnicity, the rate of low-birth-weight births was 7.2 per 100 live births in the Inglewood Oil Field communities and 7.0 per 100 live births in Los Angeles County as a whole. There was no statistical difference in the rates of low-birth-weight births in the Inglewood Oil Field communities compared to Los Angeles County, after adjusting for race/ethnicity. There were differences in rates of low-birth-weight births among racial/ethnic groups with African

Americans having the highest rates of low-birth-weight births in the Inglewood Oil Field communities as well as in Los Angeles County. These disparities in low-birth-weight births represent another significant public health challenge throughout the county.

4.9.3 Birth Defects

For 28 of the 29 categories of birth defects, there was no statistically significant difference in the Inglewood Oil Field communities compared to Los Angeles County as a whole. Babies born in the Inglewood Oil Field communities between 1990 and 1997 were slightly more likely (1.2 times as likely) to be born with a limb defect compared to babies countywide. Limb defects are not known to be caused by exposure to petroleum products. Since multiple comparisons were made, the increase may be explained by statistical chance.

4.9.4 Cancer

The analysis found no evidence of elevated rates of acute myelogenous leukemia (AML), the type of cancer most definitively linked to petroleum products (benzene) or three of the other types of blood-related cancer for any of the race/ethnic groups examined. There was an excess risk of chronic myelogenous leukemia (CML) in non-Hispanic whites based on the occurrence of two cases above the expected number in 2000 through 2005. CML has not been consistently linked with exposure to petroleum products from oil fields or refineries. These two additional cases of CML may be explained by statistical chance, because the analysis examined multiple comparisons. Furthermore, in most of the studies examining this issue, occupational exposure to specific petroleum-based chemicals, such as benzene, was measured, rather than residential proximity to oil wells.

4.9.5 Community Survey

The community survey was developed to quantify self-reported illness and environmental concerns among residents living near the Inglewood Oil Field. The community was defined by a 1/5-mile buffer around the oil field and participants were randomly selected. Surveying was conducted by telephone in both English and Spanish. A total of 1,020 residents participated. The survey results were compared to a health survey conducted for all of Los Angeles County in 2007 to provide a comparison between those living in proximity to the Inglewood Oil Field and residents of the county as a whole. The results indicated that the prevalence of health conditions reported by respondents to the Inglewood Oil Field survey were similar to those in Los Angeles County, with the exception that more reported high blood pressure/hypertension in the area around the Inglewood Oil Field than in the Los Angeles County survey. The survey also found that the racial/ethnic disparities that exist in Los Angeles County were also reflected in the Inglewood Oil Field community (greater African Americans report hypertension and heart disease and the 46 percent of respondents in the Inglewood Oil Field community survey were African American compared to 9 percent in the Los Angeles County survey. Other issues addressed in the survey were smoking (13 percent of respondents reported smoking), eating fast food more than once per week (38 percent), and being obese or overweight (26 percent and 39 percent respectively).

With regard to the Inglewood Oil Field, participants were asked about the presence of offensive odors, illnesses caused by outdoor air pollution, and noise. Of the respondents, 86 percent did not notice any odors, and of those that did report odors, only 1.3 percent indicated concern that the odor was caused by the oil field. While 58 percent of respondents indicated concerns about air pollution, only 14.5 percent reported having an illness or symptom in the past year caused by pollution in the air outdoors. This percentage is slightly less than the percentage reported by Los Angeles County residents as a whole (17.5 percent). In regard to noise, participants were asked how much they were bothered by noise from six neighborhood sources: (1) cars and trucks, (2) airplanes, (3) garden equipment, (4) neighbors (including loud music, crying children, or barking dogs), (5) construction, and (6) oil field operations. Of the six sources, noise from the oil field was reported least frequently (LAC DPH 2012).

4.9.6 Health Assessment Limitations and Recommendations

The Health Assessment (LAC DPH 2011) noted limitations and a recommendation. The limitations were as follows:

- The analyses cannot confirm whether exposures to chemicals from oil drilling activities at the Inglewood Oil Field may be associated with a small increase in the risk of mortality, low-birth weight births, birth defects, or cancer among specific individuals living nearby, because epidemiological investigations of this type are more conclusive with larger sample sizes (more cases to analyze).
- The analyses do not take into account other important determinants of health such as behavioral risk factors (such as smoking and physical activity), social factors (such as community resilience, education, income, and access to health care) since these data were not available on the birth certificates, death records, or cancer registry records.
- The analysis cannot establish causal relationships between emissions from oil drilling activities and specific causes of death because of the lack of information on the individual levels of exposure to emissions that could establish dose-response curves and temporal relationships as well as the multitude of other risk factors that influence these disease outcomes. For example, a high-rate of mortality from asthma in the community adjacent to the Inglewood Oil Field would not prove that the oil field operations are causing asthma since there are many other potential causes, such as exposures to traffic-related air pollution, tobacco smoke, or adverse environmental conditions in the home. Alternatively, a normal or low rate of mortality from asthma would not prove that the Inglewood Oil Field is safe, again because of the many other factors that influence the rate. Thus, these results should be interpreted with caution.

All of the conclusions of the health study indicate that there is not a detectable relationship between the activities at the Inglewood Oil Field and the health of the surrounding community and that the occurrences of diseases of concern and mortality rates in the community are consistent with the rate of occurrences throughout the Los Angeles Basin. In other words, areas with no oil field operations were determined to have roughly the same mortality rate as the surveyed community around the Inglewood Oil Field. However, the report acknowledges that the data cannot determine whether there is a small effect, nor can the data address other health-related issues such as smoking, exercise, and social determinants of health. Because of these limitations, the Health Assessment recommends that local community health and safety would be more appropriately assessed by careful monitoring of the Inglewood Oil Field operations to ensure compliance with regulations and standards. In this regard, the CSD provides for Environmental Compliance Coordinator inspections and the annual Environmental Quality Assurance Program audit.

Chapter 5

Regulatory Framework

5.1 Introduction: Local Source of Energy in the Context of Community Concerns

Since high-volume hydraulic fracturing was first used for shale gas development in the northeastern United States and tight sands development in the Intermountain West, there has been extensive coverage of controversies surrounding its use. Hydraulic fracturing has been called "the environmental issue of 2011" by Time magazine, was the subject of an HBO® movie ("Gasland"), and has been at the center of the debate regarding the pace at which the United States will move towards renewable sources of energy generation.

Although most of the news has been about the development of shale gas, tight sands and coalbed methane deposits, rather than the type of oil and natural gas development that occurs at the Inglewood Oil Field, community outreach conducted as part of this study (including one public meeting and open comment period) has indicated that many of the concerns surrounding shale gas development are shared by the local community. Questions and concerns submitted by the public to Los Angeles County for evaluation in this study were clearly influenced by media coverage of controversies in other parts of the country. As identified through the community outreach conducted by the County and other studies conducted on hydraulic fracturing operations in the U.S., the primary environmental and health issues of concern associated with hydraulic fracturing operations include:

- Potential for contamination of groundwater, including drinking water supplies;
- Potential for migration of gases and related explosion hazards;
- Environmental hazards associated with the chemical packages used during hydraulic fracturing operations;
- Potential for hydraulic fracturing operations to cause earthquakes;
- Issues related to well integrity; and,
- Air emissions and greenhouse gas emissions of hydraulic fracturing operations in comparison to regular oil field operations.

Many of these concerns are addressed by the existing regulatory framework. However, public concern has led to continuing efforts to expand the regulatory framework. This section summarizes the California regulatory framework as it pertains to oil and gas development, and hydraulic fracturing. The section then summarizes regulations and ongoing studies conducted by the Federal government, and many state governments. Finally, the regulatory framework specific to the Inglewood Oil Field, including the additional regulatory overlay of the CSD provisions, is considered in the context of state and federal regulations and guidelines.

5.2 Regulatory Framework and Government-Sponsored Reviews of Hydraulic Fracturing

The federal, state, and local laws, ordinances, regulations, and standards that govern oil field development throughout the United States mandate protection or mitigations against the potential environmental impacts of the entire development process. These protections include numerous provisions in the Clean Air Act, Clean Water Act, Safe Drinking Water Act, Endangered Species Act, and the Oil Pollution Act. Extensive California regulations and local provisions regulating nuisance also apply. The Inglewood Oil Field is unusual in that it has much greater regulation and oversight of its operations than most other onshore oil fields as a result of the Baldwin Hills CSD, which governs operations at the Inglewood Oil Field.

The widespread use of hydraulic fracturing since 1949 has been addressed through this extensive regulatory framework. Hydraulic fracturing is only one part of the entire oil and natural gas development process, and does not require, by itself, individual permits or approvals in California or most other oil and gas producing states. Instead, protections required for these resources during oil and gas development also apply to the use of hydraulic fracturing in general, as a completion technique.

Natural gas drilling activity brought hydraulic fracturing well completion techniques into public prominence. Shale gas production began and was first proven successful in the current oil and gas-producing states of Texas, Oklahoma, and the Intermountain region, and was viewed as a means to more securely achieve energy independence. USEPA reviews of high-volume hydraulic fracturing as used for coal-bed methane in 2004 found no justification for additional environmental controls (USEPA 2004). Significant national and public interest in the technique emerged however, when the shale gas production reached the Marcellus Shale in the northeast United States, especially Pennsylvania. The introduction and application of new technologies led to a dramatic and rapid increase in exploration activity. Communities largely unfamiliar with the oil and natural gas industry began seeing a large influx of drill rigs and production pumps, and construction of new well pads, access roads, and supporting infrastructure such as tanks and surface impoundments. This led to public concern that environmental issues were not being adequately addressed. That initial concern was primarily related to the policy of oilfield service companies to maintain confidentiality of the precise chemical names and concentrations used in hydraulic fracturing fluids. This information was considered a proprietary trade secret and oilfield service companies maintained that to reveal the information would put them at a competitive disadvantage. As a result, several states initiated independent reviews of the environmental impacts of hydraulic fracturing with an emphasis on water quality and chemical disclosure. The most comprehensive of these reviews was the Supplemental Generic Environmental Impact Statement (SGEIS) prepared by the State of New York in 2011, following release of a Generic Environmental Impact Statement which had not specifically regulated hydraulic fracturing operations as a specific action.

Growing public attention has also led the USEPA to allocate increased resources to studying the technique. In addition, the USEPA currently has two ongoing reviews, the first focused on the potential effects of hydraulic fracturing on drinking water supplies, and the second focused on the definition of "diesel fuel" as part of a review of the 2005 EPAct provisions. The 2005 EPAct recognizes hydraulic fracturing as a well completion process, and requires a UIC permit if the fluid used for hydraulic fracturing is diesel fuel. The USEPA is the federal agency tasked with implementing the underground injection control program; however, 42 states (including California) have primary enforcement and permitting responsibility under this program. In California, the Division of Oil, Gas, and Geothermal Resources (DOGGR) is the state agency that enforces the underground injection control program. The USEPA also recently released air quality rules relative to hydraulic fracturing.

Since the passage of the 2005 EPAct, many states have adopted regulations or passed legislation requiring operators to disclose the composition of the fluids used in the hydraulic fracturing process. In 2011, the U.S. Secretary of Energy convened a shale gas Production Subcommittee made up of university, agency, and NGO experts to address the expanded production of shale gas in a safe manner (www.shalegas.energy.gov). The committee concluded that shale gas can be developed in an environmentally responsible manner, and emphasized among other things the need for improved public information, improved coordination between shale gas developers and local, state, and federal government (including the STRONGER reviews described in this Section), as well as the kinds of protections that are in place at the Inglewood Oil Field through the CSD and other regulations and voluntary reporting.

The Inglewood Oil Field is not developing shale gas reserves, but primarily oil reserves with associated natural gas. As such, some specific regulations, studies, and concerns described in this section are not strictly applicable to the Inglewood Oil Field. However, they are described in this report because they give an important context to the questions and concerns that have been raised by the community.

This section addresses the current regulatory framework governing the use of hydraulic fracturing at the time of writing, and presents the results of various studies prepared by the federal government and by individual states.

5.3 California Regulations

5.3.1 DOGGR Regulations

DOGGR was formed in 1915 to regulate all oil and gas activities in the state of California with uniform laws and regulations. DOGGR supervises the drilling, operation, maintenance, and plugging and abandonment of onshore and offshore oil, gas, and geothermal wells. By regulating these activities DOGGR aims to prevent damage to: (1) life, health, property, and natural resources; (2) underground and surface waters suitable for irrigation or domestic use; and (3) oil, gas, and geothermal reservoirs.

DOGGR responsibilities are detailed in Section 3000 of the California Public Resources Code and Title 14, Chapter 4 of the California Code of Regulations. These regulations address issues such as well spacing, blow-out prevention devices, casing requirements, plugging and abandonment of wells, maintenance of facilities and safety systems, inspection frequency and reporting requirements. DOGGR programs also include: well permitting and testing; safety inspections; oversight of production and injection projects; environmental lease inspections; idle-well testing; inspecting oilfield tanks, pipelines, and sumps; hazardous and orphan well plugging and abandonment contracts; and subsidence monitoring.

California oil and gas regulations were reviewed in 1992 by the IOGCC and USEPA, at which time DOGGR made numerous changes to its program based on recommendations provided as part of the review. For example, DOGGR initiated the Idle-Well Management Program, which aims to reduce the number of long-term idle wells by encouraging operators to reactivate or plug and abandon their idle wells. In addition, DOGGR strengthened its requirements regarding well bonds and pipelines located in environmentally sensitive areas. The State Review of Oil and Natural Gas Environmental Regulations (STRONGER), a non-profit, multi-stakeholder organization that helps oil and natural gas producing states evaluate their environmental regulations associated with the exploration, development and production of crude oil and natural gas was formed in 1999, and reviewed California's regulations again in 2002. The STRONGER Review took note of California's stringent regulations on exploration and production waste management requirements and Underground Injection Control (UIC) programs. The Review included DOGGR's public participation and outreach, interagency coordination, abandoned well program, and data management proficiency. During the 2002 review the Stronger Review team did not address, nor offer recommendations for, hydraulic fracturing operations or regulations (STRONGER 2002).

While DOGGR's regulations do not include provisions specific to hydraulic fracturing, its broad authority over oil and gas operations gas and regulations encompasses the regulation of hydraulic fracturing in order to protect life, health, property, and natural resources including water supply (under Section 3106 of the Public Resources Code).

5.3.2 Baldwin Hills Community Standards District

The Baldwin Hills CSD, on Page 9, describes hydraulic fracturing (fracing) by including it in the definition of reworking, as follows:

> *"'Reworking' shall mean recompletion of an existing well and includes operations such as liner replacements, perforating, or fracing. Reworking also includes redrilling a well that is not deepened or sidetracked beyond the existing well bore."*

The CSD does not contain specific provisions which apply only to hydraulic fracturing. Rather, the CSD addresses all environmental aspects of oil field operation, and these aspects also apply to the potential environmental effects associated with hydraulic fracturing. These include analysis and provisions that address air quality, water quality, traffic, noise, and impacts to other environmental resource categories. The Baldwin Hills CSD also addresses seismic risk, contingency measures in the event of earthquakes including a requirement for an on-site accelerometer to measure effects of seismic activity and trigger contingency actions. The CSD also analyzes cumulative impacts, and environmental justice. The Baldwin Hills CSD, and the associated EIR, are incorporated by reference in to this Hydraulic Fracturing Study. The Hydraulic Fracturing Study does not identify a new impact not analyzed in the EIR, nor does it identify impacts greater in significance than those analyzed in the EIR.

5.3.3 Proposed California Regulations

As stated above, DOGGR does not currently regulate hydraulic fracturing specifically; it does not monitor hydraulic fracturing, nor are there reporting or permitting requirements. During legislative budget hearings held in Sacramento in March 2011, representatives from the California State Department of Conservation (DOC) testified that the agency would promulgate its own rulemaking process related to hydraulic fracturing. DOGGR hosted seven workshops between May and July 2012, to gather information as part of the rulemaking process. Two workshops were conducted in the Los Angeles Basin, one in the City of Culver City on June 12, 2012, and one in Long Beach on June 13, 2013. DOGGR plans to circulate the draft regulations in Fall 2012.

In addition to DOGGR's plans for rulemaking, two bills related to establishing new regulations for the practice of hydraulic fracturing were introduced in the California Legislature during the 2011–2012 legislative session, Assembly Bill 591 and Senate Bill 1054. The Legislature adjourned for the year without passing either measure.

California Assembly Bill 591, introduced in February 2011, would have required operators conducting hydraulic fracturing to disclose the chemical constituents of the fracturing fluid to DOGGR and the public, as well as the following additional information to DOGGR:

- the source and amount of water used in the exploration or production of the well;
- data on the use, recovery and disposal of any radiological components or tracers injected into the well; and
- if hydraulic fracturing is used, disclosure of the chemical information data described above.

California Senate Bill 1054 (Pavley), introduced in February 2012, would have required well owners or operators to notify surface property owners before commencing drilling operations and hydraulic fracturing operations near or below their property. The bill would have also required that notification be given to DOGGR, the appropriate RWQCB, water supplier, and municipal government. The bill would have also extended DOGGR's permit review time from the current 10 days to 15 days and required DOGGR to submit an annual report to the Legislature that includes the number of wells with notices, and an evaluation of compliance for the notification requirements.

5.4 Federal Regulations and Studies

5.4.1 Federal Regulations

Underground Injection Control Program

At the federal level, hydraulic fracturing is addressed under the Safe Drinking Water Act (SDWA), which was enacted in 1974. The SDWA gives USEPA's Office of Water the primary authority to protect drinking water. Under the UIC Program of the SDWA, USEPA is required to protect drinking water from contamination caused by underground injection of fluids. The UIC Program established six classes of injection wells that have purposes ranging from injection of hazardous materials and sewage, mining fluids, radioactive wastes, oil and gas fluids, and carbon dioxide (CO2) sequestration. Class II wells are associated with oil and natural gas production and include injection of:

- Fluids brought to the surface in connection with natural gas storage operations, or conventional oil or natural gas production (e.g., produced water);
- Fluids used for enhanced oil or natural gas recovery; and,

- Liquid hydrocarbons being stored, usually as part of the U.S. Strategic Petroleum Reserve. (USEPA 2011b).

As part of the 2005 EPAct, the U.S. Congress included hydraulic fracturing under the authority of the UIC Program when diesel fuels are used in the fracturing process (Paragraph 1 of Section 1421(d)). The EPAct did not provide a definition of diesel fuel. As of this writing, USEPA is conducting a review to develop a definition of diesel fuel. Interpretations of "diesel fuel" vary from only the use of 100 percent diesel fuel to the use of any diesel in a chemical package. The review process began in spring 2011 and draft guidance was issued in May 2012.

The Inglewood Oil Field does not use diesel fuel, in any amount, for hydraulic fracturing, and available records indicate that it was never used.

Chemical Disclosure

In 2009, the Fracturing Responsibility and Awareness of Chemicals Act was introduced in Congress. The legislation is commonly referred to as the FRAC Act. The FRAC Act proposes regulating hydraulic fracturing by requiring public disclosure of the chemical constituents used in hydraulic fracturing fluids. The FRAC Act states that proprietary information must be released in the event of a medical emergency. Congress did not take any action of the FRAC Act in the 111^{th} session of Congress, (2009 through 2011). The Act was re-introduced in the 112^{th} Congress in March 2011 (Lustgarten 2009). Since the FRAC Act, there have also been other bills discussed or introduced in Congress.

PXP posts the chemicals used in hydraulic fracturing on the public website FracFocus.org, as described below. This disclosure is consistent with the current regulations in the various states with disclosure laws.

EPA Regulation for VOC Reduction

On April 17, 2012, the USEPA released new regulations for reducing air pollution from hydraulic fracturing under the National Emissions Standard for Hazardous Air Pollutants (NESHAPS) for oil and natural gas production. The focus is on reduction of volatile organic compounds (VOCs) that are smog precursor compounds. The new regulations will take effect in two phases:

- **Phase 1:** Before January 1, 2014, use a combustion device (flare) or gas capture to reduce VOC emissions.
- **Phase 2:** Before January 1, 2015, capture all natural gas for sale. Exceptions are provided for exploratory wells or delineated wells used to determine or define the area of a natural gas reservoir, because exploratory wells are not near a pipeline and unable to bring gas to market, and for low pressure wells that cannot supply a gathering line.

The Inglewood Oil Field already exceeds the requirements of this new regulation through compliance with SCAQMD provisions as discussed in greater detail in Chapter 4.

5.4.2 Federal Studies

USEPA's Review of the Impacts of Hydraulic Fracturing on Drinking Water - 2004

In 2004, the USEPA conducted a study that analyzed the potential for contamination of underground sources of drinking water (USDW) caused by hydraulic fracturing of coalbed methane (CBM) natural gas wells. Like shale gas, CBM is an unconventional source of natural gas. Natural gas extraction wells are drilled into coal seams, the coal seam is dewatered by pumping, and natural gas then can desorb from the coal and be brought to the surface in the well. While not all CBM wells are completed by hydraulic fracturing, a portion of the wells do require the utilization of the technique. CBM resources tend to be at shallower depths than shale gas, and accordingly have a greater potential for affecting groundwater supplies if wells are not installed and abandoned according to current standards. The USEPA conducted this study in response to public concern that completing CBM wells by hydraulic fracturing had impacted the quality of groundwater, as well as by congressional need for additional data in the development of the 2005 EPAct. The USEPA released the results of the study in a report titled *Evaluation of Impacts to Underground Sources of Drinking Water by Hydraulic Fracturing of Coalbed Methane Reserves*.

The USEPA's 2004 study was two-fold. The first part was an extensive review of existing literature on the impacts of hydraulic fracturing on USDWs. The USEPA reviewed more than 200 peer reviewed publications and interviewed more than 50 employees in the natural gas industry, representatives of state and local agencies, and 40 concerned citizens and groups. The research focused on water quality incidents potentially associated with CBM hydraulic fracturing.

The second part of the study included a review of incidents of drinking water contamination thought to be associated with CBM hydraulic fracturing operations. The USEPA reviewed studies and investigations performed by state agencies in response to citizen complaints. Complaints investigated included: (a) drinking water with unpleasant taste and odor, (b) impacts to wildlife and vegetation, and (c) loss of water in wells and aquifers. After reviewing the data and incidents, the USEPA concluded that there were no conclusive links between water quality degradation in USDWs and hydraulic fracturing in nearby CBM wells, even though thousands of CBM wells annually were being hydraulically fractured.

The USEPA did determine that in some instances, the coal beds being produced were located within drinking water sources; that is, the coal beds were shallow enough to be within fresh water aquifers. In these cases, fluids and chemicals (including diesel fuels) used for hydraulic fracturing were introduced directly into drinking water sources, because the coal beds were located in drinking water sources. As a result of this finding, the USEPA entered into a Memorandum of Agreement in 2003 with three major service companies, which cumulatively perform 95 percent of the United States' hydraulic fracturing projects, to eliminate diesel fuel from the fracturing fluids that are injected directly into USDWs.

The 2004 USEPA study concluded that hydraulic fracturing fluids in CBM wells do not threaten USDWs. Based on this conclusion, the USEPA recommended against a Phase II study (USEPA 2004).

The Inglewood Oil Field does not use diesel for hydraulic fracturing or for high-rate gravel packs.

USEPA's Additional Review of Impacts of Hydraulic Fracturing – 2011

Continued technological advancements in the field of hydraulic fracturing and the application of the technology to tight sand and shale reservoirs has made the practice more prevalent since USEPA released its 2004 report. Public interest and concerns about the impact of hydraulic fracturing on human health and the environment have grown in direct proportion with increased media and internet attention to the practice. Concerns intensified when hydraulic fracturing was introduced in the Marcellus Shale in the northeastern states in approximately 2005. As a result of increased public interest, in fiscal year 2010 the U.S. Congress' Appropriation Conference Committee directed USEPA to conduct research to study the relationship between hydraulic fracturing and drinking water resources. The purpose of the study was to answer two overarching questions: (1) Can hydraulic fracturing impact drinking water resources, and, if so, (2) what conditions intensify these impacts?

In February 2011, the USEPA published a *Draft Plan to Study the Potential Impacts of Hydraulic Fracturing on Drinking Water Resources*, with the objective of identifying the factors that have the potential to affect sources of drinking water. The study began with input from an External Science Advisory Board, which recommended that the study include:

- Use of lifecycle framework to identify important research questions;
- Direct initial research to sources and pathways of potential impacts of hydraulic fracturing on water resources, especially drinking water;
- Analysis of five to ten in-depth case studies at locations representing the full range of regional variability across the nation; and,
- Stakeholder engagement throughout the research process.

As the study focuses almost exclusively on water resources, USEPA examined how water was used during each stage of hydraulic fracturing operations and developed related fundamental research questions (Table 5-1).

To answer these questions, the USEPA study will use a combination of:

- retrospective case studies focusing on studying potential impacts where hydraulic fracturing has already occurred;
- prospective case studies focusing on sites where hydraulic fracturing will occur after research has begun so that site conditions can utilize monitoring before, during, and after hydraulic fracturing operations; and
- general scenario evaluations which will explore hypothetical situations related to hydraulic fracturing.

Table 5-1 Examination of Water Use During Hydraulic Fracturing

Water Use in Hydraulic Fracturing Stage	Research Questions
Water acquisition	How might large volume water withdrawals from ground and surface water resources impact drinking water resources?
Chemical mixing/site management	What are the possible impacts of releases of hydraulic fracturing fluids on drinking water resources?
Well construction and injection of fracturing fluids	What are the possible impacts from the injection and fracturing process on drinking water resources?
Flowback and produced water generation	What are the possible impacts of releases of flowback and produced water on drinking water resources?
Water treatment and waste disposal	What are the possible impacts of inadequate treatment or hydraulic fracturing wastewater on drinking water resources?

Source: USEPA 2011d

In each case, the research approach includes literature reviews, gathering and analyzing existing data, analytical methods, modeling/scenario evaluations, toxicity assessments, and stakeholder-suggested case studies. In addition, the USEPA will summarize the available data on chemical, physical, and toxicological properties of hydraulic fracturing fluid additives to better understand their effects and identify data gaps. The chemicals will also be compared to naturally occurring substances.

The USEPA's November 2011 Final Study Plan states that they have conducted an initial literature review, requested and received information from industry on chemicals and practices used in hydraulic fracturing, discussed initial plans for case studies with landowners and industry representatives, and conducted baseline sampling for retrospective case studies. An interim report is expected by the end of 2012 and is expected to contain a synthesis of results from the retroactive case studies and initial results from prospective case studies. A final report will be released in 2014, which will include results from the long-term prospective studies (USEPA 2011d).

The Inglewood Oil Field has very limited groundwater, no aquifers or water supplies, and is not located within or near an underground source of drinking water. The water supply for the nearby communities is derived primarily from the Colorado River and from Northern California with supplemental groundwater sources all located more than 1.5 miles from the oil field. As such, the results of the ongoing USEPA Study on the effects of hydraulic fracturing to drinking water supplies are not anticipated to produce results that are relevant to operations on the Inglewood Oil Field.

5.5 State Regulations and Studies

5.5.1 State-Specific Regulations

Hydraulic fracturing that includes diesel fuel is subject to the federal UIC program; this program is implemented by the California DOGGR, consistent with most states that have an oil and gas industry. The Inglewood Oil Field does not use diesel fuel for hydraulic fracturing.

Oil and gas producing states have regulated the practice by focusing on regulations specific to well bore integrity, well drilling and casing requirements, waste disposal, setback and operating requirements, and other conditions. The USDOE has stated that regulation at the state and local level allow laws to be tailored to the local environment, and state regulatory agencies tend to have the best information, knowledge and experience of the local conditions (USDOE et al. 2009).

State Chemical Disclosure Regulations

While regulations requiring the disclosure of the chemical constituents used in hydraulic fracturing fluids are under consideration at the federal level, several states have enacted regulations requiring chemical disclosure. Between 2010 and 2011, eight states passed chemical disclosure regulations. Wyoming was first to pass a regulation in September 2010, followed by Arkansas, Pennsylvania, Michigan, Texas, Montana, Colorado, Louisiana, and West Virginia. Ohio also amended existing laws in July 2012, to include disclosure of chemicals used in hydraulic fracturing. California, Illinois, and New Mexico have proposed rules, and several additional states appear to be considering rules.

Each state's regulations are generally consistent, although each differs slightly. For example, some regulations follow the federal proposal that companies can assert that information is proprietary. Other states require disclosure of propriety information to regulatory agencies but not the public. Table 5-2 summarizes the key provisions of the chemical disclosure regulations of the eight states that have enacted chemical disclosure laws.

Legislation was introduced in the 2011–2012 California legislative session that would have required operators conducting hydraulic fracturing to disclose the chemical constituents of the fracturing fluid to DOGGR and the public. In addition, a rulemaking process that will likely require disclosure of hydraulic fracturing chemicals is currently (as of the writing of this study) underway by DOGGR.

The Inglewood Oil Field voluntarily meets the requirements of most state chemical disclosure laws by posting the information on the publically-available website FracFocus.org, described below. As such, PXP would likely be in compliance with any reasonably contemplated chemical disclosure laws at either the State or Federal level.

Table 5-2 Summary of State Chemical Disclosure Regulations

State	Date Enacted	Enforced By	Reporting Required	Volume or Concentration Reporting Required	Proprietary Chemical Disclosure
Wyoming[a]	Sep-10	Wyoming Oil and Gas Conservation Commission	All chemicals used in hydraulic fracturing	Volume and concentration of the products are disclosed, but not of individual ingredients in chemical mixtures	Disclosed to regulators; undisclosed to the public.
Arkansas[a]	Jan-11	Arkansas Department of Environmental Quality	All chemicals used in hydraulic fracturing	None	Disclosure not required
Pennsylvania[a]	Feb-11	Bureau of Oil and Gas Management	All fracturing additives and chemicals All hazardous chemicals (as defined by OSHA) used on well-by-well basis	For hazardous chemicals only	Disclosure not required

Table 5-2 Summary of State Chemical Disclosure Regulations

State	Date Enacted	Enforced By	Reporting Required	Volume or Concentration Reporting Required	Proprietary Chemical Disclosure
Michigan[a]	Jun-11	Michigan Department of Environmental Quality	All hazardous chemicals (as defined by OSHA)	For hazardous chemicals only	Disclosure not required
Texas[a]	Dec-11	Texas Railroad Commission	All chemicals used in hydraulic fracturing.	For hazardous chemicals only	Disclosure not required
Montana[b]	Aug-11	Montana Board of Oil and Gas Conservation	All chemicals used on well-by-well basis	Concentrations of additives	Disclosure not required
Colorado[c]	Dec-11	Colorado Oil and Gas Conservation Commission	All chemicals used in hydraulic fracturing	Concentration of all chemicals	Requires disclosure of chemical family only
West Virginia[e]	Dec-11	West Virginia Department of Environmental Protection	All chemical used in hydraulic fracturing	None	Disclosure not required
Louisiana[d]	Oct-11	Louisiana Department of Natural Resources	All chemicals used in hydraulic fracturing	Concentration of all chemicals	Requires disclosure of chemical family only
Ohio[e]	Jul-12	Ohio Department of Natural Resources	All chemicals used in hydraulic fracturing	Volume and concentration of products	Disclosure not required

Self-Regulation by Industry

Disclosure of the chemical compounds used in hydraulic fracturing has been one of the primary issues that aroused public skepticism regarding the safety of hydraulic fracturing for development of shale gas in New York. As state and federal chemical disclosure laws were in development, the Groundwater Protection Council and Interstate Oil and Gas Compact Commission (IOGCC) in collaboration with the oil and natural gas industry, began examining methods to promote self-reporting and self-regulation to fill the gap and respond to public interest. This collaboration led to the development and launch of FracFocus (www.fracfocus.org) in 2011, a national hydraulic fracturing chemical registry.

FracFocus is managed by the Ground Water Protection Council and IOGCC. The mission of these organizations is conservation and environmental protection. The site was created to provide public access to reported chemicals used for hydraulic fracturing within an area of interest in a user-friendly interface. To help the public put the information into perspective, the site also provides objective information on hydraulic fracturing, the chemicals used, and the purposes they serve and the means by which groundwater is protected.

The high-volume hydraulic fracturing operations completed for this study were reported by PXP on FracFocus and are provided in Appendix B. PXP uses FracFocus on a company-wide basis for all shale oil and natural gas related hydraulic fracturing completions.

New York Supplemental Generic EIS

In 1992, New York State published a Generic Environmental Impact Statement on the Oil, Gas and Solution Mining Regulatory Program. In general, a Generic EIS (GEIS) is similar to a Programmatic Environmental Impact Report prepared pursuant to the California Environmental

Quality Act (CEQA). The New York GEIS analyzes the environmental impacts of the development of oil, natural gas, and solution mining resources, and provides options for mitigation. In this way, common or generic impacts of these activities can be considered "pre-evaluated," and if implemented in conformance with the mitigation conditions no further review is needed. Where site-specific actions differ from those evaluated in the GEIS, or where alternate mitigation is proposed, supplemental environmental review is conducted on those site-specific features.

New York's GEIS did not evaluate the effects of high-volume hydraulic fracturing as currently applied in the Marcellus Shale. As a result, the New York Department of Environmental Quality prepared a Supplemental Generic EIS (SGEIS) to study new technology and techniques related to hydraulic fracturing and to identify potential adverse impacts associated with the new technologies. The Draft SGEIS was released in September 2009 and in response to public comment, a Revised Draft was released in September 2011. The public comment period for the revised draft ended in January 2012, no further iterations have been released.

The draft SGEIS and the GEIS noted potential impacts, including water withdrawals, stormwater runoff, leaks and spills, and waste disposal. However, no adverse impacts to water resources were determined with regard to disposal of waste fluids, except that the disposal of flowback water could cause adverse impacts if not treated before disposal.

The draft SGEIS also finds that there is no significant impact to water resources likely to occur as a result of underground vertical migration of fracturing fluids through the shale formations, primarily the Marcellus Shale. The shale formations are vertically separated from the potential freshwater aquifers by at least 1,000 feet of sandstones and shales with low permeability. Furthermore, a supporting study for the draft SGEIS determined that it is highly unlikely that groundwater contamination would occur by fluids escaping from wellbores. The study notes that regulatory officials from 15 states recently testified that groundwater contamination as a result of high-volume hydraulic fracturing has not occurred (NYSDEC 2011).

In 2009, the New York City Department of Environmental Protection (NYCDEP) expanded upon the draft SGEIS, assessing potential impacts specific to the New York City water supply resulting from natural gas development in the Catskill and Delaware watersheds. Although, the Marcellus Shale in these areas has high gas production potential, these two watersheds provide 90 percent of New York City's water supply. The assessment concluded that there were potential cumulative impacts from a conceivable large-scale high-volume fracturing program in the Catskill and Delaware watersheds, which could substantially increase the risk to the New York City water supply (NYCDEP 2009). The overall recommendation of the NYCDEP study is that hydraulic fracturing not proceed, although it provides recommended mitigation measures if hydraulic fracturing does occur. However, in comparison to current and future activities to the Inglewood Oil Field, the NYCDEP assessment assumes a high density fracturing effort, which is much less than what has been done so far, and is proposed to occur, at the Inglewood Oil Field.

There are several relevant comparisons to be made between the conditions evaluated in the SGEIS, the NYCDEP study, and the Inglewood Oil Field. First, New York City's water supply, as well as much of the state, is derived from surface waters in relatively pristine areas and transported in pipes to New York City, and as such the water supply does not require filtration. The Inglewood Oil Field, however, has no surface water supplies within 10 miles, no groundwater supplies within

1.5 miles and no water transportation infrastructure. Ballona Creek is north and west of the field, but is not used for water supply. As is discussed in detail in Chapter 4, beneath the field itself, there is very limited groundwater, no aquifers or water supplies. The water supply for the nearby communities is derived primarily from the Colorado River and from Northern California; with supplemental groundwater sources all located more than 1.5 miles from the oil field (West Basin Municipal Water District 2011, Culver City 2010, City of Inglewood 2010, Golden State Water Company 2011, California American Water 2011b, see Figure 4-3b). There are no sources of groundwater supplying the City of Culver City system (Culver City 2010). The distance from water supply systems minimizes any potential risk of water quality contamination from fracturing. Note that even with this consideration, the SGEIS protections are still met by the Inglewood Oil Field, despite the much lower potential for water quality impacts.

Second, the Inglewood Oil Field has recently been the subject of a site-specific EIR, prompted by the proposal of the CSD by the County. Table 5-3 below provides a summary of the findings of the SGEIS and a comparison of its' suggested mitigation measures with the Baldwin Hills CSD regulations. In part because the CSD is site-specific, there is a greater amount and type of protections required compared to the SGEIS.

Table 5-3 Summary of Findings of the SGEIS and Comparison with Baldwin Hills CSD

Resource	SGEIS Impact	SGEIS Mitigation	Consistency with Inglewood Oil Field CSD
Water Resources	Depletion of water supply in streams	Passby Flow Requirements	No nearby streams for water supply, Cal Water indicates there is sufficient water supply to meet field needs
	Damage to groundwater resources	Pump testing and site-specific evaluation	Site specific monitoring and reporting; no local groundwater use and limited isolated occurrence of groundwater
	Water Contamination from stormwater runoff	State Pollution Discharge Elimination System (SPDES) permit with all associated requirements	National Pollutant Discharge Elimination System (NPDES permits and compliance with a site specific Construction Stormwater Pollution Prevention Plan are required
	Water Contamination from spills or hydraulic fracturing fluids in wellbores	Onsite reserve pits, blow-out preventers, secondary containment (dikes, pads, liners, sumps)	Secondary containment units, Catch Basins, containment berms, SPCC, NPDES permit
	Aquifer/Groundwater Contamination from Hydraulic Fracturing		Site specific monitoring and reporting; no local groundwater use and limited isolated occurrence of groundwater
	Contamination of soil/water from improper disposal or transportation of waste solids and fluids		BMPs required as part of SWPPP. BMPs include: operating procedures, and practices to control site runoff, spills/leaks, waste disposal
	Contamination of NYC unfiltered water supply	No hydraulic fracturing within 4,000 feet of these watersheds	Nothing comparable in California to NY unfiltered supply. No fracturing in Inglewood occurs closer than 1.5 miles (7,920 feet) from any water resource.

Table 5-3 Summary of Findings of the SGEIS and Comparison with Baldwin Hills CSD

Resource	SGEIS Impact	SGEIS Mitigation	Consistency with Inglewood Oil Field CSD
Freshwater Wetlands	Contamination from accidental release	Site-specific SEQRA review and required permits. Mandatory setbacks.	A system of catch basins around the field addresses potential for accidental releases. Regulated by NPDES program.
Ecosystems and Wildlife	Habitat fragmentation	BMPs to reduce habitat impacts, surveys and restrictions during mating migratory/mating seasons	Site specific special status species habitat protection plan and reporting Site specific Stormwater Pollution Prevention Plan
	Harm to populations due to habitat loss	Well pad reclamation	Site specific special status species habitat protection plan and reporting
	Invasive species	BMPs to reduce invasive species	Site specific special status species habitat protection plan and reporting Monitoring; restoration focused on removal of invasive species
Air Quality	Degradation of air quality	Technology standards, restrictions on sulfur content and BTEX class compounds, and public reporting	Implementation of Air Monitoring Plan. H_2S provisions. Extensive regulatory framework monitored and enforced by SCAQMD that exceeds NY requirements
GHG emissions	Increased GHG emissions due to drilling and production	GHG impacts mitigation plan	Compliance with AB 32 California Climate Change Act, GHG inventories Site specific Air Monitoring Plan
Naturally Occurring Radioactive Material	Exposure of workers and the public to harmful levels of radiation	Monitoring and testing requirements	CSD does not address because Naturally Occurring Radioactive Material does not occur onsite.
Visual	Temporary visual impacts from new structures	Visual impacts mitigation plan and design siting requirements	Landscaping Plan, Visual Site plan (removal of abandoned/unused equipment, licorice paint used on equipment)Screening landscaping, painting
Noise	Temporary Impacts from drilling and fracturing operations and traffic	Noise impacts mitigation plan	CSD Section E.5: Noise Attenuation (noise limits, back-up alarm restrictions, limited delivery hours, construction time limits, construction equipment requirements): Quiet Mode Drilling Plan including sound walls for drilling within 300 feet of residences.
Transportation	Increased traffic, damaged roadways	Road use agreements, transportation plan, road condition assessment	There is no anticipated impact/increase to traffic associated with future oil development; addressed in CSD EIR Inglewood Oil Field is an already developed, active oil field, and drilling is at existing pads to the extent feasible. Different from New York case where much of the development footprint is new.

STRONGER Reviews

In 2007 there were 33 states with either oil or natural gas production, 27 of which cumulatively produce more than 99.9 percent of the United States' oil and natural gas (GWPC 2009). The State Review of Oil and Natural Gas Environmental Regulations (STRONGER) was formed in 1999, and is a non-profit, multi-stakeholder organization that helps oil and natural gas producing states evaluate their environmental regulations associated with the exploration, development and production of crude oil and natural gas. Prior to 1999, reviews were jointly conducted by the IOGCC and USEPA. The USEPA, USDOE and the America Petroleum Institute, among others, have provided funding to support the STRONGER reviews of the State regulatory review processes. In 2009, a Hydraulic Fracturing Workgroup was formed within STRONGER to address regulatory issues specific to hydraulic fracturing as a well completion technology. STRONGER reviews in 2011 have tended to focus on oil and gas regulations as they apply to hydraulic fracturing operations. STRONGER developed guidelines for hydraulic fracturing in 2010, and reviews of this process in different states generally follow these guidelines. The guidelines are not detailed, but set forth general guidelines such as:

- Wells should be properly designed and constructed.
- Water, wastewater, and waste management should be planned and conducted carefully.
- Information on the chemicals used in hydraulic fracturing operations should be disclosed and reported.

Four states were reviewed in 2011: Oklahoma, Ohio, Louisiana, and Colorado. Pennsylvania was reviewed in 2010 and Arkansas was reviewed in 2012. There was a STRONGER review for California in 2002, but the review did not address hydraulic fracturing. The STRONGER state review process is a non-regulatory program and relies on states to volunteer for reviews. Summaries of the findings for California and the states reviewed from 2010 to 2012 follow below.

California

California regulations were initially reviewed by IOGCC and USEPA in 1992, at which time DOGGR made numerous beneficial changes to its program. For example, DOGGR initiated the Idle-Well Management Program, which aims to reduce the number of long-term idle wells by encouraging operators to reactivate or plug and abandon their idle wells. In addition, DOGGR has strengthened its requirements regarding well bonds and pipelines located in environmentally sensitive areas. STRONGER reviewed California's regulations in 2002. The STRONGER Review Team commended DOGGR's changes since the initial IOGCC/USEPA review and also took note of California's stringent regulations on exploration and production waste management requirements and UIC programs. The Review included DOGGR's public participation and outreach, interagency coordination, abandoned well program, and data management proficiency. During the 2002 review the Stronger Review team did not address, nor offer recommendations for, hydraulic fracturing operations or regulations (STRONGER 2002). This 2002 Review indicated that as of 2000, California had approximately 207 operating oil fields and produced 840,000 barrels per day, ranking fourth in the United States for oil production. Today, California produces approximately 550,200 barrels per day with 209 active oil fields (DOGGR 2011).

Oklahoma

The Oklahoma Corporation Commission and the Oil and Gas Conservation Division (OGCD) regulate oil and gas operations in the state. Hydraulic fracturing has been conducted in Oklahoma for over sixty years. More than 100,000 wells have been hydraulically fractured during this time and state regulatory agencies have never identified an instance where hydraulic fracturing has adversely affected groundwater resources. Specifically, the OGCD mapped the base of fresh water throughout the state and determined that the oil and gas producing zones were all much deeper than the base of fresh water in nearly all well locations. Consequently, the OGCD determined that the risk of drinking water contamination resulting from hydraulic fracturing operations is limited. Nonetheless, in 2010, the OGCD recently incorporated new regulatory measures, such as well completion reports, and stricter requirements for the storage and recycling of flowback water, to address this limited risk. The state also initiated a five-year plan to help manage hydraulic fracturing (STRONGER 2011a).

Pennsylvania

The STRONGER review for Pennsylvania was conducted in 2010. Hydraulic fracturing is regulated by the Department of Environmental Protection (DEP) and the Bureau of Oil and Gas Management (BOGM). Hydraulic fracturing has been used in Pennsylvania since the 1950s and nearly all of the wells drilled since the 1980s have been hydraulically fractured. According to the DEP there are no verified instances of groundwater contamination resulting from hydraulic fracturing. Pennsylvania has more comprehensive regulations than Oklahoma, likely due to the increased interest in development of the Marcellus Shale. (STRONGER 2010) For example, in 2008, BOGM began requiring plans to manage water withdrawal and protect water quality standards.

As a result of the development of the Marcellus Shale, there have been several surface and subsurface water control issues, such as water withdrawal and wastewater management. Plans must indicate how much water will be withdrawn and from where, so that the DEP can ensure that excessive water withdrawals will not impact water quantity. Produced water recycling is encouraged, and there are strong regulations for fracturing waste generation, transportation and disposal. The 2010 film “Gasland” highlighted drinking water concerns in the town of Dimock, Pennsylvania. This topic is addressed in Chapter 4, including the results of recent USEPA sampling of local supply wells in Dimock that did not detect contaminants of concern.

Ohio

Oil and natural gas operations are overseen by the Ohio Department of Natural Resources (ODNR) and the Divisions of Mineral Resource Management (DMRM). Hydraulic fracturing has been performed since the 1950s and most wells drilled today are hydraulically fractured. The STRONGER review did not identify any instances of groundwater contamination as a result of hydraulic fracturing. After an independent review of its oil and gas program, the DMRM updated its regulations pertaining to hydraulic fracturing in June 2010.

STRONGER’s 2011 review indicated that Ohio has strong reporting requirements and enforcement tools. They also praised Ohio for thoroughly reviewing potential pathways for groundwater contamination and increasing staffing levels in the DMRM. In addition, STRONGER commended Ohio for thoroughly reviewing and revising oil and gas regulations in

2010. STRONGER provided several recommendations on how to strengthen existing regulations including ensuring that sufficient information is available with regard to the chemical constituents of fracturing fluids and thoroughly evaluating the need for and availability of surface and groundwater for hydraulic fracturing operations in the context of competing water uses. The overall finding was that the regulations protect water resources. More than 800,000 wells have been fractured in Ohio without any verified instances of groundwater contamination (STRONGER 2011b).

Louisiana

Hydraulic fracturing has been occurring in Louisiana since the 1960s, and is regulated by the Louisiana Office of Conservation. Currently, the Haynesville Shale is the primary area of interest for hydraulic fracturing operations in the state of Louisiana. This formation must be fractured to be commercially productive. Work permits are required prior to well construction operations, including hydraulic fracturing. Production in the Haynesville Shale began in 1910 and there are 1,586 Class II injection wells in this area. There have been no cases of contamination of underground sources of drinking water in this area. There are also rules related to the exploration and production of gas in the Haynesville Shale, including setback, noise, vibration, odor, lighting, venting and flaring requirements. Regulations for pressure testing of casing and cementing, as well as requirements for fracturing fluid flowback storage and disposal, also exist (STRONGER 2011c).

Colorado

The Colorado Oil and Gas Conservation Commission regulates oil and gas operations, including hydraulic fracturing, which has been occurring in Colorado since 1947. Nearly all active wells in Colorado have been hydraulically fractured, and no instances of ground water contamination have been confirmed. In 2007, Colorado comprehensively updated its oil and gas regulations, resulting in several new requirements related to hydraulic fracturing including but not limited to: (a) chemical inventories at well sites are required, (b) wells must be cased with steel pipes and surrounded by cement to prevent fluid and gas leakage, (c) surface casing to a specified minimum depth is required for well control and to protect shallow aquifers, (d) setbacks, baseline water quality sampling and other improved environmental protections, (e) baseline water well sampling is required, and (f) operators developing coal bed methane (CBM) wells must inspect local plugged and abandoned wells within one-quarter mile, sample adjacent water supply wells, and meet other requirements to minimize gas or water leakage. These new regulatory provisions were all commended by STRONGER (STRONGER 2011d).

Arkansas

STRONGER issued its review of Arkansas' oil and gas regulatory program in 2012. The Arkansas Oil and Gas Commission regulates the industry, and the review concluded that the Arkansas program is well managed and generally meets the 2010 Hydraulic Fracturing Guidelines. Program strengths included an update of oil and gas rules in 2004, in response to the increased activity in the Fayetteville Shale. In particular, Arkansas was among the first states in the nation to establish a system for the public disclosure of chemicals used in hydraulic fracturing operations. The program also has an effective water well complaint protocol, and a web site with information on hydraulic fracturing, including the areas of the Fayetteville Shale with active hydraulic fracturing of wells.

The Fayetteville Shale currently has 4,000 active oil and gas wells, with plans for development of over 14,000 more natural gas wells. Both the Arkansas Oil and Gas Commission and the Arkansas Department of Environmental Quality have responded to complaints of water well contamination within the Fayetteville Shale development area. To date, neither agency has found any evidence of water contamination from hydraulic fracturing in any of the water wells tested. In addition, the United States Geological Survey office in Little Rock has recently completed a water well testing program in Van Buren County, one of the most heavily drilled counties where hydraulic fracturing operations have occurred. No evidence of contamination from hydraulic fracturing has been found in the water wells tested.

STRONGER recommended that Arkansas require agency notification prior to commencing hydraulic fracturing operations. They also recommended increased funding and staffing of the Arkansas Oil and Gas Commission to allow for inspections (STRONGER 2012).

Summary

The STRONGER reviews have focused on regulatory programs, but in each state they also evaluated records with respect to contamination of underground sources of drinking water by hydraulic fracturing activity, hence the relevance to this study. The states reviewed in 2011 and 2012 have thousands of wells that had been hydraulically fractured. No evidence for groundwater contamination was found in any of these cases. Reviews had been conducted by state agencies, federal agencies, and the U.S. Geological Survey.

Table 5-4 summarizes the findings of the STRONGER reviews as they relate to hydraulic fracturing. The first column includes strengths of the regulatory program, and the second column includes recommendations. In general the comments refer to the regulatory programs themselves.

Although the recommendations apply more to regulatory agencies than to specific oil fields, where the recommendations are specific to the process of hydraulic fracturing, the Inglewood Oil Field would either meet or exceed these recommendations. In part this is because the Inglewood Oil Field operates under enhanced environmental controls that require notification, setbacks, and other provisions as required by existing regulations, primarily the CSD. In addition, PXP is voluntarily following chemical disclosure policies that meet those recommended by STRONGER.

Table 5-4 Summary of State STRONGER Reviews of Hydraulic Fracturing

Existing Regulation Strengths as summarized by STRONGER	Recommendations from STRONGER
Oklahoma	
▪ Comprehensive regulatory standards for hydraulic fracturing have been developed which: (see following cells)	▪ Reporting requirements should include volumes of hydraulic fracturing fluids and proppants used, pressures recorded, and hydraulic fracture materials used
▪ Prohibits pollution of a fresh water from well completion activities	▪ Recycling of flowback water and use of alternate, lower quality water should be encouraged
▪ Provides minimum casing and cementing standards	▪ More stringent regulations with regard to notification to the Oklahoma Corporation Commission prior to fracturing operations should be required

Table 5-4 Summary of State STRONGER Reviews of Hydraulic Fracturing

Existing Regulation Strengths as summarized by STRONGER	Recommendations from STRONGER
▪ Provides strong regulations related to the construction and maintenance of flowback water storage tanks ▪ Requires sampling of hydraulic fracturing waste materials or flowback water to monitor chemicals of concern, primarily salts and TDS	▪ The state should procure additional funding to ensure a staffing needs are met based on expected needs in the future
Pennsylvania	
▪ Comprehensive water planning process to ensure that demands on water resources related to hydraulic fracturing are managed through a planning process	▪ Stronger casing and cementing requirements have been proposed but have not been adopted into law
▪ Regulations encourage baseline groundwater quality sampling plans	▪ Encourage more comprehensive baseline studies in situations where there are increased risk factors
▪ Potential risks must be identified in a preparedness plan, which requires operators to list chemical additives used and wastes generated	▪ Require operators to identify potential conduits for fluid migration
▪ Waste characterization is required, including generation, transportation and disposal tracking	▪ Require notification prior to hydraulic fracturing. Currently this information is only transmitted via well completion reports and DEP does not have the opportunity to inspect
▪ Strong waste storage tank/pit requirements	▪ Secondary containment requirements for tanks used in hydraulic fracturing regulations
Ohio	
▪ Comprehensive well completion reporting is required and must include type and volume of fluid used for stimulation, reservoir breakdown pressure, recovered fluid containment methods, etc.	▪ Chemical disclosure regulations should be more comprehensive than currently exist
▪ Casing and cementing plans are required during the permitting process	▪ The state should evaluate the impact of hydraulic fracturing on surface and groundwater availability
▪ Notification is required before hydraulic fracturing occurs ▪ Well permits require a comprehensive review of potential pathways for groundwater contamination ▪ Pit placement and construction guidelines are implemented through permit conditions ▪ Strong enforcement tools	▪ Stricter spill notification regulations
Louisiana	
▪ The use of alternative water sources and the recycling of waste fluids are encouraged and promoted by recent legal amendments	▪ The minimum depth of surface casing is based on the total depth of the well. To protect groundwater, the depth to the USDW and depths of productive zones should also be considered
▪ Permitting of commercial waste fluid treatment and reclamation for hydraulic fracturing water supply purposes has been streamlined to make the process easier	▪ There are no cementing requirements for well construction or for casing weights or grades. Standards should be developed to meet anticipated pressures
▪ Increase in water source and volume reporting requirements, coupled with recycling provisions has significantly decreased water demand	▪ Reporting should include materials used, volumes of fracturing fluids, proppants used, and fracture pressures
▪ Surface water has been sufficiently analyzed and there is adequate water available for anticipated hydraulic fracturing needs	▪ Spill Prevention and Control Plans are currently required, but additional contingency plans are recommended

Table 5-4 Summary of State STRONGER Reviews of Hydraulic Fracturing

Existing Regulation Strengths as summarized by STRONGER	Recommendations from STRONGER
Colorado	
▪ Operators are required to keep chemical inventories at all well sites, which must be provided to agencies and health care providers upon request	▪ To help protect water resources from contamination, standards should be developed for minimum and maximum surface casing depths. All past problems related to surface casing in a hydraulically fractured well should be considered when developing this standard.
▪ Bradenhead annulus pressure during hydraulic fracturing operations must be measured and reported in an effort to help protect groundwater	▪ Materials used, aggregate volumes of fracturing fluids, proppants used and fracture pressures should be recorded
▪ Identification of potential pathways for fluid migration is required in certain circumstance	▪ An evaluation of naturally occurring radioactive material in hydraulic fracturing wastes should be required ▪ The availability of water resources for fracturing operations should be evaluated, as water supply is a significant issue in this arid region. Plans should be implemented to maximize water reuse and recycling if it is determine that water supply is an issue ▪ Requires operators to study and address potential pathways for fluid migration in more detail ▪ Stricter regulations related to providing notification and receiving approval prior to hydraulic fracturing
Arkansas	
▪ Since 2006, AOGC reviewed and revised numerous rules concerning environmental and production related concerns associated with hydraulic fracturing	▪ Notification prior to hydraulic fracturing so field inspectors can better monitor operations and related activities
▪ Developed water well complaint protocol, guiding staff towards efficient review and response to water well complaints and identification of laboratory analysis parameters	▪ Funding to continue support of Arkansas Department of Environmental Quality and seek resources to better Department
▪ AOGC's user friendly website informs public of hydraulic fracturing operations and other pertinent information regarding hydraulic fracturing	▪ Funding to increase AOGC Staffing Levels to ensure Commission inspection goals are met

NRDC's Evaluation of Hydraulic Fracturing Wastewater and Disclosure Regulations

In May 2012, the Natural Resources Defense Council (NRDC) published a report analyzing regulations related to wastewater generated from hydraulic fracturing. The report focuses on wastewater disposal methods and regulations in Pennsylvania but notes that the issues raised are relevant everywhere hydraulic fracturing occurs.

The report states that the most common management options for shale gas wastewater are recycling for continued use during oil and gas operations, treatment and discharge to surface waters, storage in impoundments and tanks, and applying it to the land (e.g. dust suppression). NRDC highlights environmental concerns associated with each disposal method, such as accidental spills when wastewater is temporarily stored in tanks or ponds on-site, inadequate treatment at publicly owned treatment facilities, or chemicals washing off roadways as a result of the land application method. Subsequently, NRDC recommends the following policy changes to strengthen regulations: regulate discharges from treatment plants more strictly; regulate hydraulic fracturing wastewater as a hazardous waste, either under RCRA or state regulations; only allow injecting of wastewater with hazardous characteristics into Class I hazardous waste wells, and strictly regulate Class II disposal wells in the interim; and prohibit land application and temporary storage in impoundments and tanks.

At the Inglewood Oilfield, produced water is transported by pipeline to the field's water treatment plant where it is mixed with other produced water generated at the field, treated, and reinjected into the oil and gas producing formations. This is in accordance with CSD Condition E.2.(i), which requires that all produced water is contained within closed systems at all time. NRDC notes that on-site recycling can have significant cost and environmental benefits by reducing freshwater consumption as well as the amount of wastewater requiring disposal. NRDC also notes that disposal by underground injection requires less treatment than other methods and creates the least risk of contaminating the environment. NRDC notes that this method can create risks of earthquakes and can require transportation over long distances, though in the case of the Inglewood Oilfield it is transported within the field boundary via pipeline and the existence of the waterflood operation significantly reduces concerns of induced seismicity because it injects water in to the depressurized zones of oil extraction.

NRDC encourages on-site wastewater recycling, the method used at the Inglewood Oilfield for beneficial reuse of its treated produced water, and does not identify any related policy recommendations directly pertaining to wastewater reuse other than noting that the benefits of reuse can sometimes be offset by the energy use and generation of concentrated residuals (NRDC 2012a).

As noted above, the focus of the NRDC report is primarily hydraulic fracturing in the Marcellus Shale and Pennsylvania regulations. In response to the report, in July 2012, the Secretary of Pennsylvania Department of Environmental Protection (DEP) issued a letter stating that "the Report is incorrect and inapplicable to Pennsylvania in many respects." The letter asserts that the report incorrectly characterizes wastewater disposal methods currently used in Pennsylvania and the associated regulations. The letter also mentions that report underestimates the quantity of wastewater that is recycled and indicates that the NRDC is biased against the industry (Pennsylvania DEP 2012). In turn, the NRDC issued a response letter defending the report and continuing to urge Pennsylvania DEP to strengthen their regulations.

In addition to assessing wastewater regulations, in a separate article published in July 2012, NRDC conducted a comparison of disclosure regulations for hydraulic fracturing between states related to advance public notice requirements prior to hydraulic fracturing; disclosure of information concerning the geological and environmental context of the wells, comprehensive disclosure about the hydraulic fracturing "treatment" (i.e. pressures, volume and type of base fluids, depths, etc.); and disclosure about the volume of wastewater created as well as its storage, treatment and/or disposal. The article points to lack of public access to disclosed information even when disclosure regulations do exist, and poor compliance with and enforcement of regulation (NRDC 2012b).

5.6 Inglewood Oil Field in State and National Regulatory Perspective

The federal, state, and local laws, ordinances, regulations, and standards that govern oil field development throughout the United States require protections against the potential environmental impacts of the entire development process. These protections range from provisions in the Clean Air Act, Clean Water Act, Safe Drinking Water Act, Endangered Species Act, and through extensive California regulation addressing air quality, water resources, biological resources, and cultural resources, and at the local level. The Inglewood Oil Field is unusual in that it has much greater regulation and oversight of its operations than most other onshore oil fields as a result of the County of Los Angeles CSD.

The Baldwin Hills CSD, and the associated EIR, together address most of the issues that are part of a hydraulic fracturing operation, such as truck traffic, water use, community compatibility (noise, light and glare, etc.), air quality, and other environmental resource categories. In addition, the EIR evaluates cumulative impacts, and environmental justice. These two documents are incorporated by reference into this Hydraulic Fracturing Study, which evaluates the effects measured and monitored during the high-volume hydraulic hydraulic fracturing and high rate gravel packing operations conducted in 2011 and 2012, as well as past activities of this type. The Hydraulic Fracturing Study did not identify a new impact not analyzed in the EIR, nor did it identify impacts greater in significance than those analyzed in the EIR.

Exacting protective measures and close monitoring are required by the Baldwin Hills CSD and by county, regional and federal agencies. These field-specific reviews and public and agency interactions compel PXP to enforce real-time compliance with all environmental standards in the Inglewood Oil Field. The long history of oil production in the area provides operators with an excellent understanding of the local subsurface conditions and reduces standard risks and uncertainties that would be present in new operations.

Daniel R. Tormey, Ph.D., P.G.

Hydrogeologist, Geochemist, & Civil Engineer

Dr. Tormey is an expert in water and energy. He works with the environmental aspects of all types of energy and energy development, as well as water supply, water quality, hydrology, sediment transport, and groundwater-surfacewater interaction. He has well-developed skills in framing and analyzing environmental issues, and in communicating complex ideas to a wide range of audiences. Noted for the creativity of his approaches, he has conducted numerous studies related to the development of unconventional sources of natural gas, including high-volume hydraulic fracturing of oil and gas shales, and coal bed methane development.

Dr. Tormey has managed projects on behalf of government regulatory agencies (US Bureau of Land Management, US Forest Service, Federal Energy Regulatory Commission, US Bureau of Reclamation, US Army Corps of Engineers, US Office of Surface Mining, California State Lands Commission, California Public Utilities Commission, RWQCB-SD, local agencies) and for project proponents (PG&E, SCE, oil and gas companies, water agencies, among others). He has testified in the Federal Court of Claims on water rights and water takings issues. Dr. Tormey has managed the preparation of 15 Proponents Environmental Assessments for submission to the California Public Utilities Commission for projects including transmission lines and pipelines, and power plants fired by natural gas, oil, diesel, coal, and nuclear.

Dr. Tormey has evaluated environmental aspects and risks of oil and gas development and transport on many oil and gas fields in California and elsewhere in America, and more than 15 fields worldwide. He has led studies of the environmental impacts of hydraulic fracturing, water injection, and other oil and gas practices. He has evaluated beneficial reuse of produced water for agriculture, industrial, and restoration of habitat. He has studied carbon capture and storage using depleted oilfields as the storage reservoir, as well as the use of CO_2 for enhanced oil recovery. He has prepared environmental reports for pipelines carrying oil, natural gas, hydrogen, refined products, and biosolids. He has managed or been technical lead on offshore oil and gas projects, including licensing of eight liquefied natural gas (LNG) import terminals, marine terminals, and platforms (operation, abandonment, and reuse).   He has extensive experience in the preparation of environmental reviews supporting acquisition or divestiture of oil and gas producing facilities and related infrastructure.

He has worked on assessment, remediation, and restoration on many oilfields throughout the world, and is an expert on benchmarking and applying sound environmental solutions in that arena. He has pioneered bioremediation of oil-impacted soils, and has designed over 15 acres of such treatment cells. He has also considered the overall environmental setting (biological and cultural resources) of the oilfield in determining appropriate remediation responses.

Dr. Tormey has been technical lead for over two hundred projects requiring fate and transport analysis of chemicals in the environment, including modeling of chemicals in groundwater and surfacewater, study of linked groundwater-surfacewater systems, sediment transport analysis, quantification of adsorption/desorption kinetics, air dispersion modeling, among others. His work with contaminants also includes site assessment, forensic geochemistry, risk assessment, feasibility study, and site remediation. Dr. Tormey has served as a technical expert in fate and transport issues supporting either litigation and testimony in State Court, and agency testimony involving petroleum, solvents, metals, pesticides, and plastic components.

Dr. Tormey actively pursues volcanology research around the world, with a focus on interactions between geophysical variables that affect risk assessment, risk preparedness, and contingency planning.

Megan Schwartz
Senior Project Scientist

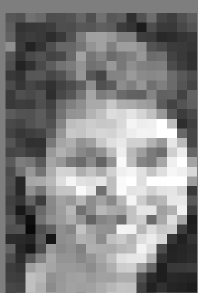
Current Position
Senior Project Scientist

Discipline Areas
> NEPA CEQA Planning
> Permitting
> Oil and Gas
> Renewable Energy
> Litigation Support
> Environmental Site Assessments

Education
> M.E.S.M. Environmental Science & Management, UC Santa Barbara, 2004
> B.A. Biological Anthropology, UC San Diego, 2002

Ms. Schwartz is a senior environmental planner and project manager with a Masters in Environmental Science and Management. She has addressed many controversial issues related to energy development in the southwestern United States and globally. Ms. Schwartz has addressed the potential impacts of proposed projects under both the California Environmental Quality Act (CEQA) and National Environmental Policy Act (NEPA). She also excels at regulatory compliance, including permitting and mitigation planning and implementation. She works with electrical local utilities and the oil and gas industry, as well as the regulatory agencies with jurisdiction over energy production.

Ms. Schwartz has worked on a variety of energy issues including hydroelectric power including dam removal on the Klamath River, oil and gas development around the world with a focus on water quality and community compatibility. She has also evaluated environmental effects of submarine cable installation, natural gas storage, transmission lines in the southwest and connecting to wind power in Mexico, and coal-fired power plants being either retired or repowered. Ms. Schwartz has been a technical lead on studies examining potential contamination of local groundwater supplies and beneficial reuse options of produced water from oil and gas fields. She has also evaluated the composition of additives used for hydraulic fracturing.



Molly Middaugh
Senior Staff Scientist

Current Position
Senior Staff Scientist

Discipline Areas
> Environmental Management, Permitting, and Compliance
> NEPA/CEQA
> Permitting
> Litigation Support
> Natural Resources Damages
> Environmental Communications
> Energy and Climate Change Policy

Education
> B.A. Environmental Analysis, Pomona College (Magna Cum Laude), 2010

Ms. Middaugh is a senior staff environmental scientist with a background in environmental science, economics, and policy. Her experience includes employment in the public, private and NGO sectors. Ms. Middaugh has worked on significant projects related to energy policy, with an emphasis on climate change, carbon offsets and international deforestation policy. She has a strong understanding of federal environmental regulations and policy that first developed when she worked for a member of the U.S. House of Representatives on Capitol Hill, as well as for the Energy and Climate Change program of the Center for Strategic and International Studies, also in Washington D.C.

Ms. Middaugh has evaluated the environmental impacts of energy and mining-related projects under the NEPA and CEQA process, as well as obtaining California and federal permits for these actions. She assists in analyzing and prioritizing environmental risks of oil and gas development. Ms. Middaugh also characterizes the chemical properties of and assesses beneficial reuses of produced water. She is currently engaged in the analysis of the chemical composition of fluids used as additives in hydraulic fracturing. She has also analyzed the environmental economic consequences in Natural Resource Damage claims.

Ms. Middaugh also works as part of the environmental communications team to translate technical scientific documents into more simple and understandable language.

FINAL REPORT

Context

In May, 2012, the authors of this report were selected by the County of Los Angeles (the "County") and Plains Exploration & Production Company ("PXP") as peer reviewers for the *Hydraulic Fracturing Study: PXP Inglewood Oil Field* prepared by Cardno-ENTRIX (the "consultant"). This report and peer review resulted from the Baldwin Hills CSD litigation Settlement Agreement.

Based on the direction provided in Term 13 of the Settlement Agreement, the objective of the peer review is to review the work of the independent consultant and provide advice to the consultant and a final evaluation to the County and PXP in order to provide an accurate and verifiable study:

> *The peer reviewer will be provided with access to all the data and materials provided to the independent expert. The peer reviewer shall agree to keep all proprietary information confidential. If the peer reviewer determines that the study is materially inadequate, incomplete or inaccurate, it shall so advise PXP's consultant who will complete the study as reasonably recommended by the peer reviewer and provide the revised study to the peer reviewer within 90 days. Upon acceptance by the peer reviewer, the study and all supporting material, including comments by the peer reviewer, shall be forwarded to the County, DOGGR, the Regional Water Quality Control Board ("RWQCB"), CAP and Petitioners and be available to the public, with any proprietary information redacted.*

In June, 2012, we began the process of reviewing the data used to develop the study, evaluating reports drafts and conducting a two day visit the site to get a perspective on the site context. What follows is a summary of the iterative process of review, advice and evaluation that led to the completion of the final study. Upon completion of the review, we both feel, based on information provided us and our own experience, that the report is adequate, complete and accurate and reflected thoughtful consideration for our comments and suggestions.

Process

We received the report draft of the study on July 14th, 2012 in compliance with the Settlement Agreement. We were also provided access to all data, research and reports used to assemble this draft at this time. We completed an initial review of the draft and the background material and developed comment and advice. These comments were communicated over a period of weeks rather than as one single response as we worked independently and then in coordination with each other and the contractor. This process allowed a number of key points to be refined based on effective criticism. The consultant responded by providing a revised draft for our review and advice. From this draft, we provided further advice and comment. The final study therefore reflects this iterative peer review process rather than a single review and response that typify journal peer review. Ultimately, the final report is more responsive to our input than may have been otherwise.

Throughout this process, we strived to offer thoughtful and timely input into the evaluation and provide advice to the consultant on ways to improve the study and ultimately to consider whether the report was materially adequate, complete and accurate. In this memo, we tried to be cognizant of this charge and summarize the process, advice and evaluation.

Evaluation of the Draft Reports

Overall Impression: For the first draft of the report, both of us concluded that the report's organization was overly complex which might have made it difficult for a general audience to understand. We found ourselves losing some key concepts due to the flow. We suggested that certain chapters be combined and that the flow reflect a time relationship. This request led the consultant to produce a second draft reflecting the reorganization. The number of chapters went from 11 to 7 in total. With this consolidation and reorganization, the second draft was far more understandable for the non-technical reader.

The major consolidations involved creating a chapter called "Environmental Effects Monitored in Conjunction with Hydraulic Fracturing Tests" by combining two chapters that split the environmental effects into two parts. Also, the overall discussion of hydraulic fracturing was taken from two chapters to one covering "past, present and future." Finally, a single regulatory chapter captured both the regulatory framework of various jurisdictions and public concerns with operations that were originally two separate chapters. This new report structure carries to the final version.

The study benefits from the tremendous amount of available data. Given the field's long history of production, there is a significant amount of data available to assess the geological and operating conditions at the field. In addition to the historic data, the current operator conducted two fully-monitored hydraulic fracturing operations and two high-rate gravel packs. Other available data includes a number of reports on geological characterization, environmental evaluations, potential community impacts, and regulations. The draft report did a reasonable job presenting a summary of this vast database. We offered some suggestions of ways to streamline the material presented to enhance readability.

Completeness: Both the first and revised draft were quite comprehensive and for the most part complete. A few areas found to be lacking in the first draft included the following:

1. Given the relevance of fluid migration to this topic, we felt that the consultant needed to expand the discussion of hydraulic connectivity given in the first draft. In the revised draft, the discussion was combined into one clear section discussing this important topic.
2. The first draft was lacking a truly representative geological cross section of the field along with a geologic map. A sequence of cross sections providing a better visualization and a geologic map of the field appeared in the revised draft.
3. Being that our experience is primarily in the northeastern USA and Canada, we thought that a better discussion was needed on how this field compares to those outside of California where many of these issues have arisen.
4. Many figures lacked scales, adequate figure captions, and legends. In the revised draft, these items were improved. Annotation was added to the remaining figures for the final report.
5. We suggested a revised discussion of induced seismicity to include the relevance of the 1983 Coalinga earthquake to potential hydraulic fracturing in the, deeper thrust-faulted, pre-Pliocene units of the Inglewood field in light of similar geologic settings and regional stress regimes. This was included in section 4.5.5.

Also, there were a few key resources were not included in the draft that, if included, could help the reader understand the issues involved with hydraulic fracturing including Frolich 2012, Myers 2012, NRC earthquake study 2012, USGS 2012, and Warner 2012. Most of our suggested references were incorporated into the revised draft and many of these references were used to respond to our concerns above.

Adequacy: As mentioned, the draft report was extremely comprehensive. There were a few areas that we did not feel were completely adequate:

1. The diagrams showing the geologic structure at the field are difficult to understand and interpret. We requested that these should be redone or the text should be expanded to explain the visual. The final draft accomplishes this.
2. The oil fields of California and this field particularly are not similar to the fields of either Texas or the northeast. This distinction needed to be adequately explained to put the discussion of environmental issues in context. The revised draft did a much better job of this.
3. The regulatory section initially did not focus on the key elements of California in a way that made it clear to us how operations are regulated. The revised draft

combined sections and brought California front and center making this much easier to follow.

Accuracy: We did not find any major inaccuracies in either draft though there were some specific statements that were either inaccurate or contradictory and needed revision. Also, there were a few statements that lacked supporting evidence and could be questioned for accuracy. We requested that these statements be corrected or supporting evidence be provided. In response to our comments the author corrected statement in revised draft or provided a rationale for leaving the text as is that satisfied our inquiry.

Topic-Specific Report Comments

In addition to the numerous typographical edits and suggestions, there were some topic-specific comments that we spent considerable time reviewing. These topics include geology, induced fractures, seismicity, environmental issues, and regulation.

Geology: We had some issues with the readability of the diagrams for non-technical audiences. The first draft included one diagram which did not convey the complexity of the field as described by the work of Elliot and others (2009). The final version includes all three of their cross sections and the description. This helps to explain the geological conditions in the field much better and helps put the 3D visualizations in context. Blade-like features in the subsurface of several of the diagrams were unexplained and easily misinterpreted as fracture orientation. These features actually represent the distribution of proppant for the hydraulic fracturing stages. The final draft clarifies this with better legends.

Induced Hydraulic Fractures: We had some trouble understanding the discussion of the height and orientation of the induced hydraulic fractures from the two Nodular Shale tests. We suggested clarification of height of induced fractures to read height of zone of induced fractures. This change was made in the final draft.

Seismicity: In addition to the comment on page three, we requested some discussion of how the operator designs the surface infrastructure for hydraulic fracturing to mitigate the impact of a seismic event similar to what occurred at Coalinga. The final draft includes a description of the required standards for structures and other surface equipment.

Environmental Issues: The report covered the environmental issues typically identified with hydraulic fracturing but these issues were spread among a few chapters. We suggested that they be combined into one chapter.

One issue that we commented on was the potential for fluid migration. The first draft did approach this topic but we felt that a clearer description needed to be included regarding why the geology limited fluid movement. In the revised report, the information presented and the flow of the discussion better explains why the lack of hydraulic connectivity minimizes the potential for fluid migration off of the site.

Since air emissions releases are of concern, the air quality section needs to be as comprehensive as possible. The draft report covered this topic well in three different chapters. We suggested that this might be more effective if most of this information could be condensed into the environmental effects chapter. This was accomplished in the reorganization of the revised draft.

There are a number of issues with hydraulic fracturing that are actually common to any oilfield operation regardless of the completion method. This includes many of the community impacts such as traffic and noise. The Baldwin Hills CSD EIR covers many of these common issues. Though we did not suggest that this study repeat the contents of the EIR, we felt that some reference should refer the reader to the appropriate EIR documents.

Regulation: The first draft covered regulations but we felt that the section should be reorganized so California regulation was covered first and that comparisons with other jurisdictions be made to California. Upon revision, the new regulation section accomplishes this effectively. The comparison table with the New York SGEIS is particularly useful to identify specific issues such as spill containment that were identified as important issues in the New York process.

Concluding Comments and Final Report Evaluation

Through the iterative review process, our comments, questions and criticisms were integrated into study in ways that, we feel, improved the final product. As peer reviewers, it is not our charge to become coauthors but to offer suggestions for improvement based on our expertise. In the end, the work remains that of the authors.

As the endpoint of the peer review process, the County and PXP has asked us to make a determination as specified in the Settlement Agreement:

> "If the peer reviewer determines that the study is materially inadequate, incomplete or inaccurate, it shall so advise PXP's consultant"

On September 30, 2012 we received from the consultant the final report for review and acceptance. Upon review, we both feel, based on information provided us and our own experience, that the report is adequate, complete and accurate and reflected thoughtful consideration for our comments and suggestions. This document serves as our final advice to the consultant, the County and PXP.

The Reviewers:

John P. Martin, Ph.D.

John is the founder of JPMartin Energy Strategy LLC which provides strategic planning, resource evaluation, project management and government/public relations services to the energy industry, academic institutions and governments. Prior to forming JPMartin Energy Strategy LLC in 2011, John spent 17 years working on energy research and policy issues at the New York State Energy Research and Development Authority and developed a series of projects targeting oil and gas resources, renewable energy development and environmental mitigation. He currently serves on the USDOE's Unconventional Resources Technical Advisory Committee. While at NYSERDA, he co-directed the Governor's Carbon Capture and Sequestration (CCS) Working Group, an interagency committee organized in 2007 to address CCS issues and served as point person on a series of technical studies looking at all aspects of hydraulic fracturing and multiwell pad development. John regularly lectures and publishes on such diverse topics as the shale resources development, carbon capture and sequestration, compressed-air energy storage, renewable energy resource development, and research policy. Prior to joining NYSERDA, he worked in academia, consulting and regional planning. He holds a Ph.D. in Urban and Environmental Studies, an M.S. in Economics and a B.S. in Geology, all from Rensselaer Polytechnic Institute. He also holds an M.B.A. from Miami University and completed graduate work in mineral economics at West Virginia University.

Peter D. Muller, Ph.D., C.P.G.

Independent consulting geologist specializing in structural geology, geologic mapping, and geologic data analysis. Presently researching subsurface migration of fluids in the northern Appalachian Basin and the relationship to hydraulic fracturing. Senior Geologist with Alpha Geoscience (2010-2012) concentrating on shale gas development in NY and PA. Professor of geology at the State University of New York at Oneonta (1983-2009; Chair 1999-2003) teaching courses in structural geology, map and field geology, engineering geology, mineral resources, waste management, physical geology, and environmental science. Worked as a staff geologist for Dames and Moore Consultants (1973-1975) and the Maryland Geological Survey (1980-1982). Peter received his BS in geology from Bucknell University (1971) and PhD in geology from Binghamton University (1980). He has extensive geological field experience in a wide range of settings, both domestic and international, and has published peer-reviewed research (articles and maps) on the structure, petrology, and tectonics of the Maryland Piedmont, the Adirondack Mountains of New York, and the Ruby and Blacktail ranges of southwest Montana.

All component information listed was obtained from the supplier's Material Safety Data Sheets (MSDS). As such, the Operator is not responsible for inaccurate and/or incomplete information. Any questions regarding the content of the MSDS should be directed to the supplier who provided it. The Occupational Safety and Health Administration's (OSHA) regulations govern the criteria for the disclosure of this information. Please note that Federal Law protects "proprietary", "trade secret", and "confidential business information" and the criteria for how this information is reported on an MSDS is subject to 29 CFR 1910.1200(i) and Appendix D.

Hydraulic Fracturing Fluid Product Component Information Disclosure

Fracture Date	1/5/2012
State:	California
County:	Los Angeles
API Number:	0403726421
Operator Name:	Plains Exploration & Production
Well Name and Number:	VIC1 635
Longitude:	-118.3771225
Latitude:	34.00234951
Long/Lat Projection:	NAD83
Production Type:	Oil
True Vertical Depth (TVD):	8,430
Total Water Volume (gal)*:	125,248

[illegible]

[illegible]

[illegible]

[illegible]

3.1.7 Data Validation and Reporting

The samples were analyzed by [illegible] Laboratories in [illegible], California; [illegible] Laboratories, Inc., in [illegible]; and [illegible] Laboratories in [illegible], Wyoming. [illegible]

- [illegible] Laboratories, Inc., [illegible], California
- [illegible] Laboratories, [illegible], South Carolina
- [illegible] Laboratories, Inc., [illegible], Ohio
- [illegible], Inc., [illegible], Wyoming
- [illegible] Laboratories, Inc., City of Industry, California

The reports from all [illegible] laboratories were reviewed for [illegible]. Data validation review was performed by [illegible], California, [illegible]. [illegible]

The quality control [illegible]. [illegible] assigned qualifier flags to the data as follows:

- J - The analyte was positively identified, but the reported numerical value is an approximate concentration of the analyte in the sample.
- [illegible] - [illegible] additional information.
- U - The analyte was analyzed for, but was not detected at or above the reported sample quantitation limit.
- UJ - The analyte was not detected at or above the reported sample quantitation limit and the reported quantitation limit is approximate and may or may not represent the actual limit [illegible] the analyte in the sample.

- [illegible]

- [illegible]

3.2 Downhole Video Surveys and Well Owner Questionnaires

[illegible]

[illegible]

- [illegible]
- [illegible]
- [illegible]

[illegible]

4.2 Water Supply Well Sampling

4.2.1 June and August 2012 Groundwater Sampling

[illegible]

[illegible]

- [illegible]
- [illegible]
- [illegible]
- [illegible]
- [illegible]

- [illegible] (U.S. EPA, 2012).

- U.S. EPA Drinking Water Advisory [illegible] (U.S. EPA, [illegible]).

In the tables of laboratory analytical results, when the value of an analytical result is less than the method detection limit (MDL) or the [illegible] limit (RL), [illegible]. The MDL and RL are defined below:

- MDL: The minimum concentration of a substance that can be measured and reported with 99 percent confidence that the analyte concentration is greater than zero; it is determined from analysis of a sample [illegible] containing the analyte.

- RL: The RL is greater than the MDL. It is laboratory specific and is [illegible]. The RL is [illegible] in the quantification of the sample concentration.

When the concentration of an analyte is between the MDL and the RL, there is confidence that the analyte is present but the actual concentration is [illegible]. These concentrations reported between the MDL and RL are [illegible] a "J" flag.

In the tables of [illegible] of field water-quality parameters and laboratory analytical results, when a reported concentration is greater than a drinking water standard or comparison value, the result value is highlighted [illegible]. In accordance with notes in the tables, [illegible] result is also highlighted.

4.3.2 Historical Groundwater Sampling Events

This section includes [illegible] from previous sampling events. These include historical sampling results from 1979 to 2008, [illegible] from 2009 through 2011 [illegible].

Previous sampling events (from 1979 to 2008) include the following:

- LGRC for the well owners following installation in 1996

- [illegible], on behalf of [illegible], from September 2006 through October 2008. The October 2008 sampling was performed [illegible]

[illegible]

- [illegible]
- [illegible]
- [illegible]
- [illegible]
- [illegible]

[illegible]

- Phase I: March 2009
- Phase II: January 2010
- Phase III: October 2010
- Phase IV: April 2011

ABSTRACT

Unconventional natural gas production in the Marcellus and Utica formations of the Northeastern United States raises concerns about potential impacts to shallow groundwater. We examined and interpreted 13,040 analyses from pre-drilling groundwater samples from domestic water wells in northeastern (NE) Pennsylvania and 8004 samples from water wells in the "Western Area" which includes southwest Pennsylvania, eastern Ohio, and north-central West Virginia. These samples were acquired on behalf of Chesapeake Energy Corporation as part of its local pre-drilling water supply monitoring program. We evaluated concentrations of major ions and metals relative to federal drinking-water-quality standards upon which regulatory decisions are often based. Chesapeake's dataset, the most comprehensive for these areas, shows that exceedance of at least one water-quality standard occurs in 63% of water well samples in NE Pennsylvania and 87% in the Western Area. In NE Pennsylvania, 10% of the samples exceeded one or more of the United States Environmental Protection Agency's (USEPA) primary maximum contaminant levels (MCLs) for drinking-water supplies, 46.1% of the samples exceeded one or more of USEPA secondary maximum contaminant levels (SMCLs), and another 7% exceeded one or more of USEPA health advisory or regional screening levels for tap water.

In the Western Area 8% of samples exceeded one or more MCLs, 65% exceeded one or more SMCLs, and 15% exceeded one or more health advisory or regional screening levels for tap water. Chesapeake's dataset, orders of magnitude larger than any in previously published literature, shows that water-quality exceedances relate to factors such: as where the sample occurs within the groundwater flow system, the natural groundwater chemical type (hydrochemical facies), the geologic unit producing the water, and/or the topographic position (valley versus upland). Our comparison of these results to historical groundwater data from NE Pennsylvania, which pre-dates most unconventional shale gas development, shows that the recent pre-drilling geochemical data is similar to historical data. We see no broad changes in variability of chemical quality in this large dataset to suggest any unusual salinization caused by possible release of produced waters from oil and gas operations, even after thousands of gas wells have been drilled among tens of thousands of domestic wells within the two areas studied. Our evaluation also agrees with early researchers such as Piper (1933) and Lohman (1939, 1937) who found that the saline waters in both areas underlie fresher groundwater. The saline water is naturally-occurring connate brine or salt water which has not been flushed by circulating meteoric water; rather than vertical migration of salt water from deep strata such as the Marcellus shale as suggested by Warner et al. (2012). Elevated metals concentrations, particularly iron and manganese, partly relate to sample turbidity; dissolved metals would provide a more accurate measurement of metals in shallow groundwater than does the total metals analysis typically required by regulations.

1. Introduction

The recent (post-2005) drilling and production of "unconventional" natural gas from the Marcellus and Utica Shale formations (Devonian and Ordovician age, Appalachian Basin, eastern North American) sparked broad public concern that shallow groundwater may be affected by recent drilling or production activities (e.g. Vidic et al., 2013; Kramer, 2011). Natural gas and oil produced from tight shale, coal beds, and tight sands using horizontal drilling and/or hydraulic fracturing techniques are termed "Unconventional". State regulatory agencies responded to this concern by generating regulatory frameworks designed to assess pre-drilling (baseline) water supply quality to identify possible changes in solute concentrations related to hydrocarbon extraction. Conventional oil and gas development, coal mining, agricultural development, septic effluent discharges, road salting, commercial development, and industrial development all have occurred in Appalachia for over 100 years; therefore this region cannot be viewed as "pristine" in the strictest sense. Without a proper understanding of pre-existing groundwater geochemical variability, investigators may incorrectly conclude that unconventional oil and gas development has altered shallow groundwater quality when it has not (i.e. a false positive).

In this paper, we present interpretation of the inorganic chemical composition of over 21,000 samples of groundwater collected by third party contractors from individual domestic or stock water-supply wells before Chesapeake Energy Corporation (Chesapeake) drilled nearby Marcellus and Utica shale oil/gas wells in Pennsylvania, West Virginia, and Ohio. In our analysis, we compare this pre-drilling data to the combination of federal water-quality standards and guidelines, and evaluate whether geology, topographic position, groundwater circulation patterns, groundwater chemical types (hydrochemical facies), and sample turbidity relate to water quality.

Chesapeake's dataset is unparalleled in size and is orders of magnitude larger than prior studies (e.g. Molofsky et al., 2013, 2011; Warner et al., 2012; Boyer et al., 2012). In northeast (NE) Pennsylvania we interpreted 13,040 groundwater sample analyses from 12,844 domestic/stock water wells and in southwest (SW) Pennsylvania, eastern (E) Ohio, and north-central (NC) West Virginia (collectively termed the "Western Area"), we interpreted 8004 sample analyses from 7983 water wells. Combined, these datasets provide the most comprehensive information on general chemistry and trace elemental composition of shallow groundwater in the Appalachian Basin to date.

2. Background

Unconventional and conventional oil and natural gas production in the Appalachian Basin commonly extract naturally occurring saline waters from oil and gas source beds and these produced saline waters usually exceed drinking-water standards for trace metals, major solutes, and dissolved solids (e.g. Chapman et al., 2012; Siegel et al., 1991). However, trace metals, major solutes, and dissolved solids also naturally exceed regulatory concentrations in many shallow groundwater aquifers in the Appalachian Basin (Ayotte et al., 2011; DeSimone, 2008). Some of these exceedances occur because shale and other rocks in the Appalachian Basin naturally contain potentially soluble minerals incorporating trace metals (e.g. iron, manganese, strontium, and barium) that are common in deep formation fluids (e.g. Siegel et al., 1987). Road de-icing and septic-system effluent can also contribute salinity to potable groundwater. Saline connate water occurs naturally at the base of all shallow freshwater flow systems in both areas (e.g. Williams et al., 1998; Feth, 1970, 1981; Poth, 1963; Lohman, 1939, 1937; Piper, 1933). Exceedances of drinking-water standards in water wells of the Appalachian region have occurred long before unconventional oil and gas development began (e.g. Gross and Low, 2012; Chambers et al., 2012; Low and Galeone, 2006; Williams et al., 1998; Stoner et al., 1987; Taylor, 1984; Matisoff et al., 1982).

Several recent studies in the Appalachian Basin addressed possible changes in potable groundwater chemical conditions prior to and after unconventional shale gas development. Warner et al. (2012) concluded, from variations in salinity, that deep Marcellus shale water may have naturally migrated upwards in the geologic past to shallow aquifers in NE Pennsylvania; a finding challenged by Engelder (2012). In contrast, Boyer et al. (2012) and Molofsky et al. (2013, 2011) found no evidence that methane or dissolved ions are systematically related to oil and gas operations.

Historical studies (e.g. Razem and Sedam, 1985; Poth, 1973a,b; Poth, 1973c, 1963; Carswell and Bennett, 1963; Lohman, 1939, 1937; Piper, 1933) provide detailed discussions on the natural occurrence of groundwater chemistry and connate brines found at shallow depths throughout Appalachia (including NE Pennsylvania and the Western Area). For example, Lohman (1939) noted that in north-central Pennsylvania: "*Most of the waters that contained more than 100 parts of sodium were from the Chemung formation* [now referred to as the Lock Haven Formation] *or from formations or deposits overlying the Chemung, and probably represent diluted connate water, that is, sea water that became trapped in the marine sediments at the time of deposition and subsequently diluted by meteoric water*." Fresh groundwater of meteoric origin flushes the salt water from the upper-most rocks, but only partially flushed it from deeper rocks, or from strata that have little groundwater circulation (such as in valleys) which Poth (1963) noted is where deep groundwater moves upward.

Eighty years ago, Piper (1933) reported circulating groundwater in bedrock of SW Pennsylvania evolves from young calcium-magnesium bicarbonate (Ca-Mg-HCO_3) water type in the uppermost groundwater, to older sodium-bicarbonate (Na-HCO_3) type at intermediate depths, and still older water deeper (and often in valleys) mixing with residual connate sodium-chloride (Na-Cl) brines. Piper (1933) also found that the presence of coal and carbonate minerals in rocks of Appalachia plays an important role in the occurrence of iron, sulfate, and hardness in groundwater.

However, there has not yet been a groundwater study that determines if chemical quality in groundwater prior to unconventional gas exploitation has been systematically maintained. To this end, we interpret the largest and densest dataset on groundwater quality available for Appalachia: 21,044 analyses from 20,827 domestic groundwater wells in Pennsylvania, Ohio, and West Virginia, orders of magnitude larger than prior studies. These samples were collected as part of Chesapeake's pre-drilling sampling program. Because many wells were nearby and in place prior to any sampling for a new unconventional gas well, this pre-drilling database also serves as a means to explore if prior drilling has modified natural groundwater quality.

Our study and many of the more recently referenced studies lack well-log data for the water wells sampled. This inhibits certain evaluations, but the overall size of the dataset provides significant information about general water-quality patterns. Reliance on previous work (e.g. Razem and Sedam, 1985; Poth, 1973a,b,c, 1963; Carswell and Bennett, 1963; Lohman, 1939, 1937; Piper, 1933) that described groundwater flow system conceptualization helped put these data into proper context. The United States Geological Survey (USGS) is currently conducting a groundwater availability study of the Appalachian Plateaus (USGS, 2014) where Pennsylvanian- and Mississippian-age groundwater flow systems are being studied.

3. Study area and general hydrogeology

Chesapeake's contractors collected and analyzed pre-drilling samples in NE Pennsylvania (Fig. 1) and in a Western Area, covering SW Pennsylvania, NC West Virginia, and E Ohio (Fig. 2). We evaluated these two geographic areas separately since the geology, physiography, and hydrogeology of the two regions differ. Unconventional gas in the Marcellus Formation is being developed in NE Pennsylvania, whereas unconventional gas and hydrocarbon liquids are being developed in the Western Area from both the Utica and Marcellus shales.

In NE Pennsylvania (Fig. 1) the sampling density averages 1 sample per 1.5 square kilometers (km^2) and approximately 98% of samples were collected from Bradford, Sullivan, Susquehanna, and Wyoming Counties; in the Western Area (Fig. 2) sampling density averages approximately 1 sample per 4.7 km^2.

A generalized stratigraphic column for NE Pennsylvania and the Western Area is provided in Fig. 3. The general hydrogeologic settings of both study areas (Razem and Sedam, 1985; Poth, 1973a,b,c, 1963; Carswell and Bennett, 1963; Lohman, 1939, 1937; Piper, 1933) have been known for many years as well as the general geochemical variability of shallow groundwater. Potable groundwater in NE Pennsylvania generally occurs in the upper 250 meters (m) of the subsurface, and overlies a freshwater-saline interface approximately 250 m deep under uplands and approximately 60 m deep beneath valleys (Williams, 2010). In NE Pennsylvania, relief is greater and regional flow systems are mostly found in valley bottoms where groundwater flow is controlled by regional dip of formations, topography, and hydrogeological boundaries coincident with large river valleys (Carswell and Bennett, 1963). In NE Pennsylvania, potable groundwater comes from fractured sandstones, siltstones, and shale of the Catskill and Lock Haven formations of Upper Devonian age (Figs. 1 and 3), alluvial deposits, and glacial outwash. Approximately 1500–3000 m of underlying rock separates the Marcellus and Utica shales producing commercial gas from these drinking-water aquifers in our study areas.

The Catskill and underlying Lock Haven formations consist of deltaic and marine shale, siltstone, sandstone and conglomerate interbedded with carbonaceous sediments and sometimes coal (e.g. Wilson, 2014; Castle, 2000; Taylor, 1984; Piotrowski and Harper, 1979). Precipitation recharges shallow groundwater systems through vertical shallow fractures and unconsolidated materials, and groundwater naturally discharges to streams in intervening valleys or as side-slope springs (e.g. Williams et al., 1998; Seaber et al., 1988).

In the Western Area, potable groundwater comes from Mississippian- and Pennsylvanian-age fractured rocks of the Allegheny-Pottsville formations and the Conemaugh and Dunkard groups (Fig. 2). These fractured rocks consist mostly of fluvial-deltaic non-marine shale, siltstone, sandstone, and limestone interbedded with commercially minable coal (Stoner et al., 1987; Razem and Sedam, 1985). In the Western Area, where relief is lower than in NE Pennsylvania, there is less driving head necessary to form deep flow systems. Here, groundwater flow is characterized by short flow paths typically extending no more than a few tens of kilometers (encompassing local and intermediate flow systems) with fresh water extending a few tens of meters below land surface before salt water is encountered (USGS, 2014). Permeable coal units above streams can act as drains and can be regional potable water aquifers (e.g. Carswell and Bennett, 1963).

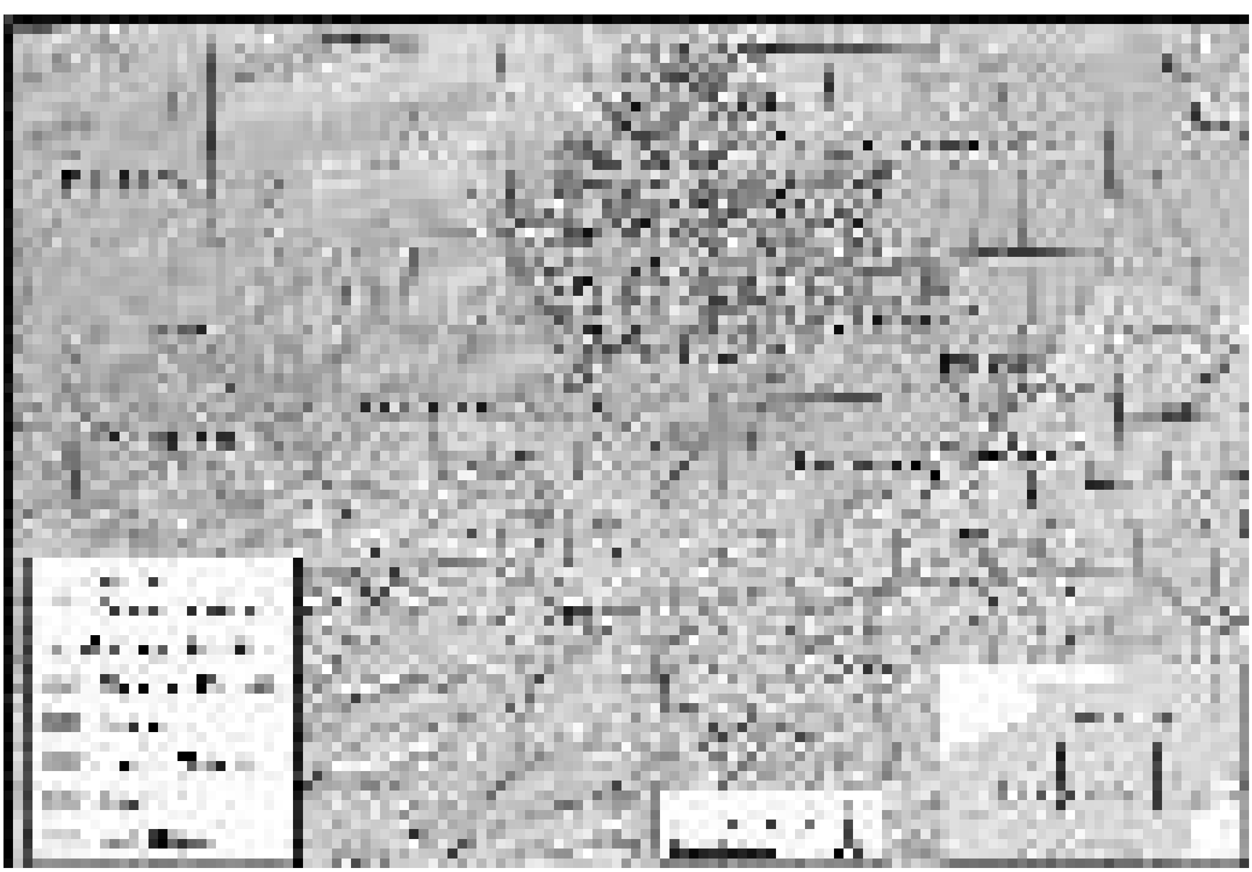

Fig. 1. Chesapeake's pre-drilling sample sites and key stratigraphic units in Northeast Pennsylvania. Samples that fall outside of the key stratigraphic units are categorized in the "Other" formation category. Approximately 98% of pre-drilling samples were collected from these 4 counties in NE PA: Bradford, Sullivan, Susquehanna, and Wyoming.

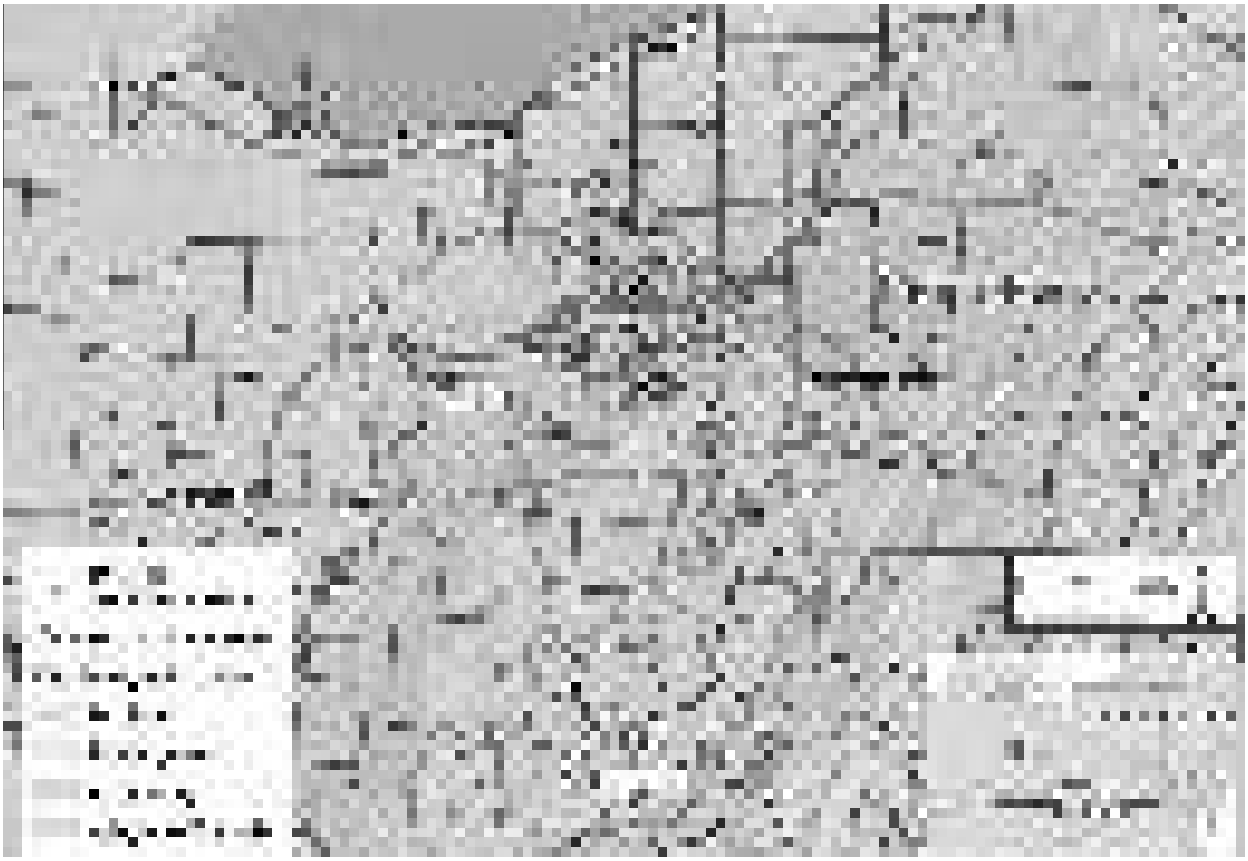

Fig. 2. Chesapeake's pre-drilling sample sites and key stratigraphic units in the "Western Area". Samples that fall outside of the key stratigraphic units are categorized in the "Other" formation category.

In both areas, shallow wells typically yield fresh water whereas deeper wells generally find salt water (in valleys, shallow wells also commonly find salt water). According to Piper (1933), Lohman (1937, 1939), and Poth (1963) the salt water is connate water (salt water present during marine deposition) but has been modified by various physical and chemical processes. In the upper-most rocks, connate salt water has been flushed by recharging meteoric water in contrast to deeper water only being partially flushed or not flushed at all by circulating meteoric waters.

In NE Pennsylvania, groundwater typically evolves along flow paths from a Ca-HCO_3 hydrochemical facies to a Na-HCO_3 facies and finally sometimes to Na-Cl facies groundwater in valley discharge areas (e.g. Molofsky et al., 2013; Williams et al., 1998; Callaghan et al., 1998). Domestic water wells can also intersect isolated coal lamina within the Catskill and Lock Haven formations (e.g. Wilson, 2014; Molofsky et al., 2011). Where the coal occurs, particularly in the Western Area, oxygenated recharge water leads to groundwater with high concentrations of iron and sulfate from pyrite oxidation.

Most private domestic water wells completed in consolidated bedrock in both the Western Area and NE Pennsylvania consist of open-rock wells, with only a short surface casing driven through the shallow, unconsolidated sediments or unstable bedrock. As a result, there is no filter pack to filter out clay- and silt-sized sediment and other particulates since the well bore is open to the formation. In contrast, water wells completed in alluvium and glacial deposits in stream valleys are typically open-ended completions (casing with an open end). Screened completions are rare in domestic wells (Williams et al., 1998).

4. Methods

4.1. Regulatory framework

The geochemical dataset we describe consists of data compiled from Chesapeake's groundwater quality survey programs designed to sample domestic/stock water wells within a radius of 762–1219 m from proposed unconventional oil and gas well sites prior to drilling operations. The spacing of sampling was done according to accepted state regulatory programs, but Chesapeake often went beyond the requirements of these programs (for example the required pre-drill sampling distance per Pennsylvania Department of Environmental Protection (PADEP) regulations in Pennsylvania is 762 m, but Chesapeake often extended the sampling distance to 1219 m). Chesapeake's contractors collected 13,040 pre-drilling samples from domestic or stock water-supply wells in NE Pennsylvania between June of 2009 and January 2012. In the Western Area 8004 samples were collected by contractors between September of 2009 and June 2012. Pre-drilling sampling continues in both areas and all data is released to relevant state agencies and individuals whose groundwater was sampled.

Although these samples were collected to provide *pre-drilling* water quality reference points at the local scale, conventional oil and gas drilling had occurred in both regions prior to 2007. In the four primary counties of NE Pennsylvania (Bradford, Sullivan, Susquehanna, and Wyoming), where 98% of these pre-drilling sampling data were collected, approximately 78 conventional wells had been drilled from 1900 through 2012, compared to about

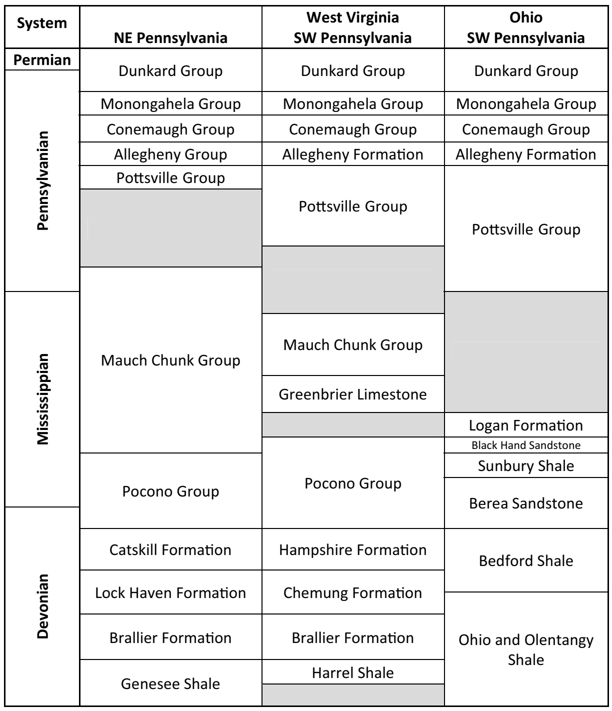

Fig. 3. Generalized stratigraphic columns for Paleozoic rocks in Pennsylvania, West Virginia, and Ohio that occur at/near the surface or are part of bedrock aquifers in the study areas (modified from Lloyd and William (1995), Trapp and Horn (1997), Ohio Geological Survey (1998), and USGS (2012)). The Dunkard Group includes the Greene, Washington and Waynesburg formations in Pennsylvania, West Virginia, and Ohio. The Pocono Formation is also known as the Burgoon Formation or Burgoon Sandstone in Pennsylvania. The lower portion of the Pocono Formation is also known as the Huntley Mountain Formation in Pennsylvania. The stratigraphy for SW Pa is most similar to West Virginia or Ohio.

1934 unconventional wells from 2007 through 2012 according to PADEP records (PADEP, 2015). Prior to 2007, approximately 5 unconventional wells had been drilled in NE Pennsylvania, and slightly over 30 in the Western Area.

Therefore, while the dataset represents pre-drill samples for specific future unconventional oil/gas wells, the same samples also reflect *post-drilling* samples for oil/gas wells than may have been in place at the time of sampling. Siegel et al. (2015) recently reported from the same dataset in NE Pennsylvania that there is no systematic increase in dissolved methane proximate to existing gas and oil wells. In the Western Area there are a much larger number of pre-existing conventional wells dating back to the mid-1800s.

4.2. Water well sampling protocols

Chesapeake's contractors collected groundwater samples from actively used domestic or stock water wells (from water outlets before treatment systems or pressure tanks, if possible) three to six months before natural gas drilling began in accordance with state regulatory programs. No samples were collected from public water systems. Sampling adhered to individual state regulatory protocols, and samples were analyzed in accordance with established US Environmental Protection Agency (USEPA) test methods and internal laboratory standard operating procedures (SOPs) using best practices accredited by the National Environmental Laboratory Accreditation Program (NELAP) and/or state regulatory authority. Chesapeake used three national contract laboratories for the analytical testing and four national contract environmental engineering firms to collect and process the groundwater samples. Chesapeake personnel did not collect, handle, or transport any pre-drilling samples.

In some instances more than one sample was collected from the same well. In almost all of these instances, only one additional sample was collected. In NE Pennsylvania, approximately 196 additional samples were collected, and in the Western Area approximately 21 additional samples were collected. These additional samples constitute a very minor portion of the dataset, and almost all were still collected as pre-drilling samples. Where these additional samples exist, the water-quality evaluation only used the highest concentration for a particular parameter.

As per protocols, unfiltered water samples were collected after allowing water to run for approximately 15 min to clear water lines and pressure tanks. Field measurements for water temperature, turbidity, pH, and specific conductance were made using standard field instruments (e.g. handheld YSI 556MPS multi-parameter meter and Lamotte 2020 field turbidity meter).

Once stability in field measurements were obtained, the sample aliquot was field-preserved with nitric acid to pH < 2 standard units (S.U.) for metals analyses and one or more unpreserved aliquots were collected for general chemistry parameters. Unpreserved aliquots for dissolved light gases were also collected and those results will be discussed in another paper. All samples were shipped to analytical laboratories overnight under chain-of-custody control and maintained at 6 °C or less.

The standard pre-drilling analytical parameter lists for both NE Pennsylvania and the Western Area are shown in Table S1 in Supplemental Information. This parameter list included 38 different laboratory analytical parameters as well as 4 field parameters. Figs. S1 (NE Pennsylvania) and S2 (Western Area) in the Supplemental Information present box and whisker plots showing percentiles for each parameter. Tables S2 (NE Pennsylvania) and S3 (Western Area) in the Supplemental Information summarizes the key statistics (such as mean, median, minimum value, maximum value, percentiles, and standard deviation) for each parameter. Analytical detection limits were equal to or below applicable water-quality standards noted in Table S1 (Supplemental Information). All analyses were done according to USEPA protocols and quality assurance, with appropriate instrumentation; the reader is referred to USEPA for details on these standard laboratory approaches (USEPA, 2014).

The analytical data was reviewed for Quality Control and Quality Assurance by third party contractors who uploaded the data into an electronic database maintained by Chesapeake.

4.3. Drinking-water standards and benchmarks

We compared the pre-drilling groundwater data to USEPA drinking-water standards (USEPA, 2015a) and guidelines: primary maximum contaminant levels (MCLs), secondary maximum contaminant levels (SMCLs), health advisory levels (HALs), or regional screening levels (RSLs) for tap water (USEPA, 2015b). The USEPA primary drinking water MCLs are enforceable health-based standards applied to public-water systems whereas SMCLs are non-enforceable standards for contaminants that may cause cosmetic or esthetic effects to the water. The USEPA HALs provided information on constituents (such as sodium) that may affect human-health. Finally, USEPA RSLs are risk-based screening levels considered protective for human health. Although we recognize that these standards are locally enforced differently, they have in practice been considered the same in the public debate over unconventional gas development (ATSDR, 2011).

If there was no MCL for a parameter, we used the SMCL. If no MCL or SMCL was available, we used a HAL or RSL for tap water. All regulatory drinking-water standards or guidelines used in this evaluation are provided in Table S1 (Supplemental Information).

4.4. Water well topographic position

Heisig and Scott (2013), Williams et al. (1998), and Stoner et al. (1987) identified possible relationships between water chemistry and topographic position in the Appalachian Basin and we similarly assessed this by classifying water chemistry in wells in "upland" or "valley" topographic settings. We include hilltops and intervening slope areas in the upland category; valleys include valley floors.

Topographic position can be broadly used as a proxy for groundwater residence time, or age based on subsurface flow paths through aquifers. Fig. 4 shows a generalized conceptual hydrochemical flow model for the Appalachian Plateau. Typically, older groundwater becomes more mineralized due to water–rock interactions along flow paths and mixing with connate brines. Streams in valley settings of the Appalachian Plateau serve as local- to intermediate-scale groundwater discharge zones, along with side-slope springs. Groundwater in major river valleys, the terminus of local, intermediate and regional groundwater flow paths, can be more mineralized than groundwater in upland settings. The left-hand side of the Fig. 4 reflects conditions more representative of the Western Area where interlayered coal seams containing pyrite lead to more sulfate in shallow groundwater than found in NE Pennsylvania.

We evaluated topographic position in NE Pennsylvania and the Western Area by two automated approaches. The first, the Topographic Position Index (TPI) method (Jenness et al., 2013; Weiss, 2001) compares (LiDAR) elevation at a particular location to the mean elevation in a neighborhood around the location. The second method uses average valley widths (after Molofsky et al. (2011)) and then applies buffers of corresponding size to stream centerlines from the National Hydrography Dataset (NHD) to validate the locations of valleys. We used the same buffers used by Molofsky et al. (2011); a 305 m buffer for the larger streams and a 152 m buffer for the smaller streams. In our analysis, we only used those wells where both methods agree with respect to occurrence of water type relative to topographic position.

4.5. Water well completion depth and geology

We estimated the probable formation that each well was set in by overlaying the well locations onto GIS shape files of USGS or state geologic survey bedrock maps (Nicholson et al., 2007; Pennsylvania Bureau of Topographic and Geologic Survey, 2001).

Information about well depth was provided by the well owner. Williams et al. (1998) noted that there are three water well types in common use in NE Pennsylvania: an open-hole well, an open-end well, and a screened well. Williams et al. (1998) noted that screened wells are mostly used in non-domestic wells completed in unconsolidated deposits, while the first two are used in most domestic completions.

We did an extensive review to match water-well logs in the Pennsylvania Groundwater Information System (Pennsylvania Department of Conservation and Natural Resources, 2014) database with the domestic/stock water wells from which the pre-drill samples were obtained, with limited success. Taylor (1984) published well completion data from 890 wells in Bradford, Susquehanna, Sullivan, and Wyoming counties of NE Pennsylvania wherein he showed completion information for wells based upon topographic setting (i.e. valleys, side slopes, or hilltops). Almost all wells completed on hilltops and side slopes were open-hole completions in the Catskill and Lock Haven formations, and in the valleys over 71% of the domestic wells after penetrating alluvium were still open-hole completions in the bedrock. Water wells in valley settings therefore cannot be assumed to be completed only in unconsolidated materials. Most high capacity wells for public, irrigation, industrial or commercial needs are completed in unconsolidated materials, but this is not the case with domestic water wells, which make up the entirety of the pre-drilling dataset.

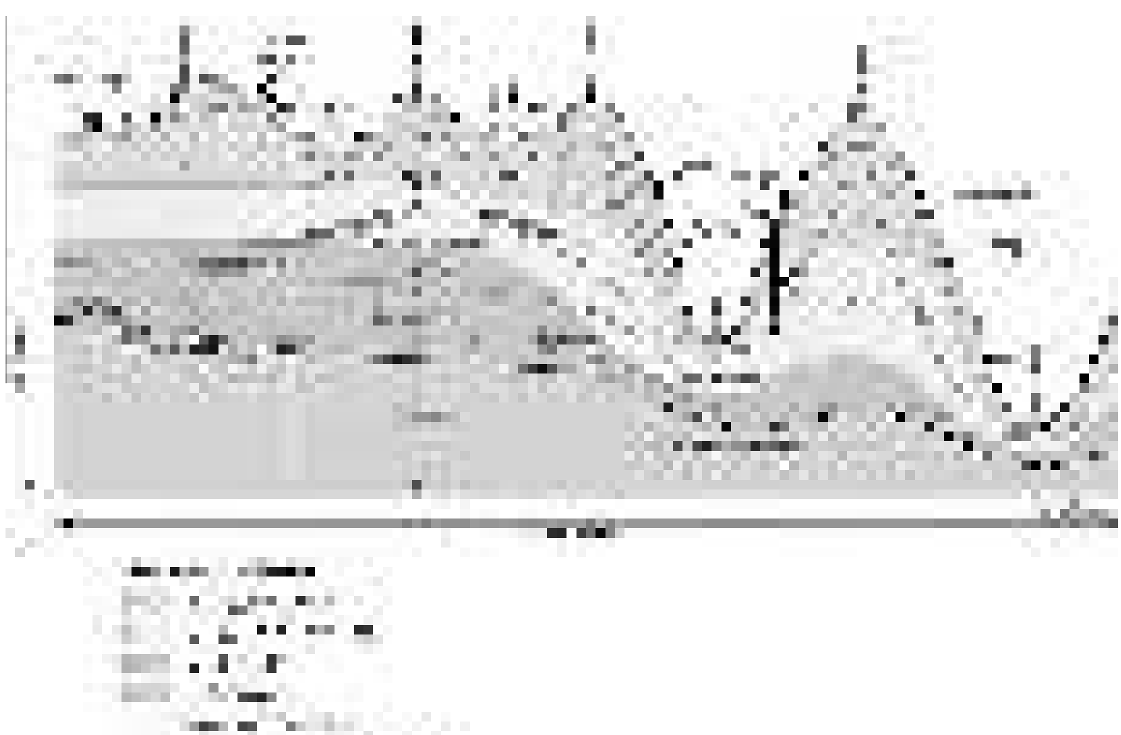

Fig. 4. Conceptual diagram showing groundwater flow zones in the Appalachian Plateau for different hydrogeologic settings and relationship with hydrochemical facies (modified after Fleeger (1999) and Wunsch (1995)). In the "Western Area", flow systems are shallower with waters in both regions discharging to streams possibly having variable chemistries based on the nature of the local convergence of flow systems at different scales—local, intermediate, and regional.

For our analysis we assumed that domestic water wells on side and upland areas overwhelmingly consisted of open-hole wells obtaining water from fractured bedrock. We knew the mapped bedrock formation underlying valleys and assigned valley wells per that bedrock type, knowing that there will be some unknown percentage of wells that would actually be completed only in the overlying alluvial or glacial deposits. However, our review showed that the common practice in the four-county area of NE Pennsylvania is to drill through unconsolidated sediments, set steel surface casing, and complete an open-hole well in the bedrock formations.

We also used well depth estimates to evaluate completion intervals in the valleys. Information provided by Taylor (1984) showed that the median depth for water wells completed within unconsolidated materials in valleys was 18.3 m (75th percentile was 28.3 m) for the four-county area representing the majority of the pre-drilling samples. When we evaluate the water well depth database for NE Pennsylvania, approximately 75% of wells completed in valleys have depths that exceed the median value of 18.3 m for unconsolidated deposit wells.

For geological evaluations involving these data, we have removed those wells that are more likely to be completed in unconsolidated deposits in valley settings which have reported well depths less than 28.3 m (approximately 3000 wells removed). Removing these shallow valley wells removes most of the potential influence of the unconsolidated deposits. After completing this process, we found essentially no difference in median parameter values of concentrations measured between the two datasets, showing that wells in valleys are mostly completed in bedrock formations, or that unconsolidated deposits have nearly identical water quality.

Table S4 (Supplemental Information) provides our estimate of the number of samples from each geological group or formation in NE Pennsylvania and in the Western Area. Table S5 (Supplemental Information) provides estimates of the number of samples from each geological formation in a particular topographic position (upland or valley setting).

We assumed that the bedrock unit supplying the groundwater to the water well was the same as the bedrock unit mapped at the ground surface or sub-cropping beneath the valley sediments. This is a reasonable assumption for the majority of wells because of the near horizontal attitude of the formations and overall thicknesses. For example, the Catskill and Lock Haven formations can be 1707 m (Inners, 1981) to 1219 m (Taylor, 1984) thick, respectively, compared to a median well depth in this area of 50.3 m (maximum reported well depth of 518 m). In NE Pennsylvania, 94% of the pre-drilling samples were from locations overlying the Catskill or Lock Haven formations.

For simplification in the Western Area, we evaluated bedrock at the Group level rather than the individual formation (see stratigraphic column in Fig. 3). For example, we combined the Greene, Washington, and Waynesburg formations into the Dunkard Group. In the Western Area, 90.5% of the pre-drilling samples were from the Allegheny/Pottsville formations and the Conemaugh Group. Our broad approach would lead to misidentification of the geology only where wells are extremely deep (and could intersect a different unit) or near the contact between formations; a very small fraction of the overall dataset. In areas where alluvial or glacial deposits were present, most domestic water wells were still completed into bedrock, and steel casing driven through the unconsolidated deposits.

4.6. Analysis of data

We used Microsoft Access and Excel, and Stata® software, version 11.2 (StataCorp., 2009) to calculate summary statistics. We provide a summary of the pre-drilling analytical data including key statistics as well as boxplots for analytes in the Supplemental Information.

4.7. Geochemical software and ion balance

We used the water-quality analysis program AquaChem® (Schlumberger, 2011) to generate Piper trilinear diagrams, calculate ion-charge balances, and determine primary ion water types. Piper diagrams visually characterize the broad geochemical evolution of shallow groundwater and can distinguish different groundwater types, mixtures of waters, and in some cases, major geochemical processes along groundwater flow paths (e.g. Hounslow, 1995).

We classified groundwater type or hydrochemical facies by selecting the single cation and anion present in each sample with highest percentage of cation or anion concentration (as milliequivalents per liter, meq/L). For convenience and the purpose of this broad synthesis, we did not address in detail mixed-water types, although the Piper diagrams show that geochemical mixing widely occurs. For example, mixed water types such as calcium-sodium bicarbonate (Ca-Na-HCO_3) or Ca-Mg-HCO_3 do occur within our study areas. It is possible that subdividing our broad regions into smaller areas will lead to better understanding of specific geochemical processes conditional with natural water chemistry. We include results only with a charge balance within ±7% in all groundwater hydrochemical facies evaluations. However, the full dataset, regardless of charge balance, was used for comparisons to relevant drinking-water standards.

4.8. Water treatment by water well owners

As part of our study, we determined whether water samples were collected prior to or after a home water-treatment system (a bag filter for sediment removal, water softener, and far less commonly, a home/tap reverse-osmosis unit). In cases where the water-treatment status was unknown, it was assumed that he water was sampled before any treatment in accordance with the sampling program protocols.

Table S6 (Supplemental Information) shows the breakdown of sample numbers that were treated, untreated, or unknown for each region. We excluded all treated and unknown samples, regardless of treatment system type, in hydrochemical facies classification by Piper diagrams. Although our approach excluded many samples for this specific evaluation, over 2600 untreated samples remained in NE Pennsylvania and over 3400 samples in the Western Area within a charge balance of ±7%. These are still large datasets by any measure and are sufficiently representative of the total population.

In our interpretation of arsenic, barium, cadmium, chromium, iron, lead, lithium, manganese, mercury, silver, sodium, and strontium water-quality patterns, we used all sample results regardless of charge balance or whether the water sample was collected after a treatment system. We used total results (unfiltered samples) since state regulatory agencies base their assessments on concentrations of total metals in water-supply systems, not dissolved solutes even if particulates occur in the water. We understand that from a regulatory standpoint, turbid water can lead to an inference of contamination. In turbid water, metals bound in the crystal lattices of clay-sized particulates become incorporated in the chemical analysis. These particulates are natural, and regulators may interpret these results as contamination presumed in the dissolved state when, in fact, it is not present. We wanted to assess how prevalent such false positives could be.

5. Results

5.1. Quality of analyses

In addition to evaluating ion charge balances for individual samples, the mean of all charge balances can provide an assessment of overall quality of a database (Fritz, 1994) and should be close to zero. The mean raw ion charge balance (with 1 standard deviation) was 0.30 ± 7.82% and 1.77 ± 6.07% for NE Pennsylvania and the Western Area, respectively. The overall mean of the absolute ion charge balance is 4.53 ± 6.37% and 3.86 ± 5.01%, for NE Pennsylvania and the Western Area, respectively.

If we only consider those data with ion balances within ±7%, then for NE Pennsylvania the overall mean ion balance is 0.49 ± 3.17% and the absolute mean balance is 2.63 ± 1.84%. Similarly for the Western Area, the overall mean ion balance is 1.41 ± 2.97%, and the absolute mean balance is 2.74 ± 1.82%. These mean ion balances are considered excellent for both groups of samples. For NE Pennsylvania, 83% (9361) of the samples with analyzed major ions balanced within our ±7% criterion and within the Western Area, 88% (7042) of the samples were within ±7%. We present the summary statistics for the ion balances in Table S7 in the Supplemental Information for reference.

5.2. Pre-drilling groundwater-quality exceedances

5.2.1. Northeast Pennsylvania

Table 1 shows the percent of exceedances of USEPA water-quality standards from the pre-drilling groundwater samples in NE Pennsylvania. Fig. 5a–k shows the spatial distribution of pre-drilling samples exceeding standards for arsenic, barium, iron, lead, manganese, sulfate, chloride, lithium, sodium, total dissolved solids (TDS), and turbidity, respectively.

Fig. S3 in the Supplemental Information shows the spatial distribution of all samples exceeding an MCL, SMCL, HAL, or RSL (excluding turbidity) for NE Pennsylvania. In NE Pennsylvania, 10.2% of the pre-drilling samples exceeded one or more MCLs (excluding turbidity). If turbidity is included then 22.1% of all pre-drilling samples exceed a MCL. Secondary MCLs were exceeded in 46.1% of the samples. Fig. 6 shows the percentage of water-quality exceedances per guideline or standard category for NE Pennsylvania.

The most common pre-drilling MCL exceedances were for turbidity (15.6%), arsenic (4.2%), lead (3.6%), and barium (3.3%). The most common SMCL exceedances were for manganese (33.9%) and iron (23.8%). Sodium concentrations exceeded the USEPA HAL of 20 mg/L in 38.5% of pre-drilling samples. Lithium exceeded the USEPA RSL for tap water in 19.1% of the well pre-drilling samples. Other metals also occasionally exceeded recommended standards. If all the MCL, SMCL, RSL, and HAL standards or guidelines are considered collectively (excluding turbidity), then approximately 63.0% of all pre-drilling samples collected from NE Pennsylvania exceeded at least one drinking-water standard, 34.3% exceeded two or more drinking-water standards, and approximately 15.4% exceed three or more standards. Including turbidity, 63.1% of pre-drilling samples exceeded one or more drinking-water standards.

Our results agree with historical water-quality studies in NE Pennsylvania (e.g. Ayotte et al., 2011; DeSimone, 2008; Williams et al., 1998; Taylor, 1984) that relied on much smaller datasets and before unconventional gas drilling began. For example, Williams et al. (1998) reported about 50% of 223 water wells sampled in a three county area within the pre-drilling sampling area of NE Pennsylvania had iron and manganese concentrations in groundwater exceeding SMCLs. Williams et al. (1998) also showed that chloride, arsenic, barium, cadmium, and lead concentrations

Table 1
Pre-drilling sample results exceeding drinking water guidelines – Northeastern Pennsylvania.

Parameter[a]	Number of samples analyzed[d]	Drinking water guideline or standard (mg/L)	Drinking water guideline or standard type[b]	Number of Samples exceeding guideline or standard[d]	Percent of Samples exceeding guideline or standard[d]
Arsenic	11,034	0.010	MCL	462	4.2
Barium	11,074	2.0	MCL	362	3.3
Benzene	11,075	0.005	MCL	1	<0.1
Cadmium	11,034	0.005	MCL	4	<0.1
Chloride	11,073	250	SMCL	221	2.0
Chromium	11,034	0.1	MCL	0	0.0
Ethylbenzene	11,075	0.7	MCL	0	0.0
Iron	11,075	0.3	SMCL	2647	23.8
Lithium	1729	0.04	RSL	331	19.1
Lead	11,032	0.015	TTL	405	3.6
Manganese	11,074	0.05	SMCL	3752	33.9
Mercury	11,034	0.002	MCL	0	0.0
Surfactants[c]	11,071	0.5	SMCL	28	0.3
pH	11,073	6.5–8.5 S.U.	SMCL	645	5.8
Selenium	11,032	0.05	MCL	17	0.2
Silver	11,034	0.1	SMCL	0	0.0
Sodium	11,074	20	Advisory	4263	38.5
Strontium	3423	12	RSL	10	0.3
Sulfate	11,075	250	SMCL	82	0.7
TDS	11,075	500	SMCL	554	5.0
Toluene	11,075	1	MCL	0	0.0
Turbidity	11,076	5 NTU	MCL	1738	15.7
Xylenes	11,075	10	MCL	0	0.0

TDS: Total Dissolved Solids.
[a] Samples analyzed for metals were not filtered during sampling or analysis. Some of the results may represent samples collected after a treatment system (e.g. particulate filter, water softener, etc.) within the water distribution system.
[b] Guideline or Standard types (see Table 1): MCL –USEPA primary Maximum Contaminant Level for public drinking water supplies; SMCL –USEPA Secondary MCL; RSL – USEPA Regional Screening Level for tap water (January 2015); TTL – treatment technology action level for lead defined by USEPA for public drinking water supplies; Advisory –USEPA drinking water health advisory for individuals on a restricted sodium diet.
[c] Surfactants analyzed as methylene blue active substances (MBAS).
[d] For duplicate samples only sample with highest value used for each parameter.

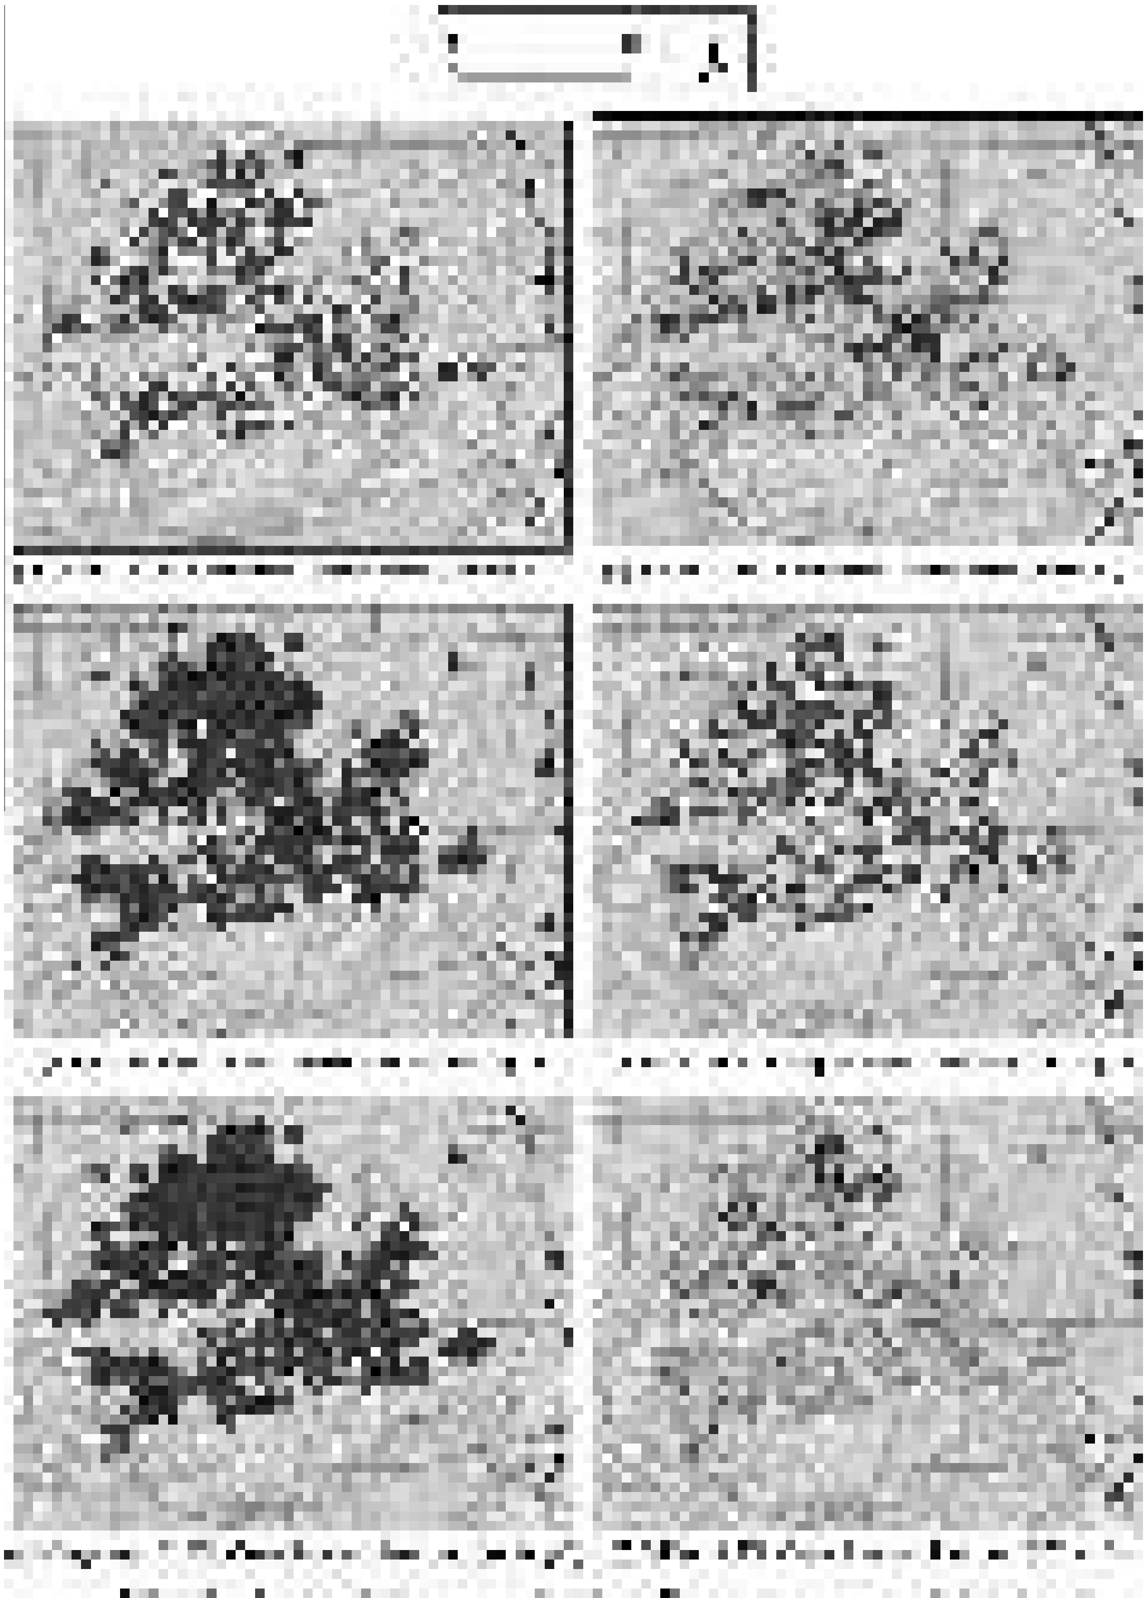

Fig. 5. Distribution of trace metals and other constituents in pre-drilling groundwater samples in Northeastern Pennsylvania. Samples exceeding the applicable MCL or other drinking water standard are shown with a red symbol; such elevated concentrations occur commonly in pre-drilling samples across the study area. The applicable standard and percent of samples exceeding that standard are listed beneath each map. For wells sampled more than once, the sample with the highest value is shown. Layers are vertically stacked in order shown in legend and some "no exceeds" may be covered.

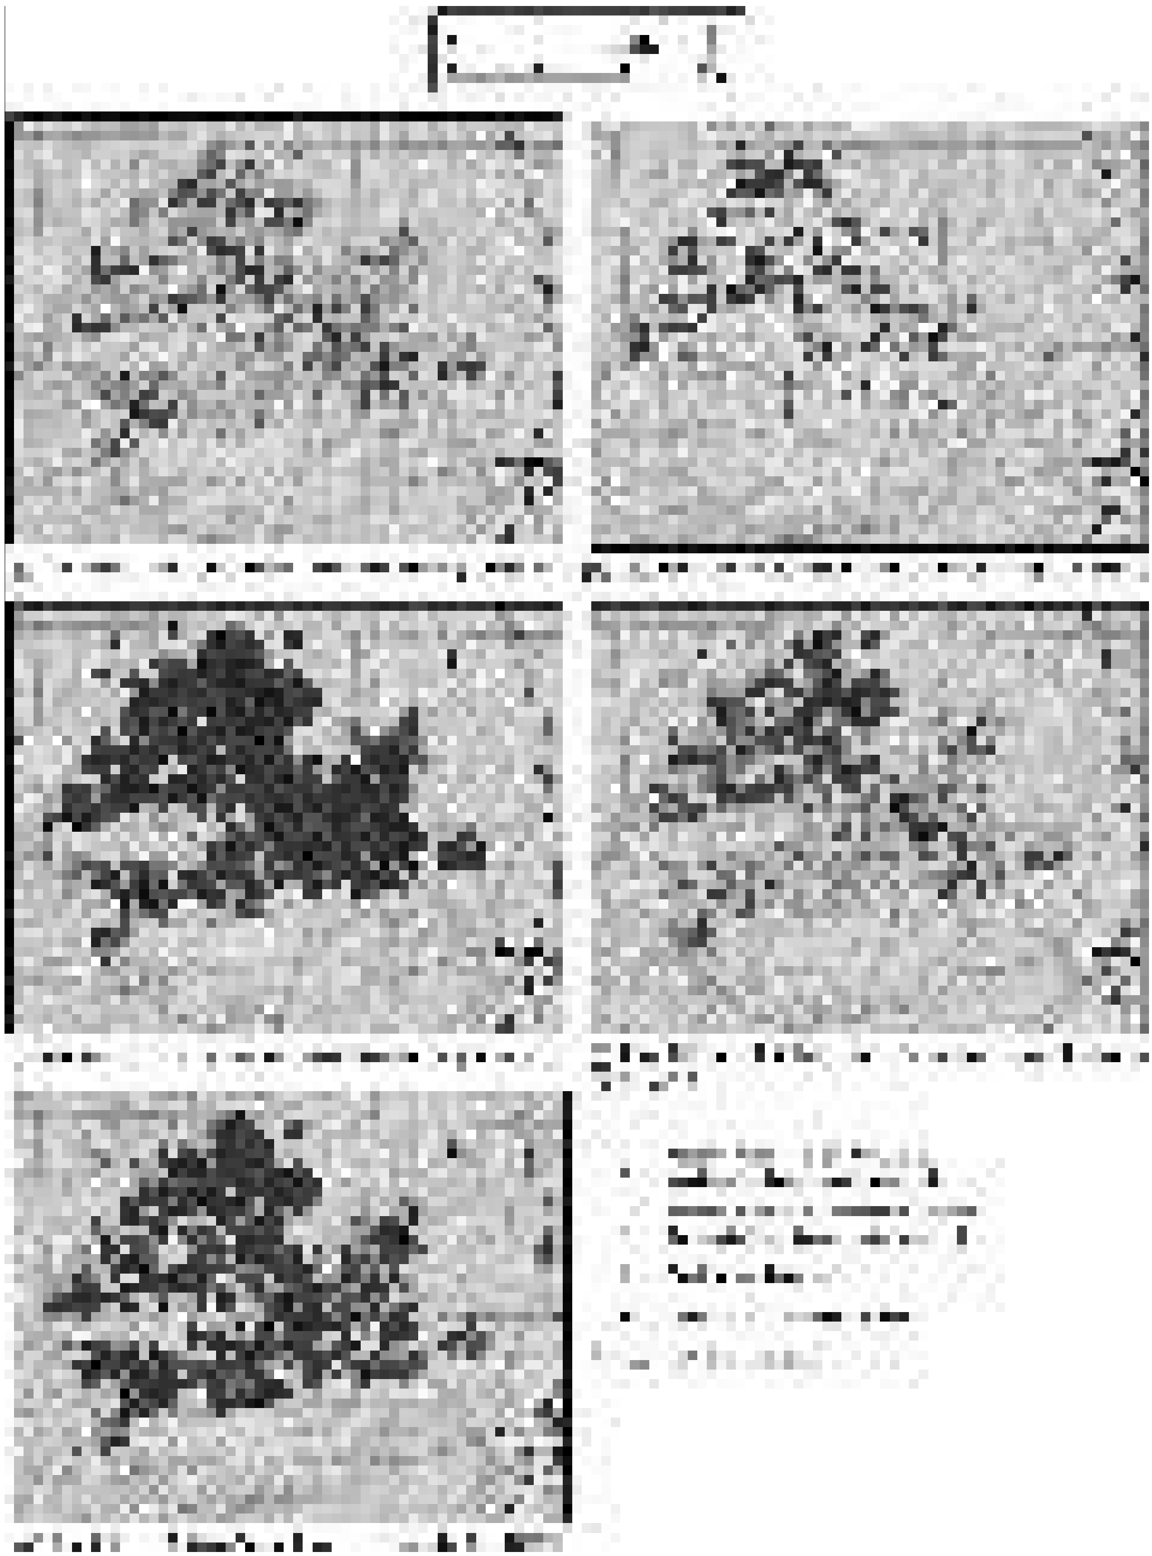

Fig. 5 (*continued*)

in groundwater can also exceed MCLs/SMCLs, especially in restricted-flow zones containing shallow naturally-saline groundwater, and about 40% of sodium concentrations in that study exceeded the HAL.

Table 2 compares the key water-quality parameters from the historical data provided in Williams et al. (1998) and Taylor (1984) to the 2009–2012 pre-drilling data for the Catskill and Lock Haven formations. The median chloride, TDS, and sodium concentrations in the pre-drilling data, shown in Table 2, have similar ranges as the historical data (pre-2007) from the Catskill and Lock Haven formations. These major parameters defining groundwater tie closely with water-quality type.

The Williams et al. (1998) pre-1987 historical data from the Catskill and Lock Haven formations also show that collectively

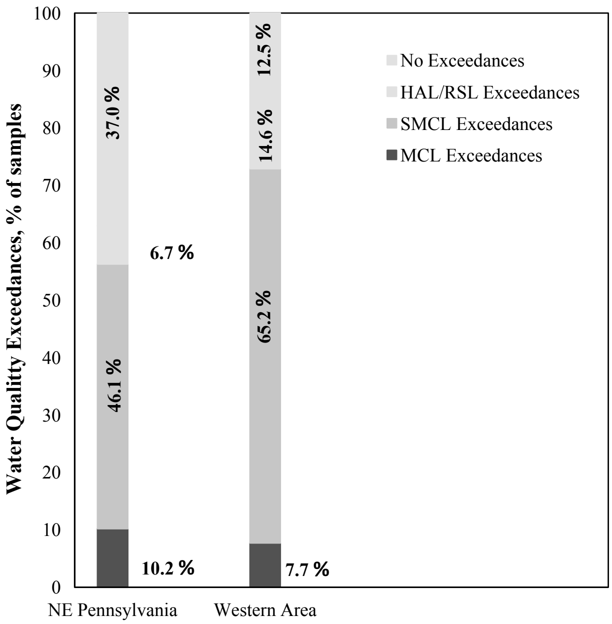

Fig. 6. Figure showing the percentage of water-quality exceedances in NE Pennsylvania and the "Western Area" by guideline. MCLs are USEPA maximum contaminant levels. SMCLs are USEPA secondary maximum contaminant levels. HALs are USEPA health advisory levels and RSLs are USEPA screening levels for water consumed at the tap. Turbidity exceedances are excluded from this chart. Each sample included only once; if there was an exceedance of a primary MCL, then the sample was not considered in the evaluation of the remaining guidelines, and so forth.

22% of historical samples exceeded an MCL, compared to approximately 9.6% (Catskill and Lock Haven samples only) in the 2009–2012 pre-drilling data, with the most common MCL exceedances in the historical data caused by arsenic, barium, selenium, and lead.

Battelle (2013) evaluated pre-2007 historical groundwater data from about 500 water wells (undivided by geological formation) in Bradford and Susquehanna Counties of NE Pennsylvania. Table 3 shows a comparison of the historical groundwater data from the Battelle (2013) report (pre-2007) compared to the pre-drilling data. The median values for all parameters are very similar.

5.2.2. Western area

Table 4 shows the distribution of major solutes and trace metals of interest compared to USEPA water-quality standards for pre-drilling water well samples in the Western Area. Fig. 7a–k shows the spatial distribution of pre-drilling samples that exceed USEPA drinking-water MCLs, SMCLs, RSLs, or HALs for: arsenic, barium, iron, lead, manganese, sulfate, chloride, lithium, sodium, TDS, and turbidity, respectively.

Fig. S4 in the Supplemental Information shows the spatial distribution of pre-drilling sample sites that exceed one or more MCLs, excluding turbidity. In the Western Area 7.7% of all pre-drilling samples exceeded one or more MCLs (excluding turbidity). If turbidity is included then 39% of all pre-drilling samples exceed an MCL. Secondary MCLs were exceeded in 65.2% of the samples.

Excluding turbidity (36.2%), the most commonly exceeded MCLs in pre-drilling samples from the Western Area are lead (4.4%) and arsenic (3.1%). If all of the MCL, SMCL, RSL, and HAL water-quality standards are considered collectively (excluding turbidity) then 87.5% of pre-drilling samples exceed one or more drinking-water standards. About 63.8% of all pre-drilling samples exceeded two or more drinking-water standards, and approximately 31.1% exceeded three or more drinking-water standards. Including turbidity, 88.7% of pre-drilling samples exceeded one or more drinking-water standards. Fig. S4 in the Supplemental Information also shows the spatial distribution of those samples that exceed a SMCL, HAL, or RSL. The most commonly detected natural exceedances of SMCLs were manganese (53.5%), iron (50.0%), and TDS (22.8%). The sodium USEPA HAL of 20 mg/L was exceeded in 51.8% of samples collected from water wells in the Western Area.

Our findings in the Western Area are also consistent with local and national historical water-quality studies (e.g. Ohio USEPA, 2012; Gross and Low, 2012; Chambers et al., 2012; Ayotte et al., 2011; DeSimone et al., 2009; DeSimone, 2008; USGS, 2006; McAuley and Kozar, 2006; White and Mathes, 2006; Stoner et al., 1987; Razem and Sedam, 1985; Matisoff et al., 1982). For example, Razem and Sedam (1985) noted in a study of 100 groundwater samples collected in 1983 that SMCLs were commonly exceeded for TDS (38%), manganese (34%), iron (19%), and sulfate (17%) among other constituents, and that 62% of the samples analyzed exceeded the sodium HAL of 20 mg/L.

5.3. Sample turbidity influence on water-quality

The analysis of unfiltered samples (total analysis) for certain trace metals (e.g. iron and manganese) can produce false positives.

Table 2
Summary of historical analytical data (Williams et al., 1998 and Taylor, 1984) from the Catskill and Lock Haven formations compared to pre-drilling data (2009–2012) for Northeastern Pennsylvania (units are in mg/L). Historical data compared to full pre-drilling dataset for each formation, and also to the dataset where shallower wells were excluded (those <p75) in valleys.

Parameter	Catskill Formation Median concentrations (mg/L)				Lock Haven Formation Median concentrations (mg/L)			
	Historical Pre-1987 Williams et al., 1998 (Taylor, 1984)		Pre-drilling 2009–2012 All Data [Shallow valley wells excluded]		Historical Pre-1987 Williams et al., 1998 (Taylor, 1984)		Pre-drilling 2009–2012 All Data [Shallow valley wells excluded]

[a] Samples analyzed for metals were not filtered during sampling or analysis. Some of the results may represent samples collected after a treatment system (e.g. particulate filter, water softener, etc.) within the water distribution system.
[b] Guideline or Standard types MCL –USEPA primary Maximum Contaminant Level for public drinking water supplies; SMCL –USEPA Secondary MCL; RSL –USEPA Regional Screening Level for tap water (January 2105); TTL – treatment technology action level for lead defined by USEPA for public drinking water supplies; Advisory –USEPA drinking water health advisory for individuals on a restricted sodium diet.
[c] Surfactants analyzed as methylene blue active substances (MBAS).
[d] For duplicate samples only sample with highest value used for each parameter.

Particulates induced during pumping of water wells are included in analysis of unfiltered samples. When water wells are pumped, the increased velocity of water moving through the formation and the well bore induces clay- to silt-sized sediment into the water. The USEPA recognizes this problem and advocates pumping at rates less than 100 milliliters per minute (mL/min) to minimize turbidity during sampling of monitoring wells (Puls and Barcelona, 1996). Domestic water wells pump at much higher rates, and consequently, turbidity can occur even under normal use. We found about 15.7% of the samples in NE Pennsylvania and 36.2% of samples in the Western Area had turbidity exceeding the USEPA MCL of 5 nephelometric turbidity units (NTU). Many exceedances of total iron and manganese SMCLs relate to this turbidity, confounding true appraisal of trace metals concentrations from a scientific perspective or to characterize potential contamination. In rare cases, low pH in upland areas can react with domestic plumbing, and cause an occasional false-positive issue, but based upon our review, this is likely rare in both regions studied. We provide details on this part of our study in Appendix A of the Supplemental Information.

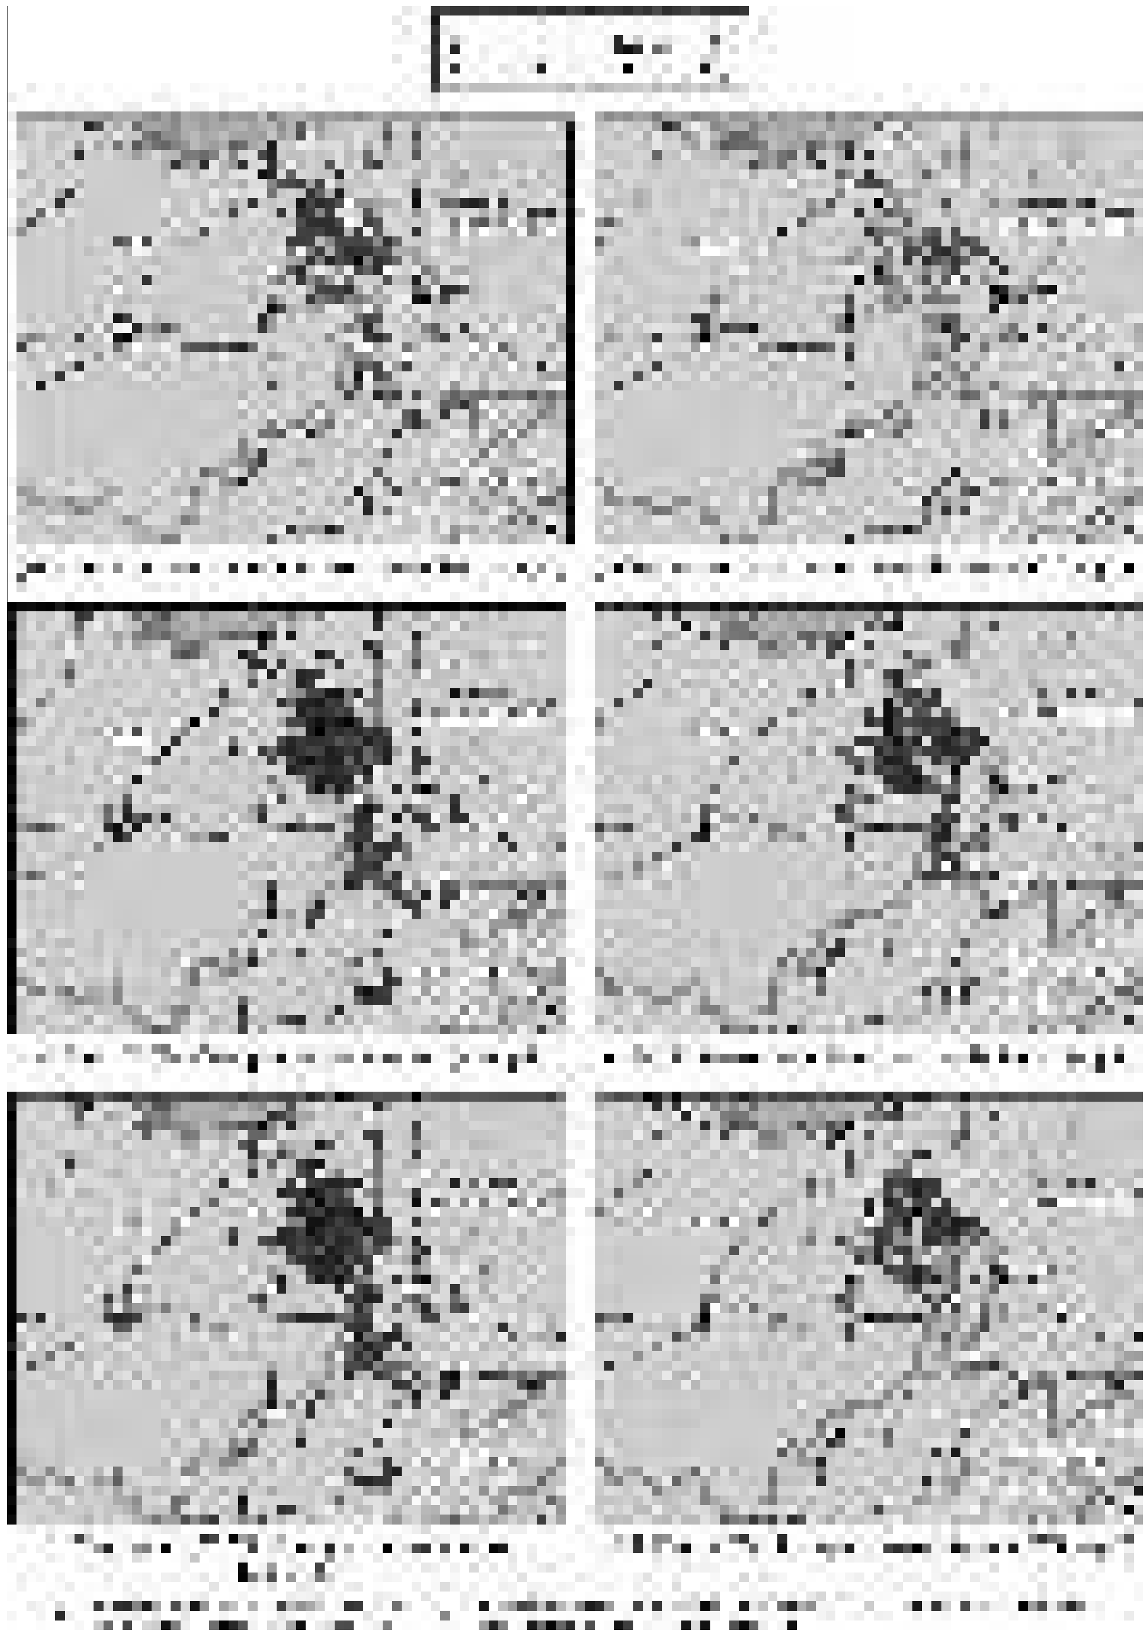

Fig. 7. Distribution of trace metals and other constituents in pre-drilling groundwater samples in the "Western Area". Samples exceeding the MCL or other groundwater standard are shown with a red symbol; such elevated concentrations occur commonly in pre-drilling samples across the study area. The applicable standard and percent of samples exceeding that standard are listed beneath each map. Layers are vertically stacked in order shown in legend and thus some "no exceeds" may be covered. For wells sampled more than once, the sample with the highest value is shown.

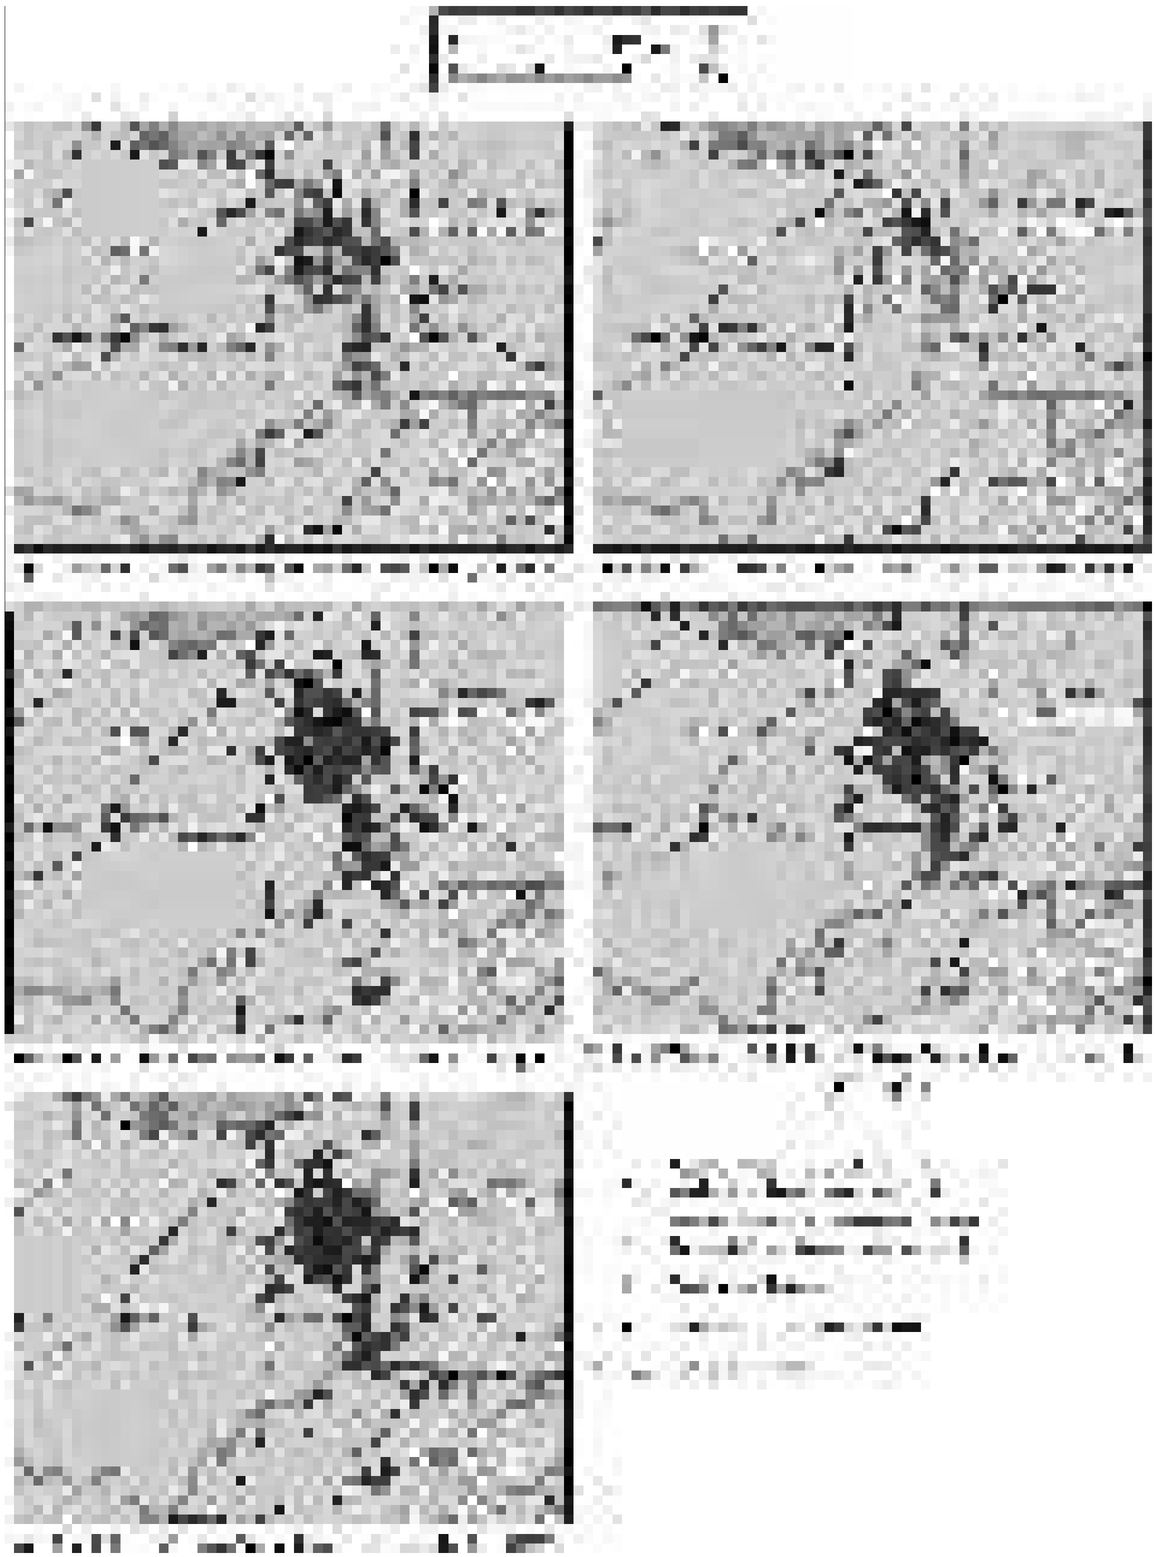

Fig. 7 (*continued*)

5.4. Hydrogeological relationships, regulatory exceedances, and hydrochemical water type

Piper trilinear diagrams for NE Pennsylvania (Fig. 8) and the Western Area (Fig. 9) show a geochemical evolution along flow paths from a Ca-HCO_3 groundwater type on recharging hilltops to sodium enriched waters along valley flanks and in valleys, where discharging groundwater with higher salinities naturally occur. Sodium derives from a combination of natural calcium and magnesium ion exchange with sodium found in clays within the formation matrix and fracture surfaces.

All major-ion water types occur in valley and upland settings in both NE Pennsylvania and the Western Area. But in upland areas in NE Pennsylvania (where deep freshwater groundwater circulation

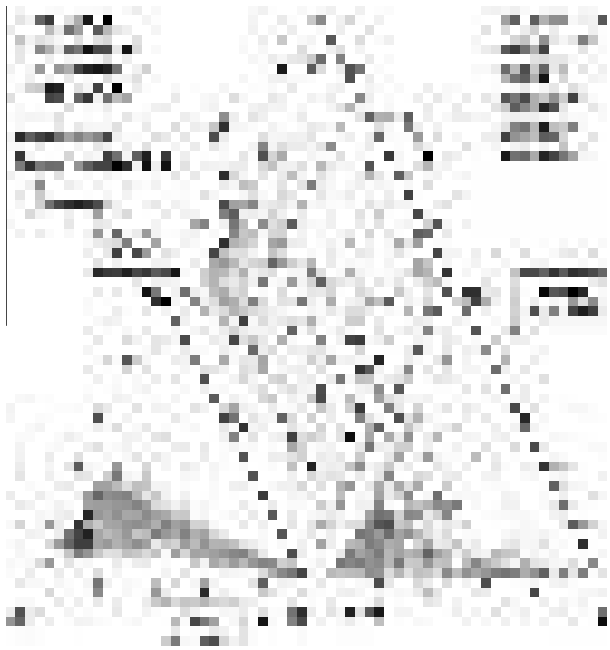

Fig. 8. Piper trilinear plot of pre-drilling samples in Northeastern Pennsylvania in four categories of sodium concentration. Circles in the diamond field are scaled to the concentration of TDS in the sample. The samples included here are known to be untreated and are within the ±7% criteria on the ion charge balance ($n = 2610$). Water types are after Deutsch (1997).

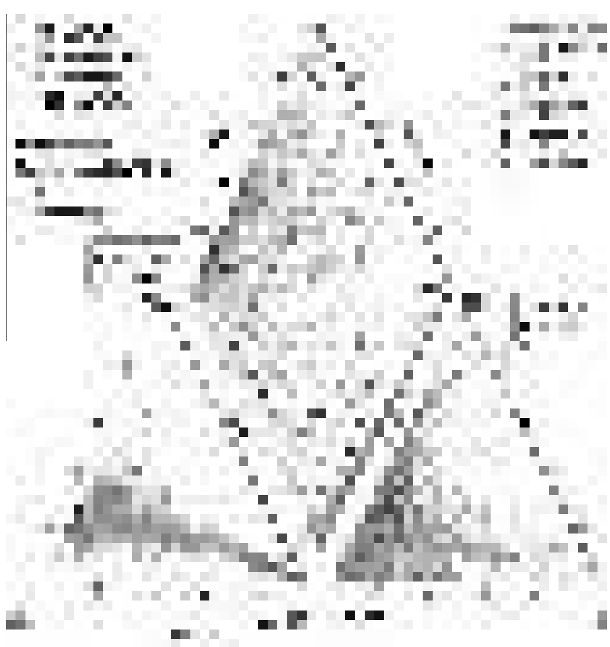

Fig. 9. Piper trilinear plot of pre-drilling samples in the "Western Area" in four categories of sodium concentration. Circles in the diamond field are scaled to the concentration of TDS in the sample. The samples included here are known to be untreated and are within the ±7% criteria on the ion charge balance ($n = 3439$). Water types are after Deutsch (1997).

patterns have developed), most water wells are too shallow to encounter Na-HCO_3/Na-Cl water types. In NE Pennsylvania about 88% of water from Carboniferous-age Burgoon Sandstone and Huntley Mountain formations are Ca-HCO_3 dominated water types. Most of these water wells occur in upland recharge areas. In contrast, the Devonian-age Lock Haven and Catskill formation samples mostly occur in lowland areas (Shultz, 1999) and have more Na-Cl and Na-HCO_3 water types (combined at 22.1%) than the stratigraphically and topographically higher aquifers. The more frequent occurrence of Na-Cl groundwater type in the Lock Haven and Catskill formations is consistent with what Williams et al. (1998) found. The Lock Haven and Catskill formations produce groundwater of a Na-Cl type from naturally saline intervals that Williams et al. (1998) termed "*restricted flow zones*" that are not being continuously flushed by active circulation of fresh groundwater (Risser et al., 2013). In the Western Area freshwater flow systems are shallower due to smaller topographic relief, and wells drilled in both valley and upland settings are equally likely to encounter all water types. There, water type and water quality do not associate with geological formation (except where carbonates and coal formations occur, which add sulfate).

In NE Pennsylvania, lithium and sodium exceeding water-quality standards are more likely to be found in water wells drilled into the Catskill and Lock Haven formations than in others. Likewise, arsenic and lead exceeding standards are more likely to be found in water wells drilled into the Burgoon Sandstone and "Other" formations. Table 5 shows common water-quality exceedances related to samples collected from water wells completed into these formations in NE Pennsylvania. Detailed summary of the sample counts (and exceedances) for each parameter for each geological unit is provided in Table S8 in the Supplemental Information.

Table 6 provides a comparison of common water-quality guideline exceedances from water wells to their geological completion formations in the Western Area. Overall, water wells drilled into the Allegheny-Pottsville Formation have the poorest water quality followed by the Other formations and the Monongahela Group. A detailed summary of the sample counts (and exceedances) for each parameter for each geological unit is provided in Table S9 in the Supplemental Information.

The groundwater type (hydrochemical facies) is closely associated with water-quality exceedances. For purposes of this study we have categorized the water types based upon the dominant single major anion and cation. However, many of the water types actually consist of mixtures of anions and cations which often show as mixed water types such as calcium-sodium-bicarbonate (Ca-Na-HCO_3) or Ca-Mg-HCO_3.

Exceedances of water quality criteria also relate to specific geochemical water types. In NE Pennsylvania more than 50% of the pre-drilling samples with Na-Cl type groundwater exceed drinking-water guidelines for manganese, TDS, and sodium (Table 7). For calcium sulfate (Ca-SO_4) type waters, 50% of samples exceed water-quality guidelines for iron, manganese, sulfate, sodium, and TDS. Table S10 in the Supplemental Information provides detailed sample counts (and exceedances) for each parameters compared to groundwater type.

All but one SMCL and RSL exceedance for chloride and strontium, respectively, occurred in either Na-Cl or Ca-Cl type groundwater. The majority of sulfate SMCL exceedances occur in $CaSO_4$ or Other water types. The Other water types (more than one sample) were magnesium bicarbonate (Mg-HCO_3), magnesium sulfate (Mg-SO_4), and sodium sulfate (Na-SO_4). The Mg-HCO_3 is consistent with shallow recharging groundwater in carbonates, and the latter two types could be reflective of unusual local geochemical processes involving ion exchange, carbonate geochemistry, and/or sulfur oxidation.

In the Western Area (Table 8), iron, manganese, sulfate, and TDS exceed guidelines in over 50% of Ca-SO_4 type groundwater. Over 75% of the samples exceed guidelines for sodium in all water types except Ca-HCO_3 and Ca-Cl. The Ca-SO_4 water type is associated with groundwater sourced from coal-containing formations. The Other water types consist of Mg-HCO_3, Mg-SO_4, and Na-SO_4. The

Table 5
Water-quality exceedances based upon water wells drilled into each geological unit – Northeastern Pennsylvania.

"Other" groundwater types include: Mg-HCO_3, Mg-Cl, Mg-SO_4, and Na-SO_4.

Mg-HCO_3 is consistent with shallow recharging groundwater in carbonates, and the latter two types could be reflective of unusual local geochemical processes involving ion exchange, carbonate geochemistry, and sulfur oxidation.

The specific number and percentages of water-quality exceedances for each groundwater type are provided in Table S-11 the Supplemental Information for the Western Area.

5.5. Topographic position relationship to groundwater quality

5.5.1. Northeast Pennsylvania

Williams et al. (1998) found that groundwater with higher concentrations of sodium, chloride, barium, and strontium was associated with water wells located in valley settings in NE Pennsylvania. Table S12 in the Supplemental Information provides a summary of groundwater type per topographic position for NE Pennsylvania and the Western Area.

In NE Pennsylvania, we found the large preponderance (85.7%) of the pre-drilling samples with Na-Cl water type occurring in water wells completed in valley settings with the next greatest water type percentage in valleys being Na-HCO_3 water type (53%). However, depending upon location, well depth, and specific fractures intersected, it is possible to intersect younger and local/intermediate flow systems that contain Ca-HCO_3 or Na-HCO_3 water types.

The pre-drilling samples in NE Pennsylvania show that samples exceeding water-quality guidelines for barium, chloride, and strontium (87.1%, 86.3%, and 100%, respectively) typically occur in water wells found in valley settings. In contrast, most sulfate exceedances (91.4%) occur in water wells completed in upland settings where coal beds are more prevalent and waters are better oxygenated.

Approximately 83% of the water wells drilled to depths greater than 61 m occurred in upland areas. Table S-13 in the Supplemental Information provides a summary of individual water-quality exceedances by topographic setting.

5.5.2. Western area

For the Western Area, as noted in Table S-12 in the Supplemental Information, there seems to be little relationship between water type and topographic position. Potable groundwater circulation in the Western Area extends only a few tens of meters deep and most local to intermediate scale groundwater circulation paths are a few kilometers in length. Most water types occur at a percentage close to the overall percentage of samples in each topographic category (69.9% uplands, 30.1% valleys), but do not necessarily correlate. Na-Cl type groundwater type seems to be more likely in valley settings (37.4%), but the relationship between water quality and topography remains unclear, even with this large dataset.

There also is no substantial relationship between water-quality exceedances and topographic position for the Western Area, with the possible exception of barium and lithium. Barium exceedances of water-quality standards are higher in valley settings (63.0%) compared to upland settings (37.0%). Lithium exceedances are higher in upland settings (82.8%) than valley settings (17.2%). In the Western Area lower topography and dissected terrain coupled to coal seams leads to an inherently more complicated hydrochemical setting compared to NE Pennsylvania, and finding little relationship between water quality types with topographic settings is expected.

Approximately 91% of the water wells drilled to depths greater than 61 m occurred in upland areas. The specific number and percentages of water-quality exceedances for each parameter per topographic setting (upland versus valley) are provided in Table S-14 in the Supplemental Information.

6. Discussion

Our results, based on a dataset that is orders of magnitude greater than previous studies on quality of shallow groundwater of Appalachia, agree broadly with the results of most prior studies. The general pattern of geochemical evolution with their commensurate exceedances of water-quality standards is clear. For example, Na-Cl water in NE Pennsylvania is associated with water-quality standard exceedances for many parameters. These exceedances occur in valley settings and low-lying areas.

Fig. 10, as an example, shows that most (88.8%) of the Na-Cl groundwater type (pink dots) with higher total dissolved solids occur in major river valleys and associated tributaries.

In the Western Area, high salinity may occur in wells located both on valley slopes and even in upland areas where coal seams occur with oxidizable pyrite (Razem and Sedam, 1985). The combination of sulfide oxidation, ion-exchange, carbonate dissolution

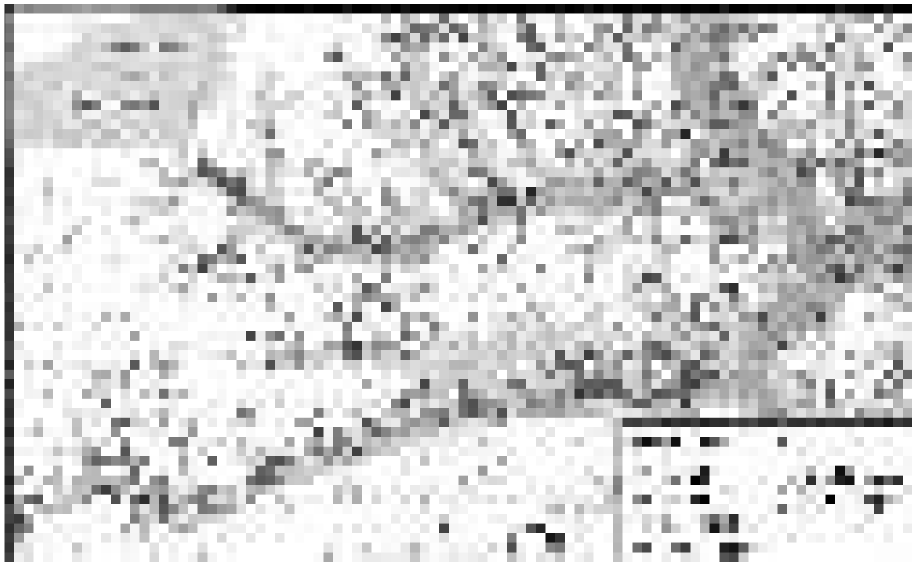

Fig. 10. Relationship between total dissolved solids (TDS) concentration, water type, and topography shown for a detail area in Bradford County, Northeastern Pennsylvania. TDS concentration is represented by symbol size. Water type (based on a simple classification using the dominant major anion and cation present in the sample) is represented by the color of the symbol as described in the legend. Streams and generalized topographic elevations are shown in gray for reference. Samples of Na-Cl and Na-HCO_3 water types are more prevalent in valleys and are associated with higher TDS concentrations.

and the intersection of deeper saline waters produce a broad range of water types. These processes are well known in the Appalachian Basin (Razem and Sedam, 1985). However, the same overall processes of chemical evolution should apply, as water types shift from Ca- to Na-dominated with increased age and residence time.

In both regions, the following reaction largely control the geochemical evolution of the groundwater.

Ion exchangeable clays in the aquifer rocks replace calcium and magnesium with sodium (Eq. (1)):

$$Ca^{2+} + Na_2\text{-Clay} = 2Na^{2+} + Ca\text{-Clay}. \tag{1}$$

This reaction, when driven to completion, result in Na-HCO_3 geochemical facies waters. When these waters mix with saline water near the bottom of deep wells (or restricted flow zones) or in discharge zones in valleys, the water becomes enriched even more in sodium and chloride, typically resulting in a Na-Cl type water.

In the Western Area, in particular, the oxidation of pyrite in coal leads to the generation of sulfate and hydrogen ions from sulfuric acid (e.g. Eq. (2)):

$$2FeS_2 + 7O_2 + 2H_2O = 2Fe^{2+} + 4SO_4^{2-} + 4H^+. \tag{2}$$

This in turn leads to oxidation of the ferrous iron species to ferric iron in solution or as a solid iron hydroxide or oxyhydroxide (e.g. Eq. (3)):

$$FeS_2 + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + 2SO_4^{2-} + 16H^+. \tag{3}$$

The acid generated then dissolves more carbonate and other minerals in the aquifer, increasing the calcium and other metals in solution, causing higher dissolved solids consisting of sulfate from the pyrite oxidation and calcium and alkalinity from the carbonate minerals.

Our study confirms prior understanding of the natural evolution of water quality in shallow aquifers in the Appalachian Basin. Groundwater quality is affected by a number of factors resulting in local variability related to different combinations of geologic formation and topographic position of the water well which, in turn, relates to the underlying position of the well in local, intermediate, and regional flow systems. Most water wells are completed as open holes and so may obtain water from multiple fractures, changing with hydrologic season and recharge events, which add to the variability of the groundwater chemistry.

In the future it may be possible to parse this large dataset into smaller regions to evaluate these relationships in more detail, either statistically or through geochemical modeling approaches. However, these exercises are beyond the scope of this paper, which was intended to re-evaluate previously identified water-quality variability using a much larger dataset. Overall, we see no broad changes in variability of chemical quality in this large dataset to suggest any unusual salinization caused by possible release of produced waters from oil and gas operations, even after thousands of gas wells have been drilled among tens of thousands of domestic wells within the two areas studied. What we find confirms what others have historically reported: there is wide variability in water quality in potable groundwater in the Appalachian Basin, and much of this water naturally exceeds regulatory standards. Those previous reports used much smaller datasets, and were published many decades earlier, thus confirming and supporting our conclusions.

7. Conclusions

The results of our study, from the analysis of 21,044 pre-drilling groundwater samples, have broad implications regarding the characterization of background chemistry in shallow groundwater supplies of the Appalachian Plateau, especially when assessing potential impacts from oil and gas operations. This very large dataset, in combination with previous studies, shows we can broadly conclude that in both NE Pennsylvania and the Western Area the groundwater commonly exceeds drinking-water guidelines, by means of natural processes. These exceedances are not random, but are related to factors such as geological formation/lithology, sample turbidity, age or residence time of the groundwater, and where within the groundwater flow system the sample was collected. There is also an association with groundwater type and TDS/salinity concentrations. In NE Pennsylvania there appears to be an association with water quality and topographic position (valleys versus uplands), whereas, in the Western Area this relationship is not as strong. Based on our study, 63.1% of the water wells sampled in NE Pennsylvania and 88.7% in the Western Area had pre-drilling exceedances for drinking-water guidelines for one or more parameters (including turbidity). In NE Pennsylvania, 10.2% of the samples exceeded one or more of USEPA's MCLs set for drinking-water supplies, 46.1% of the samples exceeded one or more of USEPA's SMCLs, and 6.7% exceeded one or more of USEPA's HALs or RSLs for tap water. In the Western Area 7.7% of samples exceeded one or more MCLs, 65.2% exceeded one or more SMCLs, and 14.6% exceeded one or more health advisory or regional screening levels for tap water.

Our results are neither unusual nor surprising and are consistent with previous results in both areas using much smaller datasets both before and after unconventional oil and gas development (e.g. Molofsky et al., 2013; Gross and Low, 2012; Chambers et al., 2012; Low and Galeone, 2006; Williams et al., 1998; Stoner et al., 1987; Razem and Sedam, 1985; Taylor, 1984; Matisoff et al., 1982).

Comparison of historical groundwater data from NE Pennsylvania that mostly pre-dates unconventional shale gas development (pre-2007) to sampling results from Chesapeake's pre-drill baseline program (2009–2012) shows that the current groundwater quality conditions are similar to those shown in historical data. This comparison thus provides a dataset representative of regional groundwater conditions that pre-dated unconventional shale gas drilling, and provides a comprehensive understanding of aquifer systems and groundwater chemistry in the region.

Fundamentally, water-quality data from domestic water wells need to be understood within the natural geochemical context when evaluating suspected water-quality changes from shale-gas methane production or any other source. The hydrogeological setting of the water well also needs to be fully understood within the context of the mineralogy in the aquifer, the topographic position of the well within the associated flow path, the natural variability of water-quality parameters, and the naturally expected hydrochemical facies. Basic principles of groundwater flow and the hydrochemical evolution of groundwater systems in Appalachia (e.g. Piper, 1933; Lohman, 1937, 1939; Poth, 1963) indicate that saline groundwater underlying fresher groundwater is connate. This connate groundwater was present in the sediments during deposition, thus the saline waters have not migrated long vertical distances from formations hundreds and thousands of meters deeper.

We see no broad changes in variability of chemical quality in this large dataset to suggest any unusual salinization caused by possible release of produced waters from oil and gas operations, even after thousands of gas wells have been drilled among tens of thousands of domestic wells within the two areas studied. What we do find confirms what others previously found with much smaller datasets decades earlier regarding the wide variability of water quality in domestic groundwater in the Appalachian Basin, and that much of this water naturally exceeds regulatory standards.

Finally, caution should be exercised when using total metals analysis to characterize water-quality changes of any type, given the common problems associated with sampling water from domestic wells, which may include turbidity. Samples should be filtered to remove suspended particles and dissolved metals should be analyzed to provide a more accurate analysis of metals concentrations.

Acknowledgements

The authors would like to thank Chesapeake Energy Corporation for providing funding for this study and for access to their pre-drilling groundwater dataset for Ohio, West Virginia, and Pennsylvania. Special thanks goes to several anonymous reviewers who provided many useful comments to the manuscript. We also wish to thank the landowners who allowed their water wells to be sampled. Additional relevant information is provided below:

- Chesapeake Energy Corporation provided funding for the authors of this paper through their organizations of employment, and, in the case of the senior author (Don Siegel), privately, to do basic research to explore and evaluate this very large dataset, and for the preparation of the paper. Data used in this paper were collected on behalf of Chesapeake by paid third party consultants to comply with regulatory programs. The analysis and interpretations, and report writing, were conducted by the named authors of the paper. The decision to submit the paper was that of the authors. The opinions and conclusions expressed in this paper are those of the authors and do not necessary reflect those of Chesapeake Energy.
- During the preparation of this specific paper, all authors worked for the organizations whose affiliations are noted in authorship. Mark Hollingsworth is a current employee of Chesapeake Energy Company, having worked at Chesapeake from February 2011 to present. Prior to Mr. Hollingsworth's employment by Chesapeake, he worked for TestAmerica Laboratories, Inc. which provided laboratory analytical consulting services to Chesapeake. Bert Smith is a former employee of Chesapeake Energy having worked there from May 2012 to September 2013, and has been employed by Enviro Clean Products and Services from November, 2013 to the present. Enviro Clean P&S also does consulting work for Chesapeake. Prior to May, 2013 Mr. Smith worked for Science Applications International Corporation (SAIC), which did consulting work for Chesapeake Energy. AECOM provides architecture and engineering services to government and private industry around the world, including the energy sector and Chesapeake. Rikka Bothun worked for AECOM during most of the time this paper was under preparation, but left AECOM in December, 2014 and now works for a private consulting company that does not do consulting work for Chesapeake.
- None of the following authors (Don Siegel, Bert Smith, Elizabeth Perry, or Rikka Bothun) have competing corporate financial interests exceeding guidelines presented by Applied Geochemistry. Mark Hollingsworth is a current employee of Chesapeake Energy and owns stock in the company in an amount in excess of $5000.
- Donald Siegel is the lead author and contributed to the paper's preparation, technical interpretations, and review of these data and paper. Bert Smith is the second named author and contributed to the paper preparation, technical interpretations, and review of these data and paper. Elizabeth Perry is the third named author and contributed to the paper preparation, technical interpretations, and review of these data and paper. Rikka Bothun is the fourth named author and contributed to the paper preparation, technical interpretations, and review of these data and paper. Mark Hollingsworth is the fifth named author, oversees the Chesapeake baseline dataset, contributed to the paper preparation, and in review of these data and paper.

Groundwater

Evaluation of Methane Sources in Groundwater in Northeastern Pennsylvania

by Lisa J. Molofsky[1] , John A. Connor[2] , Albert S. Wylie[3] , Tom Wagner[3] , and Shahla K. Farhat[2]

Abstract

Testing of 1701 water wells in northeastern Pennsylvania shows that methane is ubiquitous in groundwater, with higher concentrations observed in valleys vs. upland areas and in association with calcium-sodium-bicarbonate, sodium-bicarbonate, and sodium-chloride rich waters—indicating that, on a regional scale, methane concentrations are best correlated to topographic and hydrogeologic features, rather than shale-gas extraction. In addition, our assessment of isotopic and molecular analyses of hydrocarbon gases in the Dimock Township suggest that gases present in local water wells are most consistent with Middle and Upper Devonian gases sampled in the annular spaces of local gas wells, as opposed to Marcellus Production gas. Combined, these findings suggest that the methane concentrations in Susquehanna County water wells can be explained without the migration of Marcellus shale gas through fractures, an observation that has important implications for understanding the nature of risks associated with shale-gas extraction.

Introduction

Significant media attention has been focused on the potential for methane impacts in drinking water wells located within areas of hydraulic fracturing activities for shale-gas development. Distinguishing among the various sources of methane gas that may affect drinking water wells requires proper assessment of background conditions. In this study, we review the results of background methane and groundwater quality surveys, in conjunction with geologic and historical information, to develop a better understanding of the potential sources of methane levels in drinking water wells in Susquehanna County in northeastern Pennsylvania.

Susquehanna County has experienced substantial gas extraction activities in the Marcellus shale since 2006. Prior to that time, there was not a significant history of oil and gas operations in this county, thereby providing a unique opportunity to evaluate the potential effects of shale-gas extraction on groundwater resources in the Appalachian basin. Other researchers have suggested that elevated methane concentrations in water wells in Susquehanna County are the result of regional impacts from shale-gas extraction activities (e.g., Osborn et al. 2011). To test this hypothesis, we have evaluated data from the sampling and testing of 1701 water wells throughout Susquehanna County to assess the prevalence and distribution of methane concentrations in groundwater. We have also evaluated isotopic and molecular analyses of hydrocarbon gases in the Dimock Township of Susquehanna County, an area of focused sampling by the Pennsylvania Department of Environmental Protection (DEP) and the U.S. Environmental Protection Agency, to determine whether reported methane concentrations above the Pennsylvania DEP action level (7000 µg/L) in local water wells exhibit signatures consistent with Marcellus production gases, or overlying Middle and Upper Devonian gases sampled in annular spaces of local gas wells.

Our research indicates that shale-gas extraction has not resulted in regional impacts on groundwater quality in Susquehanna County, a finding which suggests that

doi: 10.1111/gwat.12056

hydraulic fracturing is not responsible for the creation or enhancement of wide-spread pathways by which Marcellus shale gas can rapidly travel to the surface.

Methods

Our study focused on characterizing the geologic and hydrogeologic context of methane occurrence in water wells in northeastern Pennsylvania. For this purpose, we have collected and reviewed the following types of information: (1) geologic data on regional structure and stratigraphy, (2) studies on aquifer dynamics and geochemical characteristics, and (3) historical documentation regarding the occurrence of hydrocarbon gases in the shallow and deep subsurface. Within this context, we have evaluated data collected from 1701 water wells in Susquehanna County to determine the prevalence and distribution of elevated methane concentrations and other groundwater parameters. We have also assessed isotopic and molecular analyses of gases from 15 water wells sampled as part of an ongoing stray gas investigation in the Dimock Township to determine the origin of methane concentrations above the Pennsylvania DEP action level.

Geologic information discussed in this article was compiled from prior studies on the stratigraphy and structure of the northeastern portion of the Appalachian basin, as well as new data acquired during exploration activities associated with recent Marcellus shale gas development. Specifically, stratigraphic information recorded during the drilling of 24 shale-gas wells located in Susquehanna and Wyoming counties facilitated the development of the geologic cross-section presented in Figure 1b. The seismic line shown in Figure 1c is based on interpretation of 57 miles of 2D seismic data acquired by Evans Geophysical (2007). Historical notations regarding the presence of shallow gas shows, historical gas fields, and bubbling springs and/or water wells in northeastern Pennsylvania were gathered from a detailed review of over a dozen documents dating back to the early 1800s.

The 1701 water samples analyzed as part of an extensive predrill water well survey from 2008 through 2011 were collected in the field and analyzed in NELAC accredited laboratories in accordance with procedures detailed in the supporting information. Statistical analyses of predrill data were conducted using Statistical Software ProUCL 4.1.01, which was developed and provided to the public by the United States Environmental Protection Agency (US EPA). Molecular and isotopic analyses of gases in shale-gas wells and local water wells in the Dimock Township were collected as part of an ongoing stray gas investigation by the Pennsylvania DEP and Cabot Oil and Gas Corporation in 2009 through 2011 using procedures detailed in the supporting information. This article also reports molecular and isotopic data from dissolved gases in Susquehanna County water wells collected by Osborn et al. (2011) and the US EPA (2012). Details of sample collection and analyses of these samples are presented in the respective studies, for which citations are provided.

Regional Geologic and Hydrologic Conditions

Deep and Shallow Stratigraphy

Knowledge of naturally occurring sources of hydrocarbon gases in both shallow and deep stratigraphic units provides critical information for evaluating potential sources and migration pathways of methane into local water wells. Natural gas in the subsurface can be both *microbial* in origin, that is, formed from the microbial breakdown of organic material, and *thermogenic* in origin, that is, formed from the abiotic degradation of organic material in formations under high temperatures and pressures at depth. Microbial methane commonly occurs in shallow bedrock and surficial deposits of alluvium (sands, silts, gravel, peat, and clay) and glacial drift (glacial till and outwash) (Coleman 1994). In Susquehanna County, these deposits can range from a few meters thick in elevated areas to tens of meters thick in lowlands (Aber 1974; Sevon et al. 1975; Inners and Fleeger 2002; Braun 2006). In areas with organic-rich shale formations, recent studies have also suggested an association between microbial methane concentrations and groundwater with longer residence times (in which progressive microbially mediated redox reactions can lead to methane production) (Kresse et al. 2012).

Surficial deposits in Susquehanna County are underlain by the Catskill and Lock Haven Formations, a series of interbedded sandstone, siltstone, and shale deposits formed during the Upper Devonian period (359 to 385 million years ago) (Figure 1b) (ICS 2010). The Catskill and Lock Haven Formations have historically been explored for reservoirs of thermogenic natural gas. These Upper Devonian deposits attained deepest burial depths at approximately 250 million years ago, at which time organic matter entrained in discrete lenses and distributed throughout the formations attained temperatures sufficient to crack to thermogenic gas (Evans 1995). Such elevated past temperatures are evidenced by the vitrinite reflectance of organic material (greater than 2.0%) observed in seams and lag deposits currently exposed in numerous outcrops and sandstone (bluestone) quarries in Susquehanna County (Laughrey et al. 2004; Weatherford Laboratories 2011).

The Bradford Sands, a series of thick sandstone deposits, form the base of the Lock Haven Formation, and are underlain by the Brallier Formation (locally known as the Elk Formation) and the Trimmers Rock Formation, which are comprised of interbedded sandstone, siltstone, and shale stratum of Upper Devonian age (Carter and Harper 2002). The Tully limestone is the youngest unit of the Middle Devonian age strata, which include the Mahantango Formation, consisting of laminated siltstone, sandstone and shales, and the organic-rich Marcellus shale, estimated to contain as much as 127 trillion cubic feet of thermogenic gas (Engelder 2009). The volume of gas contained in the Marcellus shale represents over 5 million times the volume of natural gas consumed in the United States in 2011 (24.4 million cubic feet; EIA 2012).

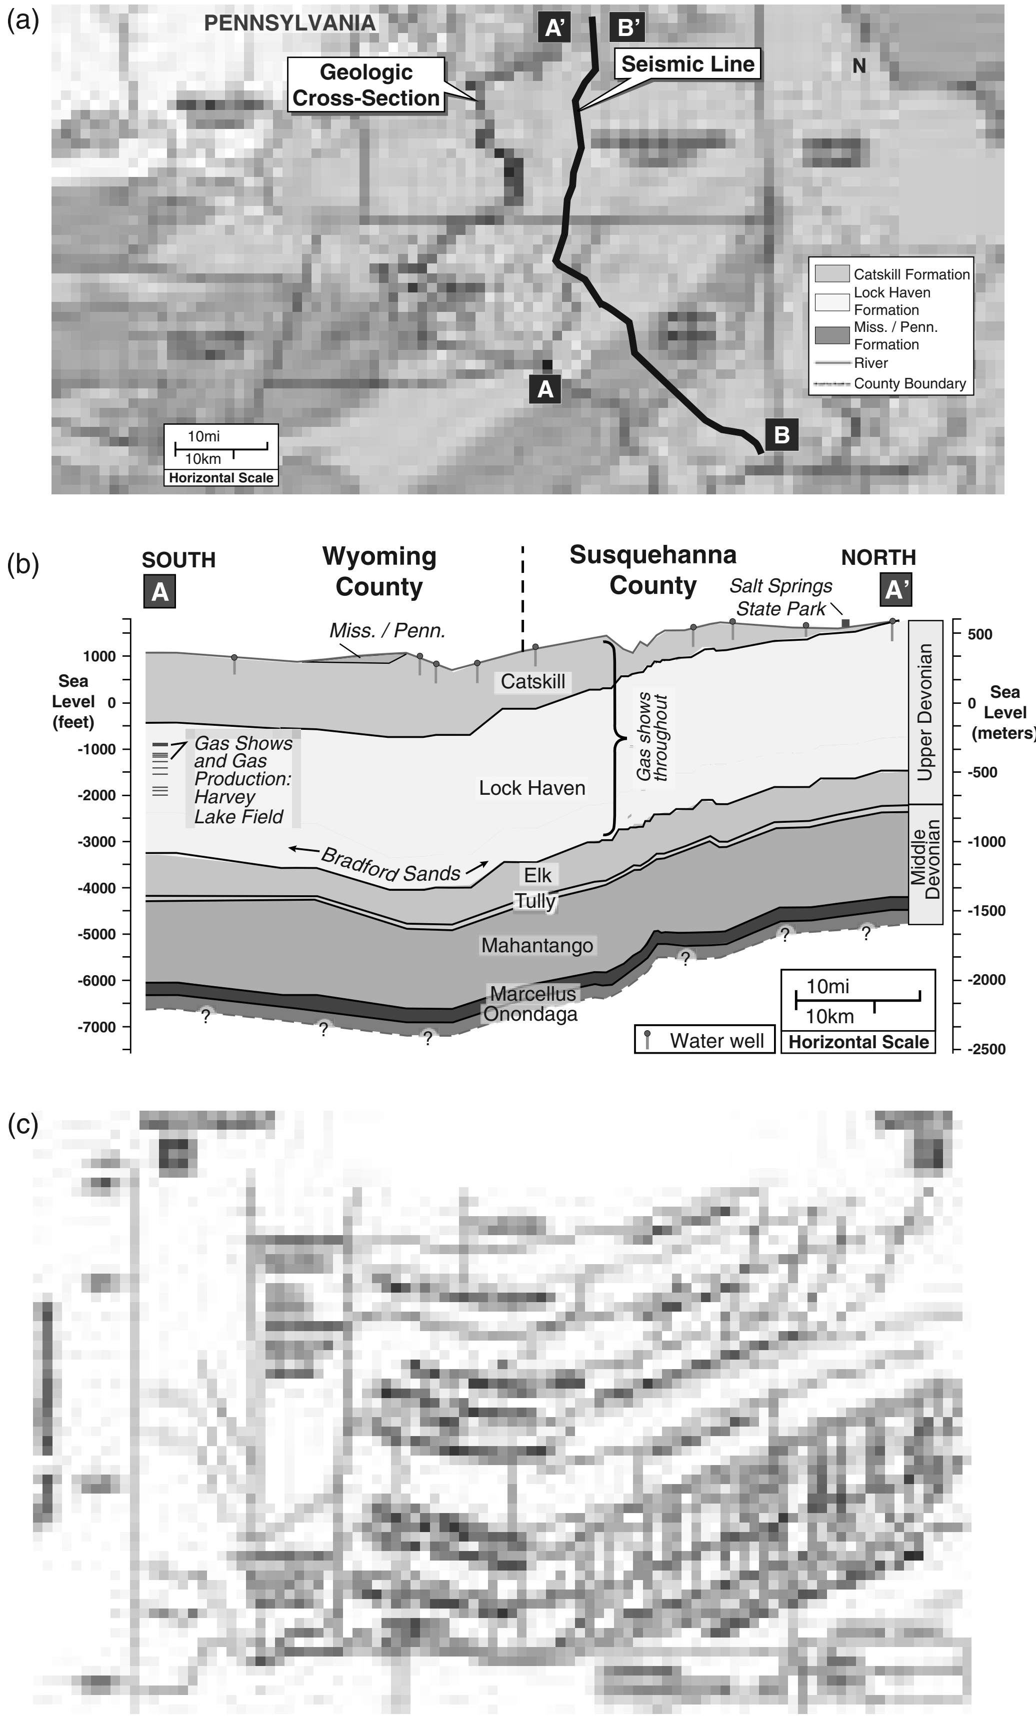

Figure 1. (a) Geographic map showing transect of wells in the cross section and seismic line. (b) Generalized cross section of Upper and Middle Devonian formations in Susquehanna and Wyoming County. (c) North-south 2D Seismic Line through Susquehanna, Wyoming, and Lackawanna County (Evans Geophysical 2007).

Fault and Fracture Systems

An extensive natural fracture network is present in both the Catskill and Lock Haven Formations, with penetrating north-south oriented vertical planar fractures bisected by multiple inferior fracture sets and bedding planes (Hollowell and Koester 1975; Geiser and Engelder 1983; Taylor 1984; Callaghan et al. 2010).

On a larger scale, seismic data provides valuable information regarding the structural setting and presence and/or absence of large-scale faults that could serve as conduits for the transport of fluids or gases. An interpretation of the stratigraphic and structural framework beneath Susquehanna and Lackawanna Counties from a portion of a regional 2D seismic line that transects the area is depicted in Figure 1c (Evans Geophysical 2007). The Upper Devonian section from the Catskill through the base of the Elk Sands shows shallow south-dipping stratigraphy interrupted by low-angle thrust faults that dip from 25° to 40° to the south. These thrust faults flatten and become bed parallel above the Tully limestone. In contrast, the Middle Devonian Marcellus to Silurian Salina Formations are interpreted to be bisected by frequent steep dipping (60° to 90°) reverse faults, back thrusts, and compressional and/or salt-related features that terminate near the top of the Marcellus or in the lower units of the Mahantango Formation in Susquehanna County (Davis and Engelder 1985; Scanlin and Engelder 2003). These faults rarely extend to the Tully stratigraphic level. This seismic section illustrates a disconnection between the distinct structural styles above and below the Tully horizon, interpreted to be a regional structural detachment that separates the shallow Catskill-Lock Haven stratigraphic section from the deeper Mahantango-Marcellus stratigraphic section. Given the presence of overpressured conditions in the Mahantango Formation and absence of such pressure above the Tully Limestone, this newly observed detachment zone, or the Tully Formation itself, is interpreted to act as a restrictive barrier to the present-day upward movement of deep formation fluids and methane from gas-charged units in the Middle Devonian Mahantango and Marcellus Formations in Susquehanna County.

Aquifer Dynamics/Water Well Construction

The great majority of water wells in Susquehanna County penetrate the fractured Catskill Formation, in which groundwater flow in unweathered bedrock appears to be controlled by secondary permeability primarily through vertical to near vertical north-south oriented fractures (as indicated by water seepage and flow, iron staining, and mineral precipitation) (Hollowell and Koester 1975; Geyer and Wilhusen 1982; Geiser and Engelder 1983; Taylor 1984). Most of the bedrock water wells are unsealed open-hole completions, with casing terminating in the shallow bedrock in order to draw water from multiple horizons at typical depths of 100 to 500 feet beneath ground surface (Lohman 1937, 1939; Taylor 1984; PaGWIS 2011). Median yields of 1146 water wells in the Catskill Formation were reported to be 0.76 and 2.2 L/s (12 and 35 gal./min.) for domestic and nondomestic wells, respectively (Taylor 1984). Valleys and streams in Susquehanna County commonly follow a pattern coincident with the presentation of vertical cross-cutting joint sets and lineaments, dense fractures, and fold trends (e.g., the orthogonal drainage patterns of Wyalusing Creek, a tributary of the Susquehanna River) (Taylor 1984; Engelder et al. 2009). Salt springs are also frequently located along linear trends associated with faulting or fracturing, suggesting the potential for connection to the deeper, and more brackish, Lock Haven Formation (Lohman 1937).

Historical Evidence for Occurrence of Shallow Natural Gas

Historical documentation suggests that the presence of methane gases in the shallow subsurface has been observed for over 200 years in Susquehanna County, long before the expansion of shale-gas fracturing in this area in 2006. For example, there are several dozen instances of flammable effervescing springs and water wells dating back to the late 1700s (Blackman 1873; Lohman 1939; Soren 1963; Breen et al. 2007; Susquehanna County Historical Society 2010; Williams 2010; Table S7 for a full list of citations). In addition, water well drillers have frequently reported encountering gas during drilling, particularly in valleys and other low-lying areas (Bell Brothers Well Drilling, Creswell Drilling, Beavers Well Drilling, Karp & Sons Drilling, JIMCON Drilling, Drake Drilling, personal communication, 2010).

Several gas fields in the past century have produced from formations less than 3000 feet below surface in northeastern Pennsylvania (e.g., Shrewsbury Gas Field, Lovelton Gas Field, Harveys Lake Gas Field), and there are numerous reports of gas shows between 80 and 800 feet during the drilling of oil and gas wells (Ashley and Robinson 1922; Hopbottom Well Record 1957; Soren 1961). For example, the 1881 publication "The Geology of Susquehanna and Wayne County" reported significant volumes of gas during the drilling of an oil boring in the Catskill Formation to a depth of 680 feet (White 1881). The presence of methane in natural springs and water wells has also been cited in adjacent New York State, where a survey of 239 water wells from 1999 to 2011 showed that 9% of water wells contained dissolved methane concentrations exceeding 10 mg/L (Kappel and Nystrom 2012). Due to potential gas contamination from natural sources, guidelines issued by the Pennsylvania DEP and other state agencies recommend the routine venting of water wells (PA DEP 2004).

Results of Sampling and Testing Programs

In addition to researching the hydrogeology, geology, and history of Susquehanna County in an effort to better understand natural groundwater conditions, we have also collected and analyzed water samples from this area to assess the presence of methane, ethane, and other water quality parameters. The results of this analysis provide additional information with regards to the distribution of hydrocarbon gases, and their association with physical geography, gas production areas, and groundwater quality.

Predrill Methane Data

This article evaluates data from 1701 water wells sampled in Susquehanna County to characterize baseline groundwater conditions during the period of 2008 to 2011. Over 900 of these samples were collected in accordance with Pennsylvania DEP regulations (Oil and Gas Act 13), which stipulates that an operator must conduct a "predrill or prealteration" water survey prior to the drilling of each gas well in order to maintain the right to contest any subsequent claims of groundwater impact. These samples were analyzed for both dissolved gas concentrations and general water quality parameters related to primary and secondary drinking water standards. Several hundred additional water well samples were collected from an 80-mile^2 area within Brooklyn, Harford, and Gibson Townships (southeast Susquehanna County), which did not have significant gas development operations at the time. These samples were intended to establish baseline methane concentrations in groundwater in areas of Susquehanna County without substantial gas extraction activities and were primarily analyzed for concentrations of dissolved gases (methane, ethane, and propane).

Collectively, these 1701 samples are referred to as "predrill" because they were sampled prior to the drilling of specific *proposed* wells; however, several of the water wells sampled were located in close proximity to *previously* drilled gas wells. As a result, 322 of the water wells have been characterized as located in a "gas production area" (defined as an area within 1 km of gas wells drilled prior to the time of sampling), while 1379 of the water wells are considered to be located in a "nonproduction area" (i.e., with no gas well drilled prior to sampling within 1 km). The 1 km radius used here to define gas production areas is considered a conservative distance, consistent with the radius utilized by Osborn et al. (2011) in northeastern Pennsylvania and New York, and larger than the current predrill sampling radius (2500 feet = 0.76 km) stipulated by the Pennsylvania DEP. Combined, 78% of the 1701 water wells sampled in either gas production or nonproduction areas contained detectable concentrations of methane, with approximately 3.4% exceeding the 7000 µg/L level at which corrective action is recommended by the Pennsylvania DEP. (As a note, the saturation concentration for methane is approximately 28,000 µg/L at atmospheric pressure, though it can vary with groundwater temperature, pressure, and salinity.)

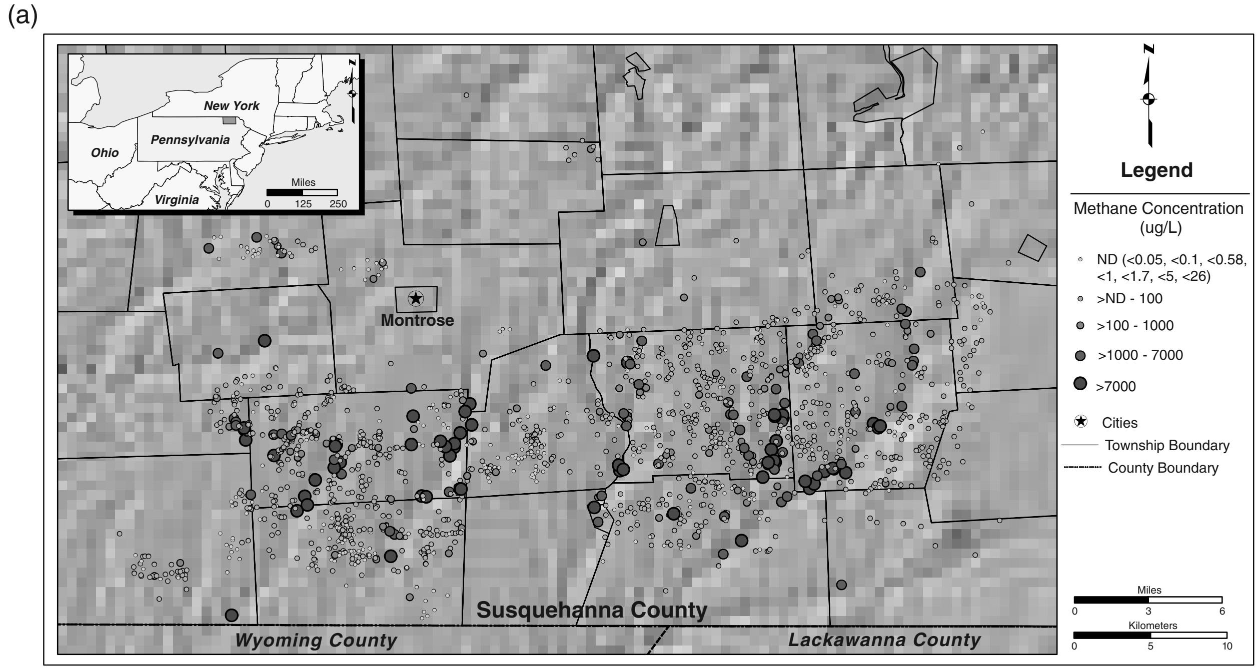
Predrill Methane Data: Valleys vs. Uplands

To evaluate the possibility of a relationship to topography, dissolved methane concentrations measured in water wells were plotted on a light detection and ranging (LiDAR) bare-earth elevation map overlain with the National Hydrography Dataset (NHD). As indicated in Figure 2a, the distribution of methane concentrations appears to be correlated to surface topography, with the higher dissolved methane concentrations located in topographic lows (valleys).

To support statistical analysis of this observed correlation, the water well population was subdivided into wells located in valleys (defined as the area within 1000 feet of a major NHD flowline or 500 feet of minor tributaries to NHD flowlines) vs. wells located in uplands (greater than 1000 feet or 500 feet from a major or minor drainage, respectively). As shown in Figure 2b, the median concentrations of the two datasets differ moderately (0.67 vs. 0.34 µg/L of methane in lowland vs. upland water wells, respectively). However, the 90th percentile concentrations differ much more significantly (1800 vs. 17 µg/L of methane in lowland vs. upland water wells, respectively), indicating that upper range methane concentrations occur considerably more frequently in valley wells. Furthermore, although valley wells represent only 51% of the total water well population, they comprise 88% of the water wells with methane concentrations that exceed 7000 µg/L (the current Pennsylvania DEP action level). A one-way Mann-Whitney U Test supports a statistically significant difference between methane levels in lowland (865 locations) vs. upland water wells (836 locations), where valley water wells contain statistically elevated methane concentrations (p-value < 0.001).

No Regional Association of Methane with Gas Production

In order to evaluate whether elevated methane concentrations in the data set exhibited a relationship to gas development activities, methane concentrations in water wells located in gas production areas were compared to those located in nonproduction areas. Of the water wells in gas production areas (322 wells), approximately 3.7% contained methane concentrations that exceeded 7000 µg/L, while 3.3% of water wells in nonproduction areas (1379 wells) contained methane concentrations above 7000 µg/L. This slight difference may be attributable to the fact that gas production areas contain a greater percentage of valley water wells (61% of 322 water wells) than nonproduction areas (49% of 1379 water wells). To evaluate whether the prevalence of valley water wells in gas-production areas was a factor, the methane concentrations of valley water wells in gas production areas were exclusively compared to those of valley water wells in nonproduction areas. Using a one-way Mann-Whitney U-test, methane concentrations in valley gas-production valley areas were found to be less than or equal to those in valley nonproduction valley areas (p-value = 0.007). A similar comparison of methane concentrations in upland water wells showed that methane concentrations in upland gas production areas were approximately equal (i.e., no statistically significant difference was observed) to those in upland nonproduction areas (two-way Mann-Whitney U-test p-value = 0.154). Furthermore, as a whole, no statistically significant difference was observed between methane concentrations



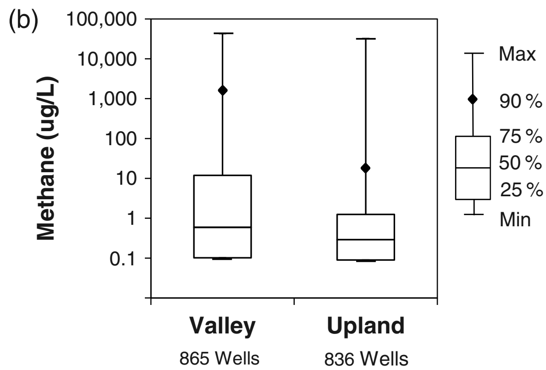


Figure 2. (a) LiDAR bare-earth elevation map showing dissolved methane concentrations from 1701 "predrill" water wells sampled in Susquehanna County. (b) Population distribution of methane concentrations in "predrill" water samples from valley and upland water wells in Susquehanna County.

in water wells in gas production areas vs. water wells in nonproduction areas (regardless of topographic location) (two-way Mann-Whitney U-test p-value = 0.503).

Origin of Methane Concentrations in Water Wells

Determining the microbial vs. thermogenic (or mixed) origin of methane concentrations in the predrill water well samples can narrow the list of potential sources. One conventional approach to assessing thermogenic vs. microbial origin relies upon the ratios of methane to ethane, where gases with ratios less than 100 have been characterized as thermogenic, while those with ratios greater than 1000 have been characterized as microbial (with ratios between 100 and 1000 typically characterized as an indeterminate origin or a mixture of thermogenic/microbial gases) (Bernard et al. 1976; Schoell 1980; Taylor et al. 2000).

However, comparison of methane to ethane ratios to available isotopic data in predrill water well samples in nearby Bradford County (located directly west of Susquehanna County) suggest that the conventional approach for characterizing thermogenic vs. microbial origin based on methane to ethane ratios may not apply in the geologic context of northeastern Pennsylvania. Specifically, Baldassare (2011) observed methane to ethane ratios ranging from 55 to 6900 in over a dozen water well samples from Bradford County that displayed traditionally thermogenic carbon and hydrogen isotopic signatures (i.e., $\delta^{13}C > -50‰$, $\delta^{2}H > -250‰$). This suggests that these water wells could contain a notable thermogenic component, despite their traditionally microbial methane to ethane ratio.

In Susquehanna County, 1540 (91%) of the 1701 predrill water well samples were analyzed for both methane and ethane concentrations. Exactly 217 of these samples contained *detected* methane and ethane, and of those samples, approximately 72% (156 samples) displayed ratios of methane to ethane greater than 1000 (Figure S2). Isotopic analyses were not performed on these predrill samples. However, several water wells in Susquehanna County were sampled as part of a stray gas investigation after nearby shale-gas extraction activities (section *Discussion* below of isotopic and molecular analyses in the Dimock Township). Samples from three of these water wells exhibited classically microbial (i.e., greater than 1000) methane to ethane ratios but traditionally thermogenic carbon and hydrogen isotopic signatures. Consequently, at this time, the thermogenic, microbial, mixed thermogenic/microbial, or microbially altered (i.e., oxidized) origin of the predrill dissolved gas samples from water wells cannot be determined.

Predrill Data: Correlation Between Methane and Other Groundwater Quality Parameters

To assess potential differences in groundwater sources, predrill water well samples in Susquehanna County were classified with regard to the relative concentrations of major cations (calcium, magnesium, potassium, and sodium) and anions (bicarbonate, chloride, and sulfate). The cation/anion composition of the groundwater is a product of the aquifer matrix (e.g., sandstone vs. shale), groundwater residence and/or rock-water interaction times, and the prominence of redox processes (Kresse et al. 2012). Consequently, for groundwater containing elevated methane levels, the water type can prove useful to understanding the flow path and retention time of water within the subsurface (i.e., stratum(s) of origin).

The Piper diagrams shown in Figure 3a and 3b plot the results for the population of 408 predrill samples for which all of the major cations and anions were analyzed. As shown, each water sample is characterized with regards to water "type" based upon the relative milliequivalent concentrations of major ions. In this sample population, five predominant water types have been identified: Ca-HCO_3 (281 samples), Ca-Na-HCO_3 (46 samples), Na-HCO_3 (20 samples), Ca-HCO_3-Cl (32 samples), and Ca-Na-HCO_3-Cl (20 samples). To characterize the relationship between water type and dissolved methane concentrations, the distribution of methane concentrations has been determined for each of the five principal water types. As shown in Figure 3b, the percentage of water samples exceeding 1000 µg/L of dissolved methane differs dramatically among water types, with 11 and 30% of the samples matching Ca-Na-HCO_3 and Na-HCO_3 water types, respectively, exceeding this level. By contrast, none of the 281 Ca-HCO_3 water type samples exceed 1000 µg/L of methane. Only a limited number of groundwater samples matched the Na-HCO_3-Cl and Na-Cl water types (four samples total); nevertheless, these samples exhibit several of the highest methane concentrations observed in the predrill dataset, with three of the four reported concentrations exceeding 10,000 µg/L.

Concentrations of individual groundwater quality parameters measured during predrill sampling were also evaluated to assess a possible correlation with dissolved methane concentrations. These data provide a comprehensive data set for the following parameters: alkalinity, barium, calcium, chloride, magnesium, manganese, pH, potassium, sodium, strontium, sulfate, and TDS. Data for an additional eight groundwater analytes (i.e., arsenic, aluminum, boron, bromide, iron, lead, nitrate, and sulfide) contained greater than 50% nondetect values and were therefore not amenable to this analysis (Figure S1).

To detect possible water quality trends related to methane, the concentration distribution for each parameter was determined for four ranges of methane concentrations: nondetect, detected to 1000 mg/L, greater than 1000 µg/L to 7000 µg/L, and greater than 7000 µg/L. The median concentrations of the following parameters were found to increase with increasing methane levels: barium, chloride, manganese, pH, sodium, strontium, and TDS (Figure S1). Median concentrations of alkalinity and potassium showed slight increases with increasing methane concentration, while median magnesium concentrations exhibited a minor decrease. Median sulfate and, to a lesser degree, calcium concentrations in groundwater were observed to inversely correlate with dissolved methane concentrations (i.e., lower sulfate at higher dissolved methane levels).

Dimock Township: Stray Gas Investigation

Isotopic and molecular analyses of dissolved gases can provide a means to differentiate between: (1) microbial vs. thermogenic gas sources, (2) distinct sources of microbial gas, and (3) distinct sources of thermogenic gas (e.g., Fuex 1977; Schoell 1980; Clayton 1991; Coleman 1994; Wiese and Kvenvolden 1994; Baldassare and Laughrey 1997). In this study, we have evaluated isotopic and molecular data from 7 gas wells, and 15 water wells sampled by the Pennsylvania DEP and Cabot Oil and Gas Corporation in the Dimock Township of Susquehanna County as part of a site-specific stray-gas investigation in 2009 through 2011. In addition, we reviewed data from 9 water wells sampled by researchers from Duke University (Osborn et al. 2011) and 11 water wells sampled by the USEPA (USEPA 2012) in the same area from 2010 through 2012. One gas sample from a bubbling salt spring approximately 13 miles northeast of Dimock, in nearby Franklin Township, was also included in our evaluation. The goal of the evaluation presented here is to utilize available molecular and isotopic data to assess whether gases in Dimock area water wells were originating from the Marcellus Shale or overlying Middle and Upper Devonian deposits.

Potential Source Gases: Isotopic and Molecular Analyses, 2009 to 2011

In 2009 and 2010, several water wells in the Dimock Township of Susquehanna County were reported to contain methane concentrations above the Pennsylvania DEP action level of 7000 µg/L (PA DEP 2009). To characterize potential proximate sources of gas migration, the Pennsylvania DEP conducted molecular and isotopic analyses of gas samples from the well cellar, the annular

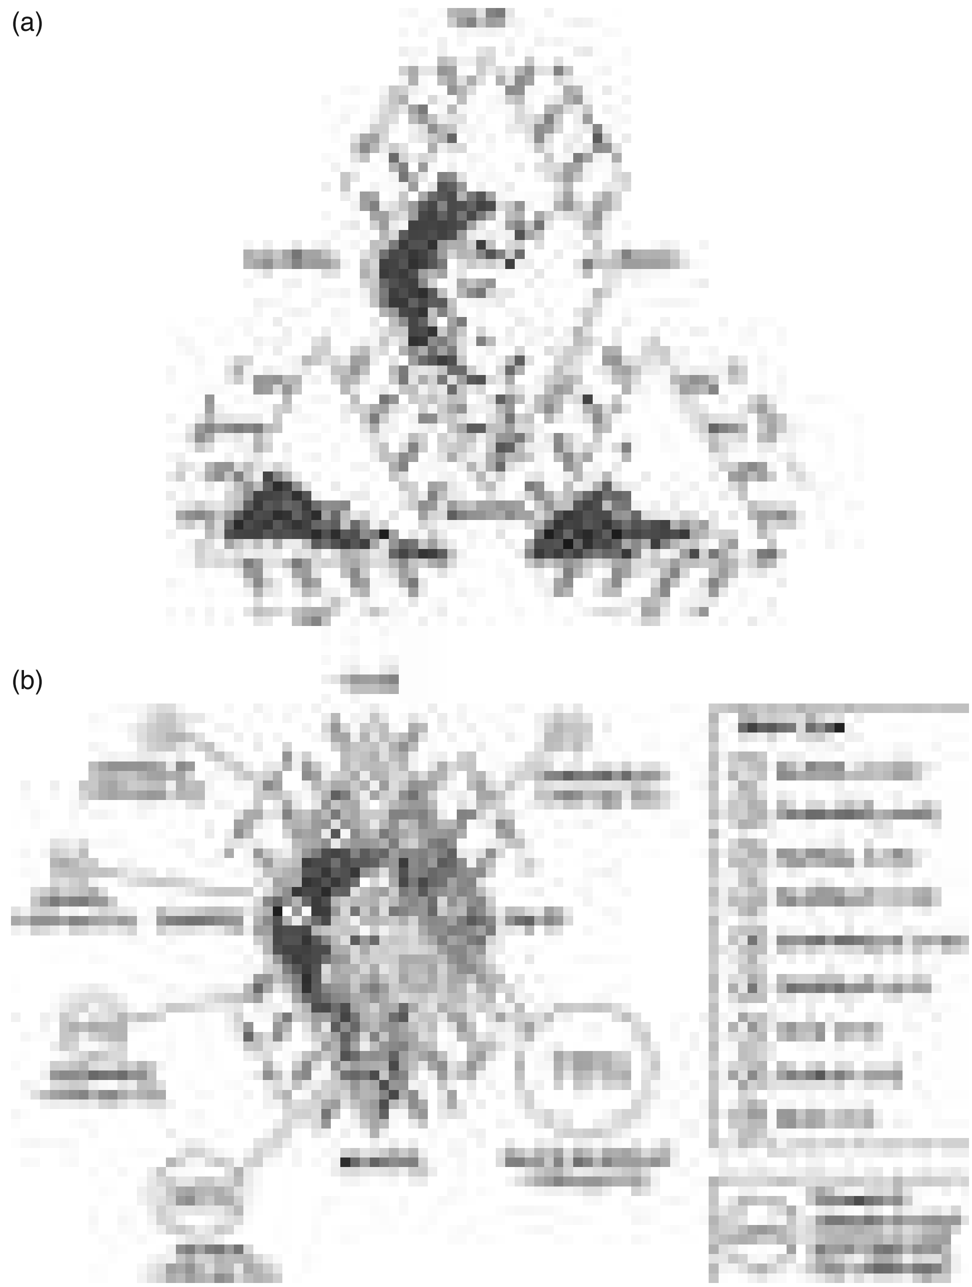

Figure 3. (a) Piper diagrams of major cation and anion composition of 408 predrill water samples. *Note: HCO_3 concentrations estimated from reported alkalinity as $CaCO_3$. (b) Percent of samples in each water type exceeding 1000 μg/L of methane. Water types determined based on those presented in Deutsch (1997).

spaces surrounding casing strings, and the production pipeline and production casing of three nearby shale-gas extraction wells (PA DEP 2010a, 2010b).

Shale-gas wells are constructed of a series of steel casing strings (i.e., long sections of steel pipe) of various diameters that are installed concentrically within the wellbore, in a telescoping fashion. These casing strings serve the dual purpose of providing structural integrity of the wellbore and isolating surrounding formations (e.g., drinking water aquifers) from the underlying production zone. The space between the casing string and the wellbore is referred to as the "annular space," which is commonly cemented in shallower casing strings, but may be left uncemented (i.e., "open") in deeper sections, depending on site-specific conditions. The annular space of a gas well is in contact with surrounding formations, and can therefore contain gases from adjacent strata that may be present naturally above the targeted gas-producing shale formation.

In the three Dimock area gas wells, gas samples were collected from annular spaces surrounding the (1) shallow casing string adjoining potential freshwater aquifers, (2) the intermediate casing string, which penetrates to a depth several thousand feet beneath surface, and (3) the production casing string, which terminates within the Marcellus shale. Within these gas wells, the annular space surrounding the production casing string was cemented from the bottom of the wellbore to a depth above the Marcellus shale. The cementing of this portion of annular space is designed to prevent Marcellus formation gases and fluids from entering the overlying section of wellbore via an open annulus. Consequently, gases sampled from annular spaces surrounding the casing strings in Dimock Township gas wells were considered to represent a mixture of those originating in formations above the Marcellus Shale (i.e., Middle Devonian Mahantango and Upper Devonian Formations), which were penetrated in some sections by open annular spaces. One gas sample was also collected from the well cellar, a sunken pit that provides access to the gas wellhead which serves as a functional interface for the casing strings and the gas production line at the surface. This sample is considered to be a composite of gases found within the annular spaces of the casing strings.

The Pennsylvania DEP also collected Marcellus shale gas (two samples, one gas well) from inside the production casing and production pipeline of a local gas well. These samples are supplemented by Marcellus shale gas (four samples, four gas wells) collected by Cabot (a primary operator in the area) from within the production casing of additional gas wells in the Dimock Township. Collectively, these analyses represent 12 samples of potential source gases from 7 shale-gas wells located within the greater Dimock Township area (see Table S2 for a full data table).

As described previously, ratios of methane to ethane can be used as an initial tool to evaluate possible differences between hydrocarbon gas sources (Bernard et al. 1976; Schoell 1980). Gases originating from the production pipeline/production casing, and annular spaces/well cellar all exhibit methane to ethane ratios less than 60, which is consistent with the anticipated thermogenic origin of these samples (i.e., methane to ethane ratio < 100). However, methane to ethane ratios of the six samples from the production pipeline/production casing (Marcellus shale gas) are slightly lower (43 to 47) than those displayed by gases from annular spaces and well cellar, where all but one of the six samples contain methane to ethane ratios between 49 and 56.

The use of $\delta^{13}C\text{-}CH_4$ values in combination with $\delta^{2}H\text{-}CH_4$ values can provide another method to distinguish different thermogenic (and microbial) gases. Values of $\delta^{13}C\text{-}CH_4$ and $\delta^{2}H\text{-}CH_4$ represent the difference between the $^{13}C/^{12}C$ and $^{2}H/^{1}H$ isotopic ratios of a sample, and that of a recognized standard. More negative values of $\delta^{13}C\text{-}CH_4$ and $\delta^{2}H\text{-}CH_4$ are said to be isotopically "depleted" in the heavier isotopes (i.e., ^{13}C and ^{2}H), whereas more positive values are said to be isotopically "enriched."

As shown in Figure 4a, the $\delta^{13}C\text{-}CH_4$ and $\delta^{2}H\text{-}CH_4$ values of Marcellus shale gas and overlying Middle and Upper Devonian gases sampled from the annular spaces of casing strings in the Dimock Township plot along a continuous trend. Based on the well-documented occurrence of less thermally mature methane in Middle and Upper Devonian Formations throughout the Northern Appalachian basin (Jenden et al. 1993; Osborn and McIntosh 2010), this trend may be interpreted to represent increasing thermal maturity, where Marcellus shale gas (buried at greatest depths) displays the most enriched isotopic signature (i.e., greatest thermal maturity).

It is important to note that mixing lines among gases of differing thermal maturities can, in certain instances, produce a pattern similar to that of a thermal maturity trendline. In this regard, our study faces similar challenges to prior studies on the origin of thermogenic gases in the Appalachian basin (e.g., Jenden et al. 1993). Nevertheless, the differences in $\delta^{13}C\text{-}CH_4$ and $\delta^{2}H\text{-}CH_4$ values for Marcellus production gases in the Dimock Township vs. Middle and Upper Devonian gases from the annular spaces or well cellar of local gas wells indicates that, although plotting along a continuous trend, the two sources may be distinguished.

The $\delta^{13}C$ value of ethane has also been utilized to provide additional information on the source of thermogenic hydrocarbon gases in the subsurface (Coleman 1994). Of the four samples of annular space and well cellar gases for which the $\delta^{13}C$ value of ethane were measured, reported values range between −34 and −35‰. The six samples of Marcellus gas from the production pipeline/production casing display similar, though slightly depleted, $\delta^{13}C\text{-}C_2H_6$ values ranging between −35 and −36‰ (Figure 4b). All reported $\delta^{13}C\text{-}C_2H_6$ values of gases from annular spaces/well cellar, and production pipeline/production casing are more depleted than the corresponding $\delta^{13}C\text{-}CH_4$ value, and therefore are said to exhibit an "isotope reversal" (i.e., a reversal of the trend traditionally observed in conventional hydrocarbon gases in which ethane is isotopically heavier, or more "enriched" in heavier isotopes, than methane). Such isotope reversals have commonly been observed in Marcellus and other Middle Devonian gases below the Tully limestone (Baldassare 2011). Comprehensive ethane isotope data are not currently available for gases present throughout the stratigraphic section in the Dimock Township. However, the magnitude of the methane-ethane $\delta^{13}C$ isotope reversal in samples from the annular spaces and well cellar (3 to 4‰ difference between methane and ethane $\delta^{13}C$ values) and those from the production pipeline/production casing (5 to 7‰ difference) suggests that Marcellus production gases may be distinguished from Middle and Upper Devonian gases in the annular spaces/well cellar of local gas wells.

It is important to note that, because of local variations in thermal maturity and possible source material, the isotopic and molecular signatures of formation gases in the Dimock Township cannot be extrapolated to represent the signatures of gases from the similar stratigraphic units in different parts of Susquehanna County or Pennsylvania. Consequently, the signatures of gases from the Marcellus and overlying Middle and Upper Devonian Units, as presented in Figure 4a and 4b, should only be considered representative of those found in the local Dimock area.

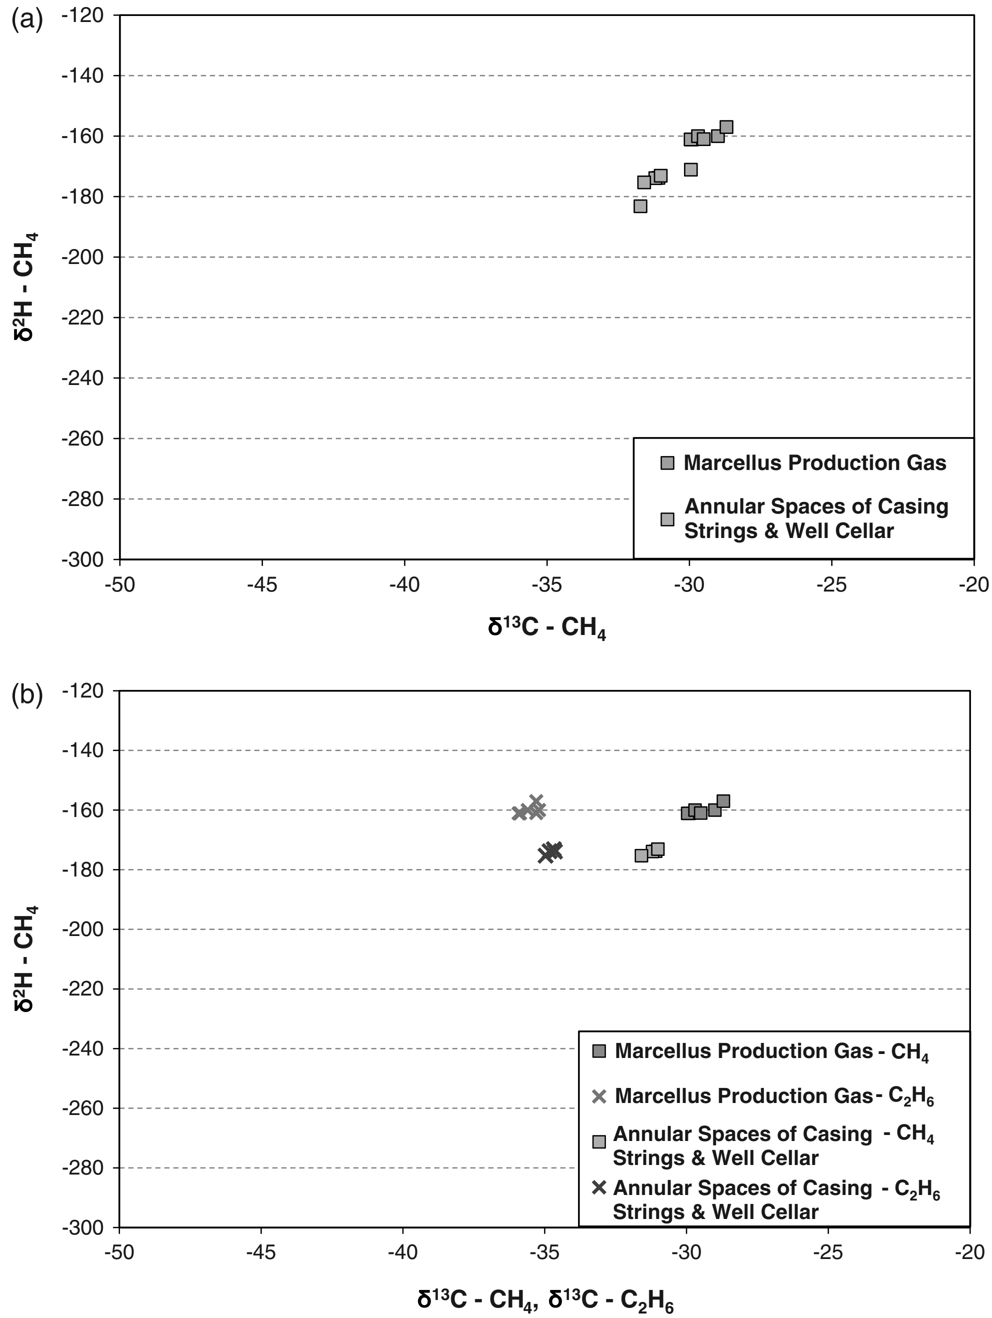

Figure 4. (a) Schoell plot of gases sampled by the Pennsylvania DEP and Cabot from production casing/production pipelines, the annular spaces of casing strings, and the well cellar of gas wells in the Dimock Township. (b) Plot of $\delta^{13}C$ values of methane and ethane (x-axis) vs. δ^2H value of methane (y-axis) in gases sampled by the Pennsylvania DEP and Cabot from production casing/production pipelines, the annular spaces of casing strings, and the well cellar of gas wells in the Dimock Township. *Only samples with reported values of both $\delta^{13}C$-CH_4 and $\delta^{13}C$-C_2H_6 are shown.

Water Well and Salt Spring Gas Samples: Isotopic and Molecular Analyses, 2009 to 2010

In addition to characterizing gases originating from the Marcellus shale and overlying deposits in the Dimock Township, the Pennsylvania DEP and Cabot analyzed groundwater samples from 15 local Dimock area water wells for this same suite of isotopic analyses (details of well depth and construction provided in Table S1). Cabot also sampled one salt spring in Salt Springs State Park, a known historical source of methane gas located approximately 13 miles northeast of the Dimock Township. Although this sample is not representative of the immediate Dimock area, it does serve as an illustrative example of the composition of gases that have been migrating naturally in the shallow subsurface in south-central Susquehanna County prior to commencement of shale-gas extraction activities. In several instances, multiple samples were obtained over the 2-year period, resulting in 23 total water well samples (8 samples of dissolved gas, 15 samples of free gas) and 1 salt spring

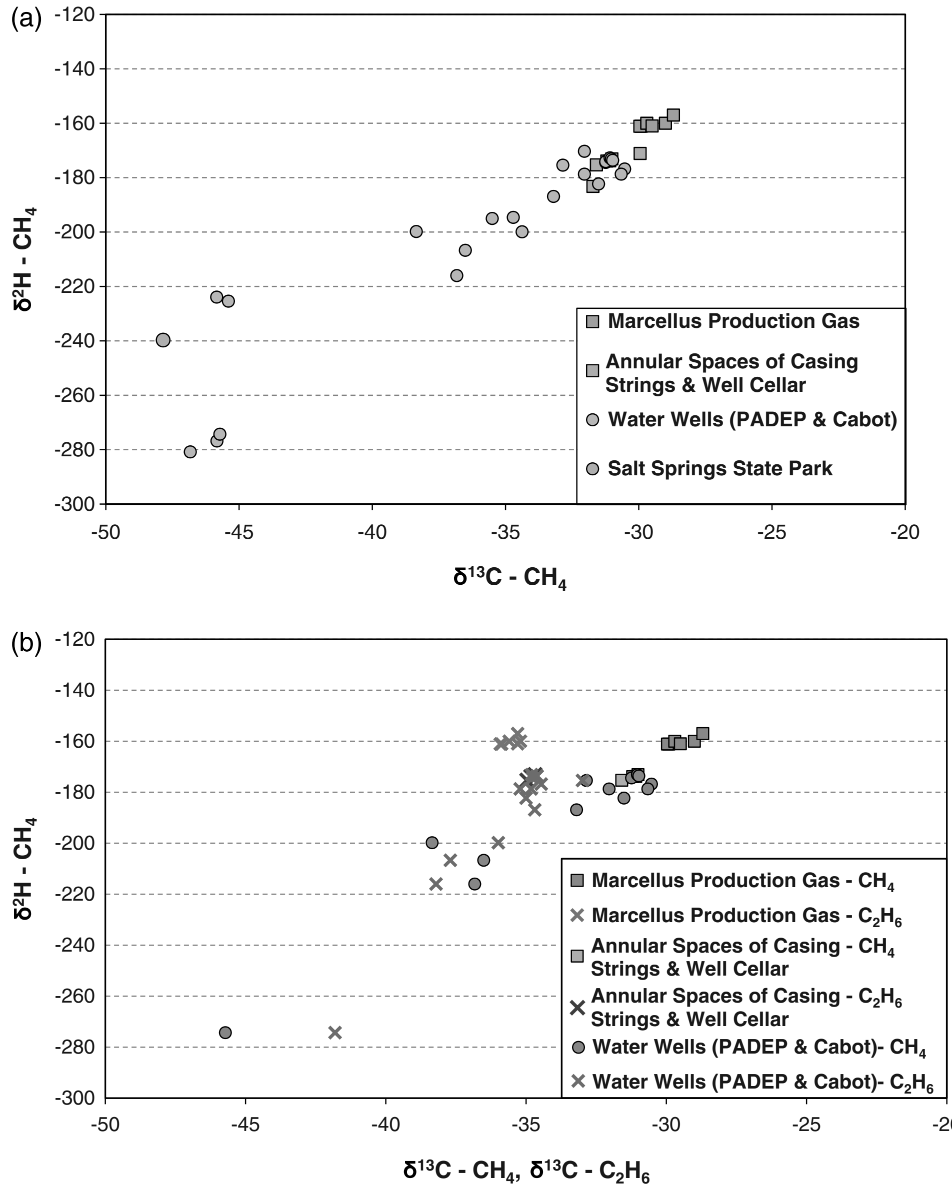

Figure 5. (a) Schoell plot showing Pennsylvania DEP and Cabot isotope data on methane samples from Dimock area water wells and Salt Springs State Park (Franklin Township). (b) Plot of δ^{13}C values of methane and ethane (x-axis) vs. δ^2H value of methane (y-axis) in gases sampled by the Pennsylvania DEP and Cabot from water wells in the Dimock Township. *Only samples with reported values of both δ^{13}C-CH_4 and δ^{13}C-C_2H_6 are shown.

sample (free gas) analyzed at Isotech Laboratories in 2009 and 2010.

For 15 of the 23 water well samples, the ratio of methane to ethane is less than 100, suggesting thermogenic origin. The remaining eight water wells and one salt spring contain methane to ethane ratios ranging from 100 to over 6000. This wide spread of values could represent several distinct thermogenic and microbial gas sources, a mixture of different sources, and/or gases that have undergone alteration during migration. The δ^{13}C and δ^2H values of methane for these same samples are presented in Figure 5a. Each of the water well samples and the salt spring sample exhibit δ^{13}C values (less than or equal to −30‰) and δ^2H values (less than or equal to 170‰) that appear consistent with those of thermogenic Middle and Upper Devonian gases sampled from the annular spaces/well cellar, microbial gases, or a mixture of the two. Based on the δ^{13}C-CH_4 and δ^2H-CH_4 values alone, samples from at least 2 of the 15 water wells contain a clear microbial component (i.e., samples from these two wells plot close to or within the traditional Schoell "microbial-fermentation" gas zone: (i.e., δ^{13}C-CH_4 between −45 and −65‰, δ^2H-$CH_4 \leq -275$‰).

The δ^{13}C value of ethane was measured in 13 of the water well samples (originating from 10 different water wells). Of these 13 samples, 11 exhibited a methane-ethane δ^{13}C isotope reversal (Figure 5b). Nine of these samples display combined methane and ethane δ^{13}C values that appear most consistent with Middle and Upper

Devonian gases sampled in the annular spaces of casing strings and the well cellar. An additional two samples still show a methane-ethane $\delta^{13}C$ isotope reversal, but exhibit more depleted methane and/or ethane $\delta^{13}C$ values than annular space/ well cellar gases. Lastly, two water samples did not exhibit an isotope reversal, and displayed notably more depleted methane and ethane $\delta^{13}C$ values than gases sampled in the annular spaces and well cellar.

Isotopic and Molecular Analyses by Osborn et al. (2011)

In 2011, Osborn et al. (2011) presented δ^2H and $\delta^{13}C$ values for dissolved gases in nine water wells sampled the previous year in "active-gas extraction areas" (i.e., within 1 km of an active gas well) in Susquehanna County. A map of sampling locations in Susquehanna County (provided in Osborn et al. 2011) indicates that a majority of the water wells sampled in active gas extraction areas were located in close proximity to the Dimock Township. These dissolved gases exhibited δ^2H and $\delta^{13}C$ values of methane that are generally more depleted than, or on the border of, the range characterized by local Marcellus production gases sampled by the Pennsylvania DEP and Cabot in the Dimock area, consistent with the signatures of Middle and Upper Devonian gases in the annular spaces/well cellar (Figure 6).

Isotopic and Molecular Analyses by USEPA (2012)

The USEPA also analyzed dissolved gases in 11 water wells in the Dimock Township in 2012 as part of follow-up sampling to the original Pennsylvania DEP stray-gas investigation (Table S6). Eight of the 11 water wells display combined δ^2H and $\delta^{13}C$ values of methane that are distinct (i.e., more depleted) from local Marcellus production gases. However, 3 of the 11 water wells contain methane with δ^2H and $\delta^{13}C$ values that plot within the elevated range of values that characterizes Marcellus production gas in the Dimock Township ($\delta^{13}C$-$CH_4 > -30‰$, δ^2H-$CH_4 > -162‰$). On this basis alone, these dissolved gases appear to match production gas samples from the Marcellus shale. However, closer examination of the data from these three water wells suggests that microbial oxidation in the subsurface is likely responsible for the elevated δ^2H and $\delta^{13}C$ values.

Specifically, samples from two of these three water wells (House 4 and 14) exhibit $\delta^{13}C$-CH_4 values that are slightly more enriched ($\delta^{13}C$-$CH_4 = -25$ to $-27‰$) than those exhibited by Marcellus production gas samples ($\delta^{13}C$-$CH_4 = -28$ to $-30‰$). However, these same samples display δ^2H-CH_4 values that are significantly more enriched (-122 and $-140‰$) than local Marcellus production gas (δ^2H-$CH_4 = -161$ to $-157‰$). The particularly elevated δ^2H signatures of the methane in these two samples is suggestive of microbial oxidation of methane, whereby both the δ^2H and $\delta^{13}C$ values of methane are altered to be enriched, but the change in the δ^2H value of methane is 8 to 14 times greater than the change in the $\delta^{13}C$ value of methane (Coleman et al. 1981).

The sample from the third water well (House 2) exhibits δ^2H and $\delta^{13}C$ values ($-160.5‰$ and $-29.4‰$, and respectively) that plot in the depleted end of the isotopic range characterized by Marcellus shale gas. However, the sample from House 2 does not exhibit an isotope reversal between the $\delta^{13}C$ values of methane and ethane that characterizes Marcellus shale gas samples.

Evaluation of a more complete suite of geochemical analyses over time could help discern the degree to which mixing of different gas sources and alteration processes in the subsurface (e.g., oxidation) have affected the signatures of water well gas samples collected by various parties in Susquehanna County.

Discussion

Isotopic and Molecular Analyses in Dimock Township

The δ^2H and $\delta^{13}C$ values of gases in Dimock area water wells sampled by the Pennsylvania DEP, Cabot, Osborn et al., and the USEPA indicate that hydrocarbon gases present in the majority of the water wells are consistent with gases in the well cellar and annular spaces of casing strings that intersect Middle and Upper Devonian formations above the Marcellus. The presence of a $\delta^{13}C$ methane-ethane isotope reversal in numerous water wells would suggest a source below the Tully Limestone in the Middle Devonian Mahantango Formation penetrated by several of the annular spaces sampled. These findings support the conclusion that the methane concentrations in these water wells can be explained with no necessary contribution from deeper Marcellus shale gas.

Isotopic and molecular analyses of hydrocarbon gases can provide valuable information on the source of natural gases, but not necessarily the mechanism of migration. In this article, for the Dimock Township, we have evaluated available isotopic and molecular analyses of local water well samples with the primary goal of assessing gas origin. To identify gas migration pathways, geochemical data should be assessed in conjunction with other lines of evidence which are not within the scope of this article. These lines of evidence include details on the construction, completion, and integrity of local gas wells and water wells. In addition, the variation of methane concentrations and groundwater quality in potentially impacted water wells over time, as well as the spatial distribution of methane concentrations in groundwater relative to potential locations of gas sources, can provide crucial information on potential pathways of migration.

The isotopic and molecular analyses presented in this paper primarily represent measurements of hydrocarbon gases in local strata and water wells in the Dimock Township. Without additional analyses of samples throughout the greater Susquehanna County area, the signatures of hydrocarbon gases in local area gas and water wells cannot be extrapolated to represent those of methane or ethane that may be found in strata or water wells throughout the region. However, the evaluation of Dimock area isotope and molecular analyses of methane and ethane provide valuable insight into the complexity associated with using geochemical fingerprinting to identify the origin of hydrocarbon gases in regions where multiple thermogenic gas sources are present naturally.

Consideration of Regional Lines of Evidence Regarding Sources of Methane in Groundwater

Methane has been present naturally throughout Susquehanna County in the shallow subsurface for at least 200 years, as indicated by the well-documented history of hydrocarbon gas shows during water well and gas well drilling, as well as natural seeps of hydrocarbon gases observed in the form of bubbling springs, ponds, and water wells. Our evaluation of 1701 recent predrill water well samples from Susquehanna County confirms that methane is common in drinking water aquifers today, with approximately 78% of sampled water wells exhibiting detected methane concentrations, and 3.4% exceeding the 7000 µg/L Pennsylvania DEP action level. Elevated methane concentrations show a clear relation to topography, with levels above the Pennsylvania DEP action level disproportionately found in valleys.

Furthermore, methane concentrations in valley water wells in gas production areas (i.e., located within 1 km of an active gas well) versus valley water wells in nonproduction areas (i.e., greater than 1 km from a gas well) show no statistical difference, indicating that the regional presence of elevated methane concentrations in valleys is a natural phenomenon. This is not an original finding, as the presence of elevated methane levels in valley water wells in the Appalachian basin has also been observed in a study in West Virginia by Mathis and White (2006), which found that methane concentrations from 170 water wells that exceeded 10,000 µg/L occurred in wells located in valleys and hillsides, as opposed to hill tops (Mathis and White 2006).

The correlation of methane concentrations with topography, rather than areas of active shale gas extraction, indicates that the use of hydraulic fracturing for shale gas in northeastern Pennsylvania has not resulted in widespread gas migration into the shallow subsurface. Certainly, as described in the 1980s by Harrison (1983, 1985), and by Gorody (2012) and King (2012), there have been instances of stray gas migration associated with the accumulation of gas pressure within and around the sides of the annular spaces of gas well casing strings in Pennsylvania, Ohio, and New York. However, the absence of a regional-scale relationship of methane concentrations to shale-gas well locations is consistent with the experience that gas well integrity and over-pressurization problems commonly result in localized, rather than regional, effects on water quality (van Stempvoort et al. 2005).

Valley water wells in Susquehanna County exhibit median methane concentrations similar to that of upland water wells; however, the 90th percentile concentrations of methane in valley wells is significantly elevated relative to upland wells. This observation suggests that some valley water wells access natural sources of elevated methane via interconnection with specific groundwater units and/or enhanced pathways of methane migration. As shown in Figures 3a, 3b, and S1, the elevated methane concentrations observed in this data set are predominantly associated with Ca-Na-HCO_3 or Na-HCO_3 water types, which in combination comprise only 16% of the sample population, yet represent 69% of the methane concentrations greater than 1000 µg/L. In addition, although only four water samples match a Na-HCO_3-Cl or Na-Cl water type, three of these samples exhibit methane concentrations exceeding 10,000 µg/L. Samples with methane concentrations greater than 1000 µg/L also exhibit relatively elevated levels of barium, chloride, manganese, pH, sodium, strontium, and TDS, and relatively lower levels of sulfate and calcium. Similar geochemical relationships with elevated methane concentrations were previously reported in a study by Perry et al. (2012) for over 14,000 predrill water well samples in Pennsylvania, Ohio, and West Virginia, as well as a study by Warner et al. (2012) for 426 shallow groundwater samples from six counties in northeastern Pennsylvania.

The association of sodium and sodium-chloride rich water types with elevated methane concentrations suggest that wells exhibiting higher methane levels are connected to deeper groundwater aquifers, which have experienced longer groundwater residence times (and therefore, longer rock-water interaction times), and/or are in contact with sodium-chloride rich waters that occur in deeper bedrock and aquifers. Specifically, water in the deeper parts of sandstone aquifers that contain carbonate components (e.g., shells or carbonate rich shale lenses) commonly transitions from Ca-HCO_3 type water to Na-HCO_3 or Na-Cl-HCO_3 type water as a result of (1) the mixing of circulating freshwater with sodium-chloride water and/or brine that occurs in deeper bedrock and aquifers, and/or (2) progressive cation exchange, whereby calcium, magnesium (and to a lesser degree, potassium) ions replace sodium on mineral exchange sites, thereby liberating sodium in groundwater (Cushing et al. 1973, Kresse et al. 2012). It follows that longer rock-water interaction results in increased cation exchange, and a transition towards sodium-bicarbonate water, containing greater concentrations of barium, boron, chloride, lithium, strontium, and TDS associated with the dissolution of carbonate and other minerals from the rock matrix. At the same time, concentrations of calcium and magnesium will decrease in groundwater with increased residence time in the subsurface, as these ions replace sodium in mineral exchange sites (Kresse et al. 2012).

Longer groundwater residence times are also associated with anaerobic groundwater conditions related to microbial consumption of oxygen and other electron acceptors (e.g., sulfate, manganese, and iron oxides) in the presence of an organic substrate. Evidence for the occurrence of these redox processes can include increased concentrations of manganese and iron from the reduction of iron and manganese oxides, as well as decreased sulfate concentrations (and associated sulfide odors) related to sulfate reduction (Kresse et al. 2012).

In Susquehanna County, deeper groundwater with longer residence times may be preferentially accessed by water wells that penetrate to the depth of deeper groundwater units or are in communication with fault and fracture networks. Comprehensive information on the depth of water wells sampled in our predrill dataset is not available. However, available information on aquifer characteristics in northeastern Pennsylvania indicates that the Lock Haven Formation contains discrete saline groundwater zones, which have been noted to produce methane gas and/or hydrogen-sulfide (Williams et al. 1998). Analysis of water quality by Warner et al. (2012) in northeastern Pennsylvania showed that water wells drawing from the Lock Haven Formation (45 wells) exhibit significantly elevated chloride and sodium concentrations (75th percentile values of 73 and 103 mg/L, respectively) compared to water wells drawing from the Catskill Formation (102 wells, with 75th percentile values of 15 and 16 mg/L, respectively). Consequently, water wells that are in contact with Lock Haven groundwater, via either their greater depth within the overlying Catskill formation and/or fracture flow networks are more likely to exhibit decreased water quality and higher methane concentrations.

Valley formation in Susquehanna County has been associated with a greater density of fractures and lineaments, which likely serve as enhanced pathways for both water and gas migration. In West Virginia, Rauch (1984) found that water wells located within 0.1 km of photolineaments (short straight lineaments representing linear stream channel or valley segments related to the surface presentation of fault and fracture networks) had significantly higher water yields than other water wells. This increased water yield was not simply related to the influence of topography on groundwater flow, as valley water wells located near photolineaments exhibited greater water flow than all other valley water wells (Rauch 1984). It follows that water wells penetrating fault and fracture networks are not only likely to produce greater quantities of water, but higher methane levels as well.

It is important to note that the presence of methane itself can alter the concentrations of certain groundwater parameters. Specifically, the oxidation of methane is associated with the reduction of oxidizing reactants (i.e., sulfate, manganese, and iron oxide), an increase in pH and bicarbonate (product of CH_4 oxidation) concentrations, and a decrease in oxidation-reduction potential (Kelly and Matisoff 1985). However, microbial oxidation should not affect the prevalence of chloride, which is a conservative ion (i.e., an ion that is not utilized in redox reactions, does not sorb readily to mineral surfaces or complex with other ions, and is not easily removed from solution) (Kresse et al. 2012). Consequently, the association of increasing chloride concentrations with methane concentrations strongly suggests the contribution of a deeper groundwater source with elevated chloride concentrations.

The significant history of gas production from the Lock Haven (and, to a lesser extent, the Catskill Formation) in northeastern Pennsylvania suggests that methane naturally present in many Susquehanna County water wells contains thermogenic components from the Catskill and Lock Haven formations. In addition, microbial methane, produced by methanogenesis in anaerobic groundwater units, may also be a strong component of the methane migrating into local drinking water wells. As discussed earlier, the present-day migration of deep thermogenic gases from the Mahantango and Marcellus Formations into the shallow subsurface in Susquehanna County appears to be limited by the presence of a regional structural detachment above the Tully stratigraphic level, which has been noted in local seismic interpretations. The data presented in this paper show that elevated methane concentrations exhibit a common association with (1) topographic lows and (2) groundwater geochemistry that reflects longer residence times and/or mixing with deeper NaCl waters. This observation suggests that elevated sources of either thermogenic or microbial methane from the Catskill and Lock Haven Formations are accruing in deep groundwater units, and/or within long discrete groundwater flow paths to lowland discharge points, that are preferentially accessed by certain valley water wells.

This evaluation represents a regional-scale assessment of trends observed in groundwater geochemistry in a large dataset during a 3-year period. However, for an individual water well, it is important to remember that factors such as proximity to roads (and therefore, the application of sodium and calcium chloride during the winter season) can result in localized variations in chloride, total dissolved solids, and other water quality parameters. In addition, seasonal fluctuations in aquifer recharge (i.e., increased influx of meteoric water between November and May), residential water use, changing weather patterns, and local well construction can also affect site-specific water quality.

Conclusion

Our evaluation of 1701 groundwater quality analyses shows that methane is common in Susquehanna county water wells and is best correlated with topography and groundwater geochemistry, rather than shale-gas extraction activities. This finding suggests that shale-gas extraction in northeastern Pennsylvania has not resulted in regional gas impacts on drinking water resources and that, in turn, the hydraulic fracturing process has not created extensive pathways by which gas from the Marcellus shale could rapidly migrate into the shallow subsurface.

Our evaluation of site-specific isotopic and molecular data from water wells in the Dimock Township suggests that hydrocarbon gases present in these water wells are consistent with Middle and Upper Devonian gases above the Marcellus sampled in the annular spaces of local gas wells. This evaluation also emphasizes the complexity associated with differentiating between multiple thermogenic gas sources that may exhibit subtle variations. Isotopic analyses were not performed on the 1701 predrill water well samples to determine the origin of elevated methane concentrations observed throughout Susquehanna County. However, consideration of regional geology, historical publications, structural data, water well completion records, and water quality data suggest that methane naturally migrating into Susquehanna County water wells is either thermogenic, likely originating from Upper Devonian deposits overlying the Marcellus shale, or microbial, originating from anaerobic groundwater units with long residence times.
